The use of the wrong pole in electrical treatment may be followed by most disastrous results; and the chances of the wrong pole being used are very numerous, sometimes even escaping the vigilance of the most experienced. The commutator of the battery may have been arranged wrongly by the instrument maker; the galvanometer may have been inserted on the wrong side of the circuit; the current may have to be arrested during an operation, and the commutator reversed by accident through the negligence or ignorance of an assistant. One operation may have required the use of the positive pole, and the next of the negative, and the necessary alterations in the battery have escaped notice. All these accidents have occurred within the knowledge of the author. I write with a sense of the strongest responsibility when I warn the profession against the indiscriminate use of electricity, and its indiscriminate use by those who have not a thorough knowledge of its action, and of the proper way of applying it, and of the construction of batteries. I have seen part of the mucous membrane of the urethra torn off and followed by profuse hemorrhage by the use of a positive pole in the treatment of stricture. I know of a case where the patient suffered from such extreme collapse after a similar operation, that the surgeon for a time was fearful as to the result. The collapse was produced, either from the current being used too strong, or when strong, suddenly broken. I have been upbraided by a surgeon for advocating the treatment of stricture of the urethra by electrolysis, because in two cases he had set up most intractable cystitis by not cutting off the current after his electrode had passed the stricture, but by passing it on and electrolyzing the coats of the bladder; and yet, when properly performed, electrolysis is the best mode of treating stricture. I have seen a patient disfigured for life by the too energetic use of the wrong pole, in treating a hairy mole on the face. In another case, an abscess or slough was produced in the upper part of the pharynx, accompanied by the most intolerable earache, by the use of the wrong pole in an attempt to electrolyze the Eustachian tube. Most profound collapse has been caused by an assistant uncoupling one of the electrodes after the electrolysis of a uterine fibroid, and before the current had been gradually reduced in strength. Very painful and disagreeable shocks have been produced when treating the same affection, by the battery having been sent home by the instrument maker with the zinc of one couple of elements placed in the wrong cell; and in another instance, by the battery being sent home with the fluid omitted from one cell. A case has been published where, no doubt, the woman's life was in jeopardy by the sloughing of a tumor produced by the use of a too strong current. I mentioned in my paper, read at Dublin, the difficulties, though not serious, which followed the use of the wrong pole in the treatment of lachrymal obstruction. I could greatly extend this list of dangers and difficulties connected with electrical treatment, but I have said enough to show that it should not be undertaken without a thorough knowledge of the apparatus to be used, and the mode of using it.

The Death of Mr. Curling, of the London Hospital.—Thomas Blizard Curling, F.R.C.S., F.R.S., Consulting Surgeon to the London Hospital, died on March 4, 1888. He had been on the staff of the London Hospital for many years, and had enriched surgical literature by frequent contributions, among which are his "Original Observations on the Association of Duodenal Ulcers with Cutaneous Burns." His larger works were a prize essay on "Tetanus," "Diseases of the Testis," and "Diseases of the Rectum."

Death of Augusto Michellacci.—Michellacci, the foremost of Italian dermatologists, died in Florence March 13, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM MARCH 13 TO MARCH 19, 1888.

BAXTER, J. H., *Colonel and Chief Medical Purveyor.*—Will proceed to Augusta Arsenal, Ga., on public business.—*S. O 62, A. G. O.*, March 16, 1888.

STERNBERG, G. M., *Major and Surgeon.*—Ordered to proceed to Brunswick, Ga., on official business, and, upon completion of the same, will return to his proper station.—*S. O. 57, A. G. O.*, March 10, 1888.

GREENLEAF, CHARLES R., *Major and Surgeon.*—Will proceed to Cambridge, Mass., on official business—*S. O. 62, A. G. O.*, March 16, 1888.

O'REILLY, R. M., *Major and Surgeon.*—Will proceed to York, Pa., and make an examination of Captain Edward B. Rhum, Twenty-first Infantry.—*S. O. 62, A. G. O.*, March 16, 1888.

CROSBY, WILLIAM D., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for two months, with permission to apply for an extension of one month, to take effect after being ordered to a new station.—*S. O. 60, A. G. O.*, March 14, 1888.

KEAN, JEFFERSON R., *First Lieutenant and Assistant Surgeon.*—Relieved from duty at Fort Sill, Indian Territory, and ordered for duty at Fort Robinson, Nebraska.—*S. O. 56, A. G. O.*, March 9, 1888.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 17, 1888.

RUSH, W. H., *Passed Assistant Surgeon.*—Detached from the Navy Yard, New York, and ordered to the Naval Hospital, Philadelphia, Pa.

STEELE, J. M., *Passed Assistant Surgeon.*—Detached from the Naval Hospital, Philadelphia, and ordered to the Coast Survey Steamer "Bache."

OBERLY, A. S., *Medical Inspector.*—Detached from the Navy Yard, Portsmouth, N. H., and wait orders.

DUBOIS, F. L., *Surgeon.*—Ordered to the Navy Yard, Portsmouth, N. H.

KEENY, JAMES, *Assistant Surgeon.*—Ordered to the Receiving Ship "Minnesota."

DEANE, C. W., *Passed Assistant Surgeon.*—Detached from the Marine Rendezvous, San Francisco, and ordered to the Coast Survey Steamer "McArthur."

AUZAL, E. W., *Assistant Surgeon.*—Detached from the Coast Survey Steamer "McArthur," and ordered to the Marine Rendezvous, San Francisco.

BIDDLE, CLEMENT, *Passed Assistant Surgeon.*—Ordered to the Naval Academy, Annapolis, Md.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

VOL. LII. SATURDAY, MARCH 31, 1888. NO. 13.

ORIGINAL ARTICLES.

THE PHYSIOLOGICAL EFFECTS OF THE EMPYREUMATIC OIL OF COFFEE, OR CAFFEON.

BY H. A. HARE, M.D.,

DEMONSTRATOR OF THERAPEUTICS AND INSTRUCTOR IN PHYSICAL DIAGNOSIS IN THE MEDICAL DEPARTMENT, AND IN PHYSIOLOGY IN THE BIOLOGICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA.

AND

JOHN MARSHALL, M.D.,

DEMONSTRATOR OF CHEMISTRY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA.

THE well-known fact that the strong infusion of coffee as ordinarily ingested, possesses certain properties in which the alkaloid caffeine is lacking, points very strongly to the empyreumatic oil of coffee as the second agent whose presence is felt. This empyreumatic oil of coffee, or caffeon, is a complex mixture of the oils contained in browned coffee, formed in the roasting as a product of destructive distillation of the organic matter in the green bean.

As long ago as 1853, J. Lehman studied the action of the oil. He distilled ground coffee, which had previously been browned, with water, and administered the aqueous distillate, which contained an unknown quantity of the drug, in tumblerful doses. These doses were repeated as often as four times in one day. The symptoms noted were nervous agitation, slight sweating, and a marked increase in the rapidity of the circulation. When twice the above amount was ingested the symptoms were congestion of the eyes, copious perspiration, sleeplessness, and in some instances purging.

The results reached by Lehman have been confirmed by Nasse, who, using animals, noted in addition to the disorders already mentioned, intestinal peristalsis of a marked type, which he claims that caffeine fails to produce. Meplain and Marvard state that caffeon slows the circulation and decreases the arterial pressure. Rabuteau considers that the oil is capable of producing symptoms of a decided toxic nature, and prevents the development of infusoria in liquids, such as milk, etc. Rabuteau goes so far as to assert that the oil is the chief factor in causing the well-known coffee wakefulness. The results of Binz, of Bonn, are, however, in direct opposition in some respects to those of Meplain and Marvard, for he found that the oil of coffee increases the number of the cardiac pulsations and stimulates respiration. Zulinski found that, when given to frogs, tetanic spasms of the muscles came on.

So far as we can discover, all of the investigators so far named, used an aqueous distillate of browned coffee containing an unknown quantity of the oil. This being the case, it seemed to us of interest to determine the effect of the pure oil in definite amount on the animal organism.

The empyreumatic oil employed by us was obtained from the freshly roasted bean, by placing the very finely ground coffee in a Soxhlet's extractor, and extracting by means of petroleum ether. In this process the fats contained in the coffee would also be extracted by the ether, but as it is likely that most of the fats were converted into empyreumatic substances in the roasting, those remaining undecomposed and extracted in company with the oil by the ether, were so inconsiderable as not to influence the physiological action. Caffeine is also very slightly soluble in petroleum ether, and on evaporating the petroleum ether and allowing the oil to stand a few days, the caffeine separates in minute crystals and subsides at the bottom of the vessel and may be removed by filtration. The petroleum ether containing the oil was allowed to evaporate at ordinary temperature, the remaining oil, after standing several days, was filtered to remove small particles of the coffee and the minute crystals of caffeine that separated. The oil obtained in this manner was of the consistency of a very dilute syrup, and was light or dark brown in color, according to the degree to which the beans had been roasted. This variation in color does not seem to have had any relation to its physiological action. It possessed to a great degree the peculiar aroma of browned coffee. The percentage of oil obtained from an average browned coffee was found to be 11.6 per cent., and from this we calculated that a cup of coffee, made in the ordinary way, provided the liquid possessed all the oil contained in the amount of coffee employed in its preparation, would contain about 3 c.c. (45 minims) of the oil.

When from one to four cubic centimetres of the pure oil are injected into the jugular vein of a medium sized dog, whose carotid artery is attached to the mercurial manometer, almost immediately there is produced an increase in the rapidity of the pulse, which continues for many minutes. If a larger dose, as much as 8 cubic centimetres, be given, the pulse is quickened for a short time, and in the course of a few minutes slowed very considerably. That the cause of the rapid pulse is not due to depression of the inhibitory apparatus, was proved by the fact that in every instance stimulation of the vagi slowed the heart quite as powerfully as if no drug had been given. The increase in rate must, therefore, be due

either to a direct stimulation of the heart itself, or the accelerator nerves. That the influence of the drug is exerted upon the heart directly seems the more probable, since if a minute amount of the oil be applied directly to the frog's heart, an increase in the pulse rate occurs. The slowing of the pulse, which comes on when larger doses are used, depends on the influence which the drug exerts directly on the heart muscle, since at this time section of the vagi fails to cause as great an increase in rate as should ordinarily occur. This might be an indication that the peripheral vagi were stimulated, were it not that at this time the pulse waves are small and feeble, and the whole tracing indicates circulatory depression. That the fall of arterial pressure occurring with the slowing of the pulse, is due to cardiac involvement rather than to vaso-motor disturbance, was proved by the fact that asphyxia at this time immediately produced a rise of arterial pressure almost equal to the normal; further than this, it was proved by experiments on the isolated frog's heart that the drug, when directly applied in large amounts, acted as a depressant, the movements becoming slower, weaker, and finally ceasing in diastolic arrest; previous to this stoppage, however, slight vermicular or peristaltic waves traversed the ventricular wall.

The contradiction which apparently exists between the results of Binz and Meplain and Marvard are therefore explainable by the supposition that the first observer used a distillate containing a smaller percentage of the oil than that of the French investigators, and as a result of this Binz found, as we have done, that the pulse-rate is quickened, while his Gallic brethren found that it was slowed. The following tables, from tracings taken by ourselves, illustrate what we have already stated.

TABLE I.—Dog, weight 12 lbs. Showing increase in pulse-rate after small doses, and the effect of stimulating the vagi.

Time.	Drug.	Pressure.	Pulse.	Remarks.
11.00	.....	140–160	132	
11.00.10	.....	140–158	132	
11.00.20	.....	140–158	126	
11.00.30	.....	140–158	126	
11.00.50	.....	140–158	134	
11.01.06	4 c. c. of pure oil.	140–158	134	Injection begun.
11.01.16	.....	158–120	134	
1.0 .26	.....	120–144	102	Injection ended.
11.01.41	.....	130–120	108	
11.01.51	.....	120–130	126	
11.02.01	.....	106–130	126	
11.04	.....	126–146	144	
11.04.10	.....	126–144	156	
11.04.20	.....	120–144	156	
11.08	.....	130–156	154	
11.08.10	.....	132–210	132	This momentary slowing of pulse probably due to irritation of the vagi when rousing for galvanization.
11.08.20	.....	142–204	156	
11.08.30	.....	144–184	144	Galvanized vagi.
11.08.40	.....	118–210	84	
11.08.50	.....	136–228	66	

TABLE II.—Dog, weight 15 lbs. Showing slowing of pulse produced by large doses (8 c. c.) of the oil of coffee, and effect of vagal section.

Time.	Drug.	Pressure.	Pulse.	Remarks.
11.50	.....	120–188	90	Showing pulse before drug was given from 140–150 per minute.
11.51	.....	118–176	86	
11.51	.....	120–188	84	
11.51.40	.....	120–188	90	
11.51.50	.....	128–196	84	
11.52	.....	122–178	90	Vagi cut.
11.52.14	.....	124 192	120	
11.52.24	.....	164–192	174	
11.52.34	.....	180–200	178	
11.52.44	.....	190–224	186	
11.52.54	.....	188–224	176	
11.53.54	.....	194–216	168	
11.54.54	.....	196–218	180	
11.55.54	.....	200–221	190	

A curious condition of the heart was found to be constant in every one of the seven tracings taken, namely, that the heart was found stopped in diastole, with all its cavities greatly distended and filled by a well-formed clot, which would stand upon the palm of the hand without breaking. In order to determine whether the drug had any effect on the blood outside of the body, we opened the carotid artery of the dog and allowed about 5 c. c. of blood to escape into a porcelain dish in which was placed 1 c. c. of the oil.

Under these circumstances the blood in contact with the oil coagulated in half the time required by the blood in the dish without the oil. Notwithstanding the fact that we have examined the oil very carefully for any foreign substance which might produce such changes, we are unable to offer any explanation of this curious change in the blood.

On the nervous system the drug has evidently an action resembling only in some of its points that generally ascribed to coffee. When one cubic centimetre of this oil was given to a medium-sized frog, by means of a hypodermatic syringe, into the posterior lymph-sac, in the course of from one to two minutes reflex movements became very much increased in scope and force, remaining so for a number of hours, and at no time did diminution of either sensation or motion appear to come on. When two cubic centimetres of the oil were injected hypodermatically into a lively Scotch terrier, in ten minutes he became quiet, and in twenty minutes was asleep in front of the fire. If aroused or disturbed, his attention could readily be obtained, but if neglected sleep again asserted itself.

The laboratory assistant now took by the mouth about 4 c.c. (about a drachm) of the oil and suffered no symptoms for three hours, when he also became so sleepy, that on returning home at 6 P.M., he did not want to eat, but was overpowered by sleep, and lying down on a sofa fell into a slumber from which his wife with difficulty aroused him in an hour or two. As this man did not know of the action of the drug, this result could hardly have been due to

imagination. His report was given voluntarily, with no questioning. Owing to the kindness of Dr. de Schweinitz we were enabled to obtain the following tests:

Case I.—A., æt. fifty-nine, female. Always passes sleepless nights, or, at the best, is very restless. Gave fifty minims of the oil at 3.58 P. M., when the pulse was 84. At 5 P. M. there was nausea but no vomiting. At 8.15 P. M. there was vomiting of mucus and the contents of the stomach, supper having been eaten in the meantime. Retired at 9 o'clock, and made the statement next day voluntarily that she had slept the entire night. There was no period of drowsiness before the sleep, and no sequelæ.

Case II.—Male, aged about fifty. Had fallen and cut his temple on the ice, he also had winter cough quite severely. Gave fifty minims at 4.17 P. M., the pulse being 66. At 7.15 no change in pulse, no drowsiness. Went to bed between 8 and 9 P. M., the pulse at this time being 110. The man was restless, but had no nausea. He passed a restless night, and had no diminution of pain in the head caused by the fall.

As pain may have been a factor in producing insomnia in this case, it is not of much value in its results as indicating what effect the drug may have on sleep.

In a third case Dr. de Schweinitz noted no change, save perhaps some increase in restlessness.

To sum up this apparent power of producing sleep, we find that in the dog and in two instances in man sleep was produced; while in two instances in man, in one of whom pain was present, the oil failed to cause sleep, but rather restlessness.

Summary.—The pure empyreumatic oil of coffee increases pulse-rate by direct cardiac stimulation in small doses, and lowers pulse-rate by a cardiac action in large doses. On the highly developed spinal cord of the frog it causes increased reflex excitability, but on the mammal, with a well-developed brain, drowsiness and sleep, although with the limited material at our disposal this is at present far from being positively proved.

The action of this oil is evidently not as powerful as is that of the alkaloid caffeine.

A CASE OF CHOLECYSTOTOMY.

By J. J. EDWARDS, M.D.,
SURGEON TO ST. XAVIER'S INFIRMARY, CHARLESTON, SOUTH CAROLINA.

Miss B., æt. fifty-four, of Irish descent, school teacher. When a child had a mild attack of yellow fever, otherwise has always enjoyed perfect health until four years ago, about the climacteric, when she experienced vague pains in right hypochondriac region, accompanied by a slight cough, which were ascribed by her physician in a neighboring city to some lung trouble. Pains were never paroxysmal or severe. No gall-stones were ever detected.

Her health began to fail in December, 1887; complained of general malaise; pain in side increased and bowels moved only after the administration of cathartics. The dejections were clay colored and very offensive, slight icterus now developed for the first time. She was advised to go to Florida to recuperate. She came to Charleston in the middle of January and consulted a physician, who attended her constantly, but gave no hope of relief and predicted an early dissolution.

I saw the case late in the afternoon of March 8th, and found a very emaciated, extremely weak, and intensely jaundiced woman, who could retain nothing on her stomach. She vomited quantities of black disintegrated blood. Her dejections were frequent and quite fetid, and consisted of dark bloody mucus. She complained of intense pain over the liver and extending down to the right iliac fossa. Her urine contained bile. Her extremities were cold, and her knees were drawn up.

Physical examination.—Liver much enlarged, reached four fingers' breadth below border of ribs. An ovoidal tumor, which accompanied respiratory movements, apparently cystic, very sensitive; that pressure on it caused nausea and faintness, with a tympanitic sound on percussion except over a very small area which was dull, and about three inches across, was readily demonstrated.

Diagnosis.—Distended gall-bladder, due to an obstructed duct, possibly by a calculus. An immediate operation was advised as the only means of relief. This was not accepted, and the friends were given until morning to decide. Ordered one grain of calomel in ten powders one every hour, and an enema of two ounces sweet oil with one drachm glycerine, also the administration of stimulants.

She passed a better night, but had weakened perceptibly. An operation was now consented to with the distinct understanding of its almost sure fatality.

With the assistance of Drs. Rhett and Buchanan the patient was chloroformed and hypodermatics given to arouse the already flagging vital forces.

A vertical incision, two and one-half inches, over the outer border of the rectus muscle through the peritoneum disclosed an enormously enlarged liver and distended gall-bladder. The incision was now enlarged downward, the needle of the aspirator was inserted into the cyst at the lowest possible point, and drew off seven and one-half ounces of bile and mucus; as the sac collapsed the needle came gradually upward until it was considerably above the lower angle of the incision. The bladder was now grasped by two catch forceps, the needle withdrawn, and an incision made between the forceps large enough to admit the finger, which readily detected several stones. The tedious process of removing them singly with forceps was begun, when, at the suggestion of Dr. Rhett, it was found much more expedient to strip them out with the finger in the abdomen; the opening in the bladder being first drawn beyond the abdominal wound. Twenty-nine stones, averaging five and one-third grains, were removed. There were adhesions between the lower surface of the bladder and the surrounding structures, through which an enlargement, possibly another stone, could be felt over the course of the common duct, but as a searcher failed to de-

tect it, and, owing to the precarious condition of the patient, it was decided to finish the operation at this stage. The peritoneum at the upper angle was first united by catgut opposite to the opening in the gall-bladder; the deep retention silk sutures down to the peritoneum were passed, but not tied. As there was constant oozing of bile, and we feared its extravasation into the abdominal cavity, Tait's procedure of uniting the sac to the peritoneum by a continuous suture passed through the abdominal walls was deviated from, and instead, the incision in the bladder was drawn up until on a level with the integument, then the peritoneum alone was united to its walls lower down by continued catgut suture, the silk sutures tied, and the mouth of the sac stitched to the integument. A large drainage tube was inserted; iodoform was dusted over and the dressing completed as usual.

Patient was put to bed and every endeavor made to rally her, but she died in collapse eight hours after the operation. The hemorrhage, consisting principally of general oozing, was considerable and hard to control. Thorough aseptic precautions were observed. The dressings were found, after death, to be saturated with bile and tinged with blood.

Reviewing the case, it would seem, in this instance, better to have aspirated first, and then allowed the patient to react; then the radical procedures, subsequently, might not have terminated so disastrously. Possibly it was wrong to have operated on the patient, in her condition, at all, but it was done in her interest and not for statistical record.

The operation, comparatively, is not a hard one, and it is surprising that it is not oftener performed.

March 11, 1888.

DYSTOCIA, DUE TO HYDROCEPHALUS, NECESSITATING CRANIOTOMY.

BY A. A. G. STARCK, M.D.,
OF PHILADELPHIA.

ON October 4, 1887, I was summoned to Mrs. D., age twenty-two years, German, in labor with her second child. A midwife in attendance gave this history. The patient considered her time up two weeks previously, and began having pains. The midwife's examination could not determine a presenting part. Bearing-down pains, however, lasted two weeks, but no progress was made in the labor. During this time she vomited everything, the egesta being mixed with bile. The act of vomiting was accompanied by severe pain in the hepatic region. On my arrival on the morning of the 4th, the patient had no pains, as they had suddenly ceased at 12 o'clock midnight. Previous to that time she had suffered throughout the afternoon and night. I first noticed that the abdomen was very large, arousing a suspicion of twins, and its contour differed from an ordinary pregnant uterus in labor, not presenting the prominent globular form generally seen, being markedly oval in shape and extending high up into the epigastric region. Upon palpation the abdomen felt smooth and tense. In the left inguinal region was a protuberance resembling a head, but larger. The fœtal heart sounds were faintly audible some distance above this. Digital examination revealed the vagina hot and swollen, and the os sufficiently dilated, but none of the fœtal parts could be distinguished until the whole hand was introduced, when a large, soft tumor was felt much like a caput succedaneum. The examination occasioned great pain.

The os uteri was not at first sufficiently dilated to allow the whole hand to pass through, but yielded in a little while to gentle dilatation with the fingers. The membranes were intact and in close contact with the presenting part, which covered the whole pelvic brim at the superior strait, dipping into the true pelvis but slightly. The hand could more readily be passed over the side where the occipital bone of the fœtus was felt, but passed with difficulty in front of the head, which seemed about eight inches in diameter, and upon this fact I based the diagnosis of hydrocephalus. The examination did not arouse any uterine pains. Complete inertia continuing, Dr. Howard A. Kelly was summoned to perform craniotomy. Not being fully informed as to the grounds of my diagnosis he came prepared to perform Cæsarean section, if there was any chance for the life of a sound child; but after a careful examination he was satisfied, from the great size of the head and the sufficient size of the maternal parts, that nothing but craniotomy was feasible. The large head could easily be outlined by palpation, lying in the first position, extending from the left side below up toward the right hypochondrium, and above it to the left lay the displaced small parts.

The patient was anæsthetized with chloroform, the external genitalia and vagina were washed with a solution of hydrarg. bichlor. 1 to 2000, the bladder was catheterized, and the head perforated by a large guarded trocar in the presenting posterior fontanelle. A stream of limpid liquid gushed out which was collected in a vessel at the bedside, draining on to Dr. Kelly's obstetric cushion, upon which the patient lay in the dorsal position. As the fluid drained away the abdomen grew visibly smaller. Gentle pressure above the pubes increased the currrent, which at the last was admixed with some blood. The abdomen was now quite relaxed, and by gentle traction on the tissues of the skull with a flat, duck-bill, bone forceps, the head collapsed and was easily drawn down, and the child delivered. The placenta followed immediately by gentle expression, after which the vagina was again douched with a weak solution of bichloride and the patient returned to her place in bed, perfectly comfortable and composed, without any pulse elevation.

The child proved to be a monstrous female measuring in length 66 centimetres (26 inches). Size of the head from chin to vertex 21 centimetres; occipito-frontal 41 centimetres. After the parts were restored as nearly as possible to their natural position, by filling the head with wood shavings, it measured as follows:

Occipito-frontal circumference	.	22½	inches.
Occipito-mental "	.	23½	"
Cervico-bregmatic "	.	19½	"
Fronto-mental "	.	16	"

The fluid contained in the skull measured five pints. The anterior fontanelle was about the size of a man's hand, the nails well developed.

The mother made a speedy recovery, and was with difficulty kept in bed after the fourth day. Her first child, born about eighteen months previously, was perfectly healthy and the labor natural.

Judging from the history I believe she had been in labor for two weeks when I saw her. The uterus made regular attempts for many days to expel its contents, but being unable to force this enormous head into the pelvis was finally exhausted and complete inertia followed.

The history justifies the opinion that had a careful examination been made at the time when the vomiting began she would have been relieved earlier, and the great risks she ran materially diminished.

The obstetric cushion is an oval rubber sheet with an inflatable rim, open on one side where fluids are discharged and conducted by an apron into a bucket. By means of its use, the constant douching and free discharge of fluid, as well as the discharge of blood and placenta, were kept from the bed and patient's clothing, and she was at once returned perfectly clean to a dry bed after the completion of the delivery.

The specimen is well preserved, and is now in the possession of the Mütter Museum at the College of Physicians.

11°4 Hancock Street, Phila., December 30, 1887.

ASEXUALIZATION AS A PENALTY FOR CRIME.[1]

BY ORPHEUS EVERTS, M.D.

A medical correspondent of the Cincinnati *Lancet-Clinic* of October 15, 1887, referring to a suggestion by Dr. Agnew, that emasculation as a penalty for the crime of rape would be followed, if inflicted legally, by satisfactory results, approves the suggestion, as if this penalty were novel and untried; and asks if the subject cannot be brought before the Academy of Medicine for discussion, with a view to influencing legislation for its adoption.

Having given the subject of emasculation a good deal of attention in the course of twenty years' constant association with, and study of, one of the several defective classes of society—not, it is true, as a contemplated penalty for the crime of rape—but as a possibly important factor in the great social problem of lessening the burden of society by bettering the condition and lessening the number of the defective classes, I beg leave to submit a proposition imperfectly embodying conclusions arrived at, and to offer in support a brief and desultory commentary.

[1] Read before the Cincinnati Academy of Medicine, February 27, 1888.

The proposition may be formulated thus:

Surgical asexualization of all criminals convicted of offences that, circumstantially considered, indicate constitutional depravities that are recognized as transmissible by heredity, is not only practicable, but expedient for the protection of society from the ever impending danger of invasion by the "savages of civilization," known as the vicious, criminal, or defective classes, and would, properly enforced, eventuate in an effectual diminution of crime, and reformation of criminals.

The scope of this proposition is much broader than that contemplated by Dr. Agnew and the *Lancet-Clinic* correspondent, and is based upon considerations much more complex and comprehensive than a species of revenge, naturally suggested to persons whose civilization is but a veneering, for all offences against the written and unwritten laws of society regulating commerce of the sexes, and often practised by outraged or enraged avengers of hymeneal infidelity, or family dishonor; as, for example, by the relatives of the noble but unfortunate Heloise upon her priestly lover and seducer, Abelard, whose name, inseparable from hers, filled for centuries so large a page in the history of true love's constancy and martyrdom.

In order to comprehend more fully the purport of the proposition submitted, it may be well to consider carefully the following facts, viz.:

(*a*) Among all undeveloped peoples, punishment for offences, criminal or otherwise, is retaliatory, vindictive, and cruel, the primary purpose being to gratify revengeful feelings by the infliction of pain upon the offender, and secondarily, to terrify others by the exhibition of cruelty and power. Further on in the history of human progress ideas of compensatory justice appear, and an eye for an eye, and a tooth for a tooth are demanded, or certain equivalents, not in kind, are made acceptable, as punitive, for misdemeanors affecting rights of property, or for minor offences affecting the rights of persons.

(*b*) But, step by step with the evolution of morals, characteristic of, and inevitably concomitant with higher reaches of human development especially appreciable within the last two or three centuries, the disposition to punish criminals by way of retaliation—blood for blood, a blow for a blow, and burning for burning—has been undergoing well marked modification. The tendency has been, and is, in all civilized states called Christian, toward, not toleration of crime or forgiveness of criminals, but a more charitable, because more intelligent, consideration of the relation of criminal conduct to antecedent and concomitant conditions affecting the lives and character of the guilty, and a recognition of the duties imposed upon society growing out of such relations.

We have reached a plane of perceptions, indeed,

in this country, where such considerations and recognitions have displaced, to a great extent, ancient ideas of retaliatory or compensatory justice, and the nature of responsibility of individuals growing out of their relation to society.

The question with us in considering any new proposition respecting criminal jurisprudence now is, not what kind or degree of torture inflicted upon the guilty will satisfy the indignation or appease the anger of offended innocence, or intimidate most effectually the evil minded and criminally disposed, but what kind of treatment shall criminals receive at the hands of society consistent with its self-protection, that is likely to eventuate in a general betterment of their conditions, and consequent improvement of their disposition? In other words, by what methods of punishment, the most kindly and considerate, can society be most effectually protected from injury and apprehension, crime most effectually diminished and prevented, and criminals most effectually reformed?

In proposing asexualization as a penalty for crime, the foregoing question has not been overlooked nor evaded; hence the use of the term asexualization as implying its applicability to both sexes, instead of emasculation, as applicable to men only. Hence, also, the extension of its applicability to an entire class of offenders, however varied their crimes, instead of its limitation to such only as do violence to the laws governing the commerce of the sexes.

Would a penal enactment embodying the proposition under consideration answer the demands of civilized society as above indicated? If so, it should be unhesitatingly adopted. If not, it should be as unhesitatingly rejected. It is my present belief that it would; that in accordance with physiological and psychological facts and principles, such consequences would follow the intelligent enforcement of this proposed method of treating criminals, as would, after a time, fully vindicate the wisdom of its adoption. In support of this affirmation, the following considerations are respectfully submitted, viz.:

(*a*) The conduct—speech and action—of all living beings is expressive of the organic instincts, capabilities, and appetences indicative of the necessities or desires of such beings.

(*b*) The organic instincts, capabilities, and appetences of all living beings, indicative of their necessities and desires, manifested by their conduct, speech, and action, may be classified under one or the other of two heads, as pertaining either to the "love of life" or the "love of sex;" the end of the one being preservation of self; the end of the other being reproduction of self, the end of both being perpetuation of the race.

(*c*) Man is not an exceptional being as to his becoming, subsisting, reproducing, or disappearing, individually, or as a race; differing only structurally and functionally from other living beings of the order to which, zoölogically considered, he belongs, to the extent of certain modifications of organs and function, common to the order, effected by disuse or increased activity of such organs in adapting themselves to new uses, under the pressure of ever-increasing capabilities and necessities, aided by the fixing quality of heredity. Therefore all human conduct, however exalted or debased, whether in pursuit of gain or glory, power on earth or heavenly approbation, or gross and grovelling gratification of the primary senses, may be referred to one or the other of these organic loves—the love of life or the love of sex.

(*d*) The love of life precedes, outlasts, and is stronger than the love of sex. Beginning with the specialization of matter as a living being, it continues and increases through all the stages of growth, diminishing with retrogressive motion, to disappear only with the final dissolution of the individual.

The love of sex develops with the development of sexual capabilities, appearing comparatively later in the growth of the more highly organized and intellectually capable beings, growing stronger with the natural growth and exercise of functional capabilities, to culminate and diminish, leaving but a memory, long before the limit of individual expectation of life has been reached.

(*e*) By far the greater exhibition of vicious conduct, including crimes, characteristic of the defective criminal classes of society, pertains to that period of individual human existence remarkable for the activity, strength, and domination of the love of sex; and is intimately related thereto, as well as associated therewith. Witness, for example, the daily chronicle of crime, of homicide, suicide, defalcation, embezzlement, etc., ascribed directly to sexual influences, or motives associated with sexual love. Witness also the vices of intemperance so often associated with and instigated by sexual excesses, or unsatisfied sexual desires; of prostitution maintained by lust; of gambling with delusive hope of gain to satisfy immediate wants growing out of the requirements of sexual relations, etc., and the nameless disorderly sensations, emotions, and imaginations leading or driving multitudes crimeward, that originate in sexual disturbances, whether of deprivation or excess.

(*f*) The physical or structural, and consequently psychical characteristics of the defective classes of society, manifested by well-marked proclivities to mental disorder, vice, or crime, developed under circumstances often to be regarded as unfavorable for such manifestations, are reproducible, and being constantly reproduced, perpetuated, and multiplied, with a tendency to exaggeration, by intermarriage of persons of like defects, according to the recognized laws or uniformity of results of the activities of living matter called heredity.

(*g*) Society can protect itself from the danger threatened by the criminal classes by either destroying their capabilities to inflict injury upon others, or by changing their desires, and, consequently, their purposes, by which their actions are instigated and controlled.

(*h*) The deprivation of animals, including man, of reproductive capabilities, effects well-marked modification of characteristics, or changes of desires, purposes, and actions, as an inevitable sequence of altered conditions, capabilities, appetences, and necessities of the altered being, without destroying capabilities and consequent desires for the maintenance of individual existence, hence practical usefulness. Such modifications, if begun early in life, are invariably manifested by gentler and more dispassionate manners, freedom from sudden and violent emotional disturbances, and less self-assertion and obstinacy of disposition.

(*i*) Nature's method of improving a species or variety of living beings is by selection, through sexual love, of the most lovable for purposes of reproduction, the most lovable being always the strongest, most capable, and most beautiful; and the assertion of strength or capability in the struggle for existence, in which the fittest, most capable survive, and the unfit, deficient, perish.

If these affirmations are all true, as I believe them to be, then certainly no other method could be devised for the suppression of crime and reformation or improvement of the criminal and defective classes of society than this proposed—the asexualization of all convicts whose crimes, circumstantially considered, indicate constitutional depravities transmissible by descent from parents to offspring, together with such legal restraints as may be found necessary to complete its efficiency.

Let us examine its promising features a little more closely, and in detail. For purposes of intimidation it presents features second only in degree of repulsiveness and terrifying power to the death penalty itself. Multitudes of men derive nearly all conscious pleasure from the indulgence of sexual appetites, and hence regard such indulgence as the chief end of being, or value of existence. The loss of sexual ability, as a token of manhood, as well as a source of exquisite enjoyment, would be contemplated with abhorrence, and avoided, if possible, by all sane men.

For purposes of reformation, it presents features more promising than any other known method, because it is in accordance with the great facts recognized by science—that all feelings, desires, purposes, and, consequently, all conduct is definitely related to antecedent relations of living mechanisms, and may be permanently modified by permanent modifications of such mechanisms or organs. Other methods—"moral instruction" of convicts in prison, etc.—are too slow and uncertain for practical purposes.

But the most important of all the features of this proposition to asexualize all constitutionally depraved convicts, is that which promises surely, however slowly, to diminish the number of the defective classes of society by limiting, to the extent of its application, the reproductive capability of such classes. For this purpose it has no practicable competitor. It is in the line of nature's suggestion, aiding "natural selection" by destroying the procreative capabilities of the "unfit," instead of, as we are now doing, carefully preserving them by public benefactions from their own tendencies to dissolution, and complacently permitting them to multiply and accumulate by unrestricted reproduction.

It may be asked—significantly, I admit—Why not capital punishment, once for all, and have done with it? Because, I answer, the death penalty, however promptly and thoroughly efficacious as a means of contributing to a more certain and rapid disappearance of the unfit and survival of the fittest, goes beyond the necessities of the case, or the requirements of nature, and destroys the man, while emasculation only "alters" him. Furthermore, whatever may have been the effect of the death penalty in the progress of society from a savage state to its present civilization (and there can be no question of its great value in times past), it has been gradually forced, by growing sentiments of disfavor, into narrower ranges of usefulness, until now, instead of being extended to all manner of crimes and misdemeanors, from wilful murder to petty theft or trespasses, it is limited in most States to two or three grand offences, and by some States utterly abolished.

It is, in fact, only when the subcuticular ancestral savagery of our natures is aroused by some extraordinarily atrocious crime, such as the assassination of Garfield, or the murder of policemen in Chicago, that we hear a general clamor for the blood of the offenders. And even in such instances public sentiment is by no means unanimous in favor of killing the convicted criminals.

It may be safely inferred, therefore, that the death-penalty will never be restored to favor sufficiently to obviate the necessity of more efficient measures than have as yet been adopted by civilized States for the reformation of convicts and diminution of the defective classes of society.

Imprisonment alone for short terms at labor, or in solitude, however cruel or humanely practised, with "moral instruction" or without, protects society but partially, and for short intervals, and fails signally to reform the imprisoned, or diminish the numbers of the classes to which they belong. Were each man or woman returned to society from our

penitentiaries deprived of reproductive capabilities, how different would be the story.

Public sentiment might not sustain such an innovation. The public sentiment of the future is destined to be more and more informed by science, and will eventually adopt its suggestions in matters of state-craft and social economy, including criminal jurisprudence, as well as in all other affairs of life.

This world with its inhabitants is slowly but surely moving into a new and more brilliant light, and freeing itself from the shadows of ancient errors and modern superstitions. Already the hilltops of science are luminous, and men of intelligence and learning no longer dwell in an atmosphere of gloom, peopled with imaginary beings, gods, and demons, and multitudinous ghastly survivals of ancestral chimeras, standing in the relation of invisible causes of all visible effects, but moving ever on and up toward the greater light, realize the fact that with every step taken, vision becomes clearer and more comprehensive, and that positions may be occupied to-day with safety that but yesterday seemed to be dangerous, if not inaccessible.

MEDICAL PROGRESS.

Loreta's Operation upon the Stomach.—Digital dilatation for fibrous stricture of the pylorus, which was first practised by Prof. P. Loreta, of Bologna, in 1822, has already in his hands given most satisfactory results in a large number of cases. The *Riforma Medica* of February 18th contains an account of a case in which the operation was recently performed by Dr. Loreta, which is of special interest, owing to the detailed way in which it is reported. In January last a man, fifty-four years of age, but looking much older, owing to his wasted and careworn appearance, came under the professor's care, with the following history: He had been excessively intemperate both in eating and drinking, and had suffered from severe dyspepsia since 1872. In 1880 he began to be troubled with vomiting, which occurred regularly four or five hours after taking food. The stomach was visibly dilated, and a splashing sound could be heard on succussion. Microscopic examination of the vomited matters gave negative results; neither blood, starch-granules, nor sarcinæ could be detected. No tumor could be felt in the hypochondriac or epigastric regions; the abdomen yielded readily to pressure with the hand, which, however, caused a slight amount of pain. At the place where this tenderness was most pronounced, a hard fibrous cord was felt at a point corresponding to the situation of the pylorus. On January 30th, after washing out the stomach with an alkaline solution, Professor Loreta made an incision along the linea alba, from the xiphoid cartilage to the umbilicus, and exposed the stomach, which was drawn partly out of the wound, and opened about midway between the greater and lesser curvatures. The index finger was then passed into the viscus in the direction of the pylorus, through which, however, it could not be pushed. A large-sized urethral bougie, and afterward an œsophageal sound were then passed through into the duodenum. By this means the stricture was so far dilated that the operator was able to get his finger through the pylorus and draw it over almost to the abdominal wound. The index of the left hand was then also passed through on the right as a guide. The pyloric orifice was then dilated by forcible divulsion with the two fingers, a proceeding which the tightness of the stricture rendered very difficult. Finally, the wound in the stomach was closed by continuous, and that in the abdominal wall by interrupted, suture, and an antiseptic dressing was applied. On February 9th the wound was healed, and the patient had completely got rid of his troublesome symptoms. Digestion was perfect, vomiting had entirely ceased, and the man had lost the look of suffering which had been so marked before the operation. Dr. Maurizio Bufalini, who reports the case, says that not a single instance of relapse after Loreta's operation has yet been heard of.—*British Medical Journal*, March 3, 1888.

Formulæ for the Local Treatment of Whooping-cough.—The *Revue Gén. de Clin. et de Thér.* of March 1, 1888, reports the following useful formulæ:

Quiniæ hydrochlor.	1 part.
Acid. benzoic.	3 parts.

Boric acid may be used as

Acid. boric. pulv., Finely pulverized coffee	equal parts.

Bismuth. subnitrat.	2 parts.
Benzoin. pulv.	1 part.

The salicylate of bismuth may be combined in

Bismuth. salicylat., Benzoin. pulv.	āā gr. 75.
Quiniæ sulphat.	gr. 15.

Also

Sodii salicylat., Benzoin. pulv.	āā gr. 75.
Quiniæ sulphat.	gr. 15.

These powders should be as fine as possible, and may be blown into the nostrils through an ordinary soft rubber tube.

The Treatment of Diphtheria by Mercurial Fumigations.—Corbin, in the *New York Medical Journal* of March 10, 1888, describes his method of treatment as follows:

I insist, when possible, that the patient be in a room where the sunlight has free entrance, that the temperature of the room shall not be lower than seventy-five degrees, and that the air shall be kept moist by the evaporation of water. During the time of the fumigations the patient receives no medicine whatever. At the beginning and end of a fumigation, milk-punch or wine is given. This I insist upon. A child's crib with barrel-hoops across the top, secured, and over these spread a flannel blanket, makes a suitable canopy or tent. In the case of a child eight or ten years of age I volatilize from forty grains to a drachm of the mild chloride. I keep the child under the canopy twenty minutes, when the blanket is removed. This is repeated every two or three hours during the first day. After this period I expect to find the cough loosened,

giving directions to prolong the intervals of the fumigations, and at once to resort to them if the cough tightens. I have had cases where they had to be continued for over a week, but not more than two or three each day. The aphonia may not disappear for a week or two, but this need excite no alarm. Let the patient receive the most thorough alimentation. The fumes are not offensive, and as a rule the child makes no resistance after the first fumigation. Generally the patient falls into a refreshing sleep, and sometimes he will point to the lamp, indicating that a fumigation is desired. The lamp had better be powerful enough to volatilize a drachm of calomel in one minute. The lamp I have constructed does this. By this means the air of the tent is not raised to too high a temperature for respiration.

Colored Light in the Treatment of the Insane.—Dr. Ponza, medical superintendent of the lunatic asylum at Alessandria (Italy), reports some experiments which he has made on the effect of colored light on lunatics. The idea was suggested to him by the observations of Robert Hunt on the favorable effect which light transmitted through violet-tinted glass had on the development of animals and plants. Dr. Ponza selected rooms with as many windows as possible, and he had the walls painted of the same color as the window-panes. A patient suffering from melancholia, who would not eat, was placed in a room with bright red walls and windows; in three hours he became quite cheerful and asked for food. Another lunatic, who always kept his hands over his mouth to keep out air and nourishment, was placed in the same room, and the next day he was much better, and ate with a hearty appetite. A violent maniac was placed in a blue room and became quiet in an hour. Another patient, after spending a whole day in a violet-colored room, was completely cured. Theoretically this appears to be a very interesting experiment, but we have good reason to believe that in practice it is of little real service. It had one very good effect, which was that it induced the medical men who were making the experiment to spend a good deal of time and attention on the patients who were under treatment. One German medical man who visited Alessandria, said it was "most excellent for the doctors." It is probable that in some future day electric light may be used for the darker parts of asylums, and then we shall be able to see whether electric light will serve to develop vitality in men as it has been proved to do in plants. In many persons of unsound mind the whole vital energy is defective, and the medical officers often feel a sad want of something which will produce energy. Stimulants of one kind and another are tried, and do some good; but we should welcome some more general natural means of improving the general health. The asylum physician looks to food, warmth, and exercise, as his great assistants; and if electricity, or blue or yellow rays, can be added, so much the better.—*British Medical Journal*, March 3, 1888.

Sciatica Caused by Varicose Veins.—Quénu, at the Surgical Society of Paris, reported that he had observed closely very many cases at the City Dispensary, and his opinion was well formed on the fact. In sixty-seven patients who had varicose veins, eleven suffered from sciatica, which disappeared with rest, and especially when the patient took the horizontal position. As treatment, M. Quénu recommended that the patient should wear an elastic stocking reaching up to the groin. M. Berger said that the above remarks were interesting, as the number of patients who have varicose veins is very great. At the same time he thought that the stocking as advocated by M. Quénu, is attended with considerable inconvenience, inasmuch as he had observed that it leaves its position and rolls like a tight cord around the thigh, thus impeding the return of the circulation.—*Medical Press*, February 29, 1888.

Poisoning by Aconitine.—*Les Nouveaux Remèdes*, No. 4, 1888, reports an interesting case of fatal poisoning by aconitine, in the following prescription.

Quiniæ sulphat.	gr. 24.
Morph. hydrochlorat.	gr. ½.
Aconitin.	gr. $\frac{3}{100}$.

In six wafers.

Death occurred after taking the second wafer, the patient being a woman suffering from neuralgia.

Investigation revealed the fact that each wafer contained $\frac{3}{400}$th of a grain instead of $\frac{3}{600}$th as intended. The druggist, instead of dividing *each ingredient separately* into sixths, had divided the mass into sixths, and then put each mass in a capsule. Inasmuch as $\frac{3}{600}$th of a grain could not readily be weighed, especial care was indicated in dividing the whole amount ordered. The authorities censured both physician and pharmacist.

A Convenient Dressing in Circumcision in Adults.—Balance describes in the *St. Thomas's Hospital Reports*, vol. xvi. p. 198, his method of dressing the penis, as follows:

When the patient is etherized the outline of the posterior border of the glans is marked on the skin with an aniline pencil. The skin of the prepuce is slit and removed up to the aniline line. The mucous membrane is next cut away, leaving only a free edge of about one-eighth of an inch in width. Any bleeding which occurs should be entirely arrested and asepsis must be insured by frequent sponging with carbolic or sublimate solutions. Numerous horsehair stitches are then inserted, so as to bring accurately together the fresh-cut edges of the skin and mucous membrane, and subsequently, after a further sponging and drying, a piece of gauze two layers in thickness, and wide enough to reach from the root of the penis nearly to the meatus, is wrapped *loosely* round the penis, and secured by several applications of the collodion brush. The setting of the collodion is hastened by the use of a fan, so that the air is kept in motion and the patient should not be allowed to recover from the anæsthetic until the dressing is quite firm and hard.

In this manner the penis is protected by a kind of carapace, and the patient is relieved from the pain and tenderness attendant upon contact with the bedclothes or other objects. In fact, the organ can be handled as if no operation had been performed. It is hardly necessary to add that erections, which are under the usual conditions so painful, cannot occur.

The patient never had any discomfort from first to last, and the day after the operation put on his trousers without my leave, and expressed himself as desirous of taking a long walk or of going to business.

The points to note are:

(1) The operation must be aseptic.

(2) The gauze should be applied *loosely*.

The dressing can be made to extend, at the will of the operator, as far forward as the meatus externus. Half an inch, however, in front of the corona is ample. If the dressing has been put on rather tightly, and some swelling of the glans beyond the dressing occurs, this can be combated by an extension of the collodion dressing forward to the urethra, or by the constant use of iced dilute subacetate of lead lotion. When necessary, the dressing can be easily removed by slitting it up by means of blunt-pointed scissors. It is usually worn for about a week. As yet I have never found it necessary to apply it a second time.

Naregania Alata.—HOOPER is quoted by *L'Union Médicale* of February 21, 1888, as introducing to the notice of physicians this plant, a native of Malabar. It is used in infusion and decoction by the natives for bilious disorders and rheumatism. An alkaloid, naregania, is derived from the bark, which is an active anti-dysenteric remedy and emetic, resembling ipecac: its dose for these conditions is fifteen grains. In small doses it is expectorant. It may be given in powder or tincture, the wine is inert.

Acute Hydrops Amnii following Nervous Shock.—HUMPHREYS reports the following interesting case, in the *Lancet* of February 25, 1888:

Mrs. S., aged thirty-three, in her ninth pregnancy, stated that she first felt the fœtal movements on October 5th. On the same day her mother was seized with a stroke of apoplexy in her house, dying the next day. The patient was first seen on October 15th. The abdomen was then greatly distended with fluid, which had been gradually collecting since the 5th, and was very tender. She now appeared to be in the ninth or tenth month of pregnancy. There were considerable dyspnœa, some palpitation, and a small weak pulse; there was also considerable lumbar pain. The abdomen measured twenty-one inches between the superior spines of the ilium, and was very tense. Dr. Galabin saw her with me on the 17th at 9 P. M., and agreed with the diagnosis of hydrops amnii, recognizing the presence of twins. The membranes were at once ruptured, nine pints of fluid escaping. The uterus contracted well, perhaps in consequence of a dose of ergot given earlier in the day. The twins were born the following morning, before my arrival, at 9 A. M. There was only one placenta, there being one chorion and two amnions. There was free direct communication between the veins of the two cords. The half of the placenta which belonged to the second fœtus had several apopleptic clots in it, and the fluid in the unbroken membranes was "very dark in color, like blood."

Terebene. — The following formula is a convenient method of administering terebene:

Terebene	1 part.
Glycerine	15 parts.
Cognac,	
Syrup. simpl.	q. s.

The mixture should contain 32 of terebene.—*Les Nouveaux Remèdes*, No. 4, 1888.

The Solubility of Saccharin.—CRESPIE gives the following interesting information regarding saccharin, in the *Provincial Medical Journal* for March, 1888:

In cold water saccharin is only slightly soluble; in water of the temperature of 120° Fahr., it is only moderately soluble; while even in boiling water it is not perfectly soluble, but when the solution is neutralized, and carbonate of soda or carbonate of potash is added to it, the solubility is greatly increased. When saccharin is added to a solution of carbonate of potash, or of carbonate of soda, carbonic acid is freely given off, and a compound of soda or potash salts with saccharin is formed. It is found that these salts are nearly as sweet as saccharin itself, and as they are soluble they are far more convenient to use. One tabloid is fairly equivalent to a lump of white sugar. He finds that it is better to put the tabloid into the cup, and then add the hot coffee or tea, and finally the milk. In a week one would get used to saccharin tabloids, and not miss the more familiar, though hardly more palatable, cane or beet-root sugar.

Alcohol, which will dissolve so many substances on which water alone will hardly act at all, will also dissolve saccharin, and no doubt in time the manufacturer of pure unadulterated sweet wines, cordials, and liqueurs, will not forget to add it to his armory. Mosso has carefully investigated the subject, and finds that one gallon of 10 per cent. alcohol will dissolve 378.7 grains of saccharin; one gallon of 40 per cent. alcohol will take up 1391.6 grains; one of 80 per cent. will hold 2550.5; while absolute alcohol will only suspend 2118.9 grains. The reader will notice that an 80 per cent. mixture of alcohol and water takes up the largest amount of saccharin; it is, by the way, often curious, but true, that the strongest solvent, as at first sight it appears, answers worse than a weaker form of the same solvent. Saccharin is also abundantly soluble in warm glycerine. At a temperature of 224° Fahr. saccharin melts, and then is partially decomposed and gives off a characteristic odor. Professor Stutzer, of Bonn, tells us that one grain of saccharin will distinctly sweeten 70,000 grains of pure distilled water.

The Use of Creolin.—SPAETH is quoted by the *Wiener medizinische Presse*, No. 8, 1888, in reporting his results with creolin in hospital practice at Frankfurt. He employed commonly gauze dipped in two per cent. emulsion of creolin, over which he placed compresses of wood-wool or gutta-percha tissue. His cases included six severe burns, five varicose ulcers, and repeated applications of creolin to wounds which had failed to heal by first intention, and which contained sluggish, exuberant granulation. Healthy granulations formed more rapidly than under any other treatment. In a case of pyæmia following amputation of the thigh, the patient was succumbing to septic infection, and the antiseptic dressings commonly used, served to increase the necrotic process. Under treatment with gauze saturated with two per cent. emulsion of creolin, a favorable reaction occurred in two days, and recovery ensued in twenty days. Spaeth has never seen symptoms of intoxication, such as often follow carbolic acid poisoning. Eczema was never caused by creolin. Spaeth is inclined to believe that creolin belongs to the benzol group. The absence of irritating effects from creolin seem to render it a most desirable addition to our means for dressing wounds.

The Treatment of Sleeplessness.—Dr. Eccles, in the *Practitioner* for March, 1888, concludes an interesting article on the treatment of insomnia as follows:

The hot bath, the hot abdominal compress, with or without previous kneading of the belly, or the whole wet-pack modified to suit the requirements of the case, and all of these followed by the most rigid observance of the recumbent position in a warm bed placed in a quiet, cool, well-ventilated room, so arranged that direct or reflected light, whether from fire or candle, shall not disturb the patient, have been found almost invariably successful aids to sleep in the different disorders of this function not dependent on pyrexial or severely painful conditions which have come under the notice of the writer. And even in cases of severe sciatic and trigeminal neuralgias the wet-pack has been employed with good results; but for the various derangements of sleep included under the general term insomnia, these expedients are only temporarily useful to initiate, as it were, the permanent restoration of the rhythmical healthy repose of mind and body of which those for whom they have been employed stood in so great need.

To effect this permanent restoration of refreshing sleep a method of treatment is needed which must break the chain of vicious circumstances under whose thraldom the patient has lost the power to sleep. The brain, in these cases often found to have been overworked, must be allowed to lie fallow as far as possible; the stomach, which has generally suffered with the other organs of digestion from the most extraordinary maltreatment, must be coaxed back again to a regular performance of its duties; while the muscular system, which has become wasted and inert from long disuse, must be called upon to fulfil its digestive and excrementitious functions, so long left in abeyance. Under the combined influence of the recumbent position in a quiet room, away from the cares of domestic, social, or business life, carefully modified diet, and massage applied as a therapeutical agent, not without regard to the mode, duration, and extent of its administration, the methods of treatment referred to above may be carried out with the happiest result in the majority of cases.

The Constitutional Treatment of Endometritis.—Chéron has found the following formulæ useful in treating the constitutional disorders requiring attention in chronic endometritis:

A mild and efficient laxative—

Sulphur. sublim.,	
Magnesiæ calcin. . . .	āā ʒ 2½.
Potass. et sodii tartrat. . .	ʒ 5.

Picric acid may be given for anorexia, when ordinary remedies fail:

Acid. picric.	$\frac{3}{10}$th to $\frac{5}{20}$th gr.
Aquæ	1 quart.

A small glassful to be taken with common red wine at meals.

To allay persistent nausea

Potass. bicarb.,	
Potass. bromid. . . .	āā gr. 30.
Aquæ commun. . . .	ʒ 15.

of this a teaspoonful is to be placed in a glass, and to it a tablespoonful of the following mixture is to be added:

Acid. citric.	ʒ 1.
Syrup. simpl.	ʒ 1.
Aquæ commun. . . .	ʒ 30.

The dose may be repeated every half hour or hour until nausea is relieved.

For the nervous symptoms of chronic endometritis the following was found useful:

Tinct. valerian. . . .	ʒ 2½.
Spirit. melissæ. . . .	ʒ 3¾.
Aquæ menth. piper. . .	ʒ 12½.
Spirit. ætheris . . .	ʒ 10.
Aquæ destillat. . . .	ʒ 30.

Dose three or four drachms daily.

A sedative lotion may also be used, as follows:

Alcohol. camphorat.,	
Glycerin.,	
Chloroform.,	
Tinct. menth. piper. . .	equal parts.

One or two teaspoonfuls should be poured upon flannel and friction made over the seat of pain.—*Revue Gén. de Clin. et de Thér.*, March 1, 1888.

The Treatment of Diphtheria by Applications of Carbolic Acid.—The Paris correspondent of the *British Medical Journal* of March 3, 1888, writes that at a recent meeting of a medical society Gaucher read a paper on the treatment of diphtheria by removing the false membranes, and cauterizing the places from which they were taken with a concentrated solution of carbolic acid. He dissolves 75 to 150 grains of carbolic acid in 2½ drachms of alcohol, and adds to this mixture 4 to 5 drachms of camphor, with a small quantity of oil. M. Gaucher obtained excellent results with this treatment in two cases. M. Joffroy stated that he employed chloral as a local application in diphtheria. This substance has more powerful parasiticide properties than carbolic acid. M. Joffroy washed the throat with a two per cent. solution of chloral; he then applied a one-fifth solution to the false membranes, which disappeared; the throat remained ulcerated; the application of the solution was continued. By this means diphtheritic angina is transformed into erythematous angina. This treatment could not be applied to children. M. Gaucher stated that he had tried chloral, but had found carbolic acid more efficacious. M. Blachez believed that false membranes might be destroyed in a less painful manner with petroleum oil. M. Gaucher remarked that the special object of his treatment was to destroy the false membranes in order to prevent secondary infection. M. Richard stated that the addition of one half per cent. of tartaric acid rendered carbolic acid much more powerfully antiseptic.

Gymnema Sylvestra, a new Therapeutic Agent.—The bitter taste possessed by certain drugs, notably quinine, is often found a serious obstacle to their being prescribed for young children, and it has long been held to be desirable that we should possess some powerful agent of agreeable flavor, capable of disguising such taste. Saccharin was supposed to be a near approach to this end, but there is, apparently, a still more promising agent

likely soon to be available, in the shape of gymnemic acid, derived from an Indian plant, the Gymnema Sylvestra. A few drops of this substance largely diluted with water will, it is said, if taken into the mouth, entirely destroy the power of tasting sweets or bitters swallowed in from two to four hours afterward. Gingerbread eaten under these circumstances produces only the hot taste of ginger to be perceived, and ordinary quinine sulphate leaves the sensation merely of so much chalk in the mouth. Its discoverer, Dr. D. Hooper, states that the acid bears many resemblances to chrysophanic acid, and in his opinion it will be found of much service in disguising the nauseous taste of many pharmacopœial preparations.—*Medical Press*, March 7, 1888.

The Treatment of Uterine Fibroids.—The theories and practice of Apostoli have led to much discussion on the treatment of fibro-myomatous tumors of the uterus, more conveniently termed uterine fibroid disease. This method, like everything else in the universe, is the effect of a cause. In this case, the cause is the danger of amputation of the uterus, balanced by the uncertainty of palliative measures. Electricity is a fascinating middle course between physic, often so impotent, and the knife, often so fatal. A fibroid uterine tumor may assume gigantic proportions, and cause serious trouble; but its increase in bulk is never rapid, in the same sense that the growth of a cyst or a sarcoma is rapid, and the menopause is often its limit. Yet it may be the source of pain, menorrhagia, and often troublesome and dangerous symptoms. Then operative measures are suggested. In the case of hysterectomy or oöphorectomy, the operation is always perilous, and depends, perhaps more than any other surgical operation, on the experience as well as the mere skill of the operator. Hence gynecologists turn to palliatives or electrolysis. With respect to palliatives, it is certain that almost any rational treatment tends to reduce the size of a large fibroid tumor. Rest, moderate purgation, and the administration of ergot without any of those incompatibles with which it is often given, all appreciably affect tumors of this kind for a time. Authorities of the negative or expectant school believe in Woodhall Spa. The amount of benefit derived from palliative treatment is ever uncertain, though permanent arrest of the tumor is occasionally effected. When an operation is contemplated, the choice lies between oöphorectomy and hysterectomy. Surgeons without special experience too often look on oöphorectomy as an easy and safe operation; but the facts have shown that, in the case of fibroids, it is often difficult or impossible, and that when possible it is perilous, owing to the difficulties experienced in securing the pedicle. Enucleation during abdominal section is not justifiable. Hysterectomy may be performed as an intraperitoneal or an extraperitoneal operation. The intraperitoneal variety is logically the better, but it is extremely dangerous. No surgeon can calculate how to tie each suture firmly enough to check hemorrhage, yet not so tightly as to cause sloughing or tearing of the thread through its track; still less can he guard against contraction or relaxation of the uterine tissues around the uterus after the return of the stump into the abdominal cavity. The extraperitoneal operation is less dangerous; but it requires nerve, dexterity, and experience, at least of other surgeons' practice. Statistics are absolutely worse than useless as guides to surgeons devoid of special experience; and decision, sad to say, is too frequently qualified by personal predilection for some operation, or by dislike for another. Unconscious hypocrisy often influences inexperienced operators. Apostoli's electrolysis is fascinating because, unlike palliative treatment, it means "doing something;" whilst many believe that it involves neither the difficulties nor the risks of operation. Experience is proving, however, that Apostoli's method requires great skill and demands many precautions, and that it is not altogether free from danger. As to permanent results, even so respected an authority as Dr. Keith depends upon the words of another, and that other is Apostoli himself. The conclusions to which we are led by the above facts are that palliative treatment is the only course which a practitioner without special experience can justifiably pursue in the case of uterine fibroids; and that the relative merits of oöphorectomy, hysterectomy, and electrolysis can only be decided by experts.—*British Medical Journal*, March 10, 1888.

An Elixir of Paraldehyde.—The following formula has been used with moderate success, though many physicians who have tried paraldehyde have given up its use, chiefly from the disagreeable breath acquired by those who take it:

Paraldehyde	ʃ℥ij.
Spirit of chloroform	ʃ℥iij.
Tinct. of vanilla	ʃ℥ss.
Syrup of raspberries	ʃ℥ss.
Aromatic elixir	enough to make ʃ℥iv.

Dose for adults, two fluid-drachms, containing one fluid-drachm of paraldehyde.—*American Druggist*, March, 1888.

Retrograde Catheterism.—The *Medical Press* states that at a recent meeting of the Paris Academy of Medicine, M. Tillaux related such a case before the Société de Chirurgie, which is full of interest. A man, aged forty-three, came to him suffering from a cicatricial stricture of the urethra, the consequence of falling *à cheval* on a piece of timber. Having found it impossible to introduce a sound, M. Tillaux tried external urethrotomy, but without better success. He then determined to cut down on the bladder over the pubes and perform catheterism from behind. After much trouble he succeeded, and the patient made a good recovery. M. Schwartz said that in a similar case he plunged a large curved trocar through the prostate into the bladder with every satisfaction. Several other members spoke in the same sense.

Salicylate of Bismuth in Dysentery among Children.—HALE, of the Philadelphia Polyclinic, has attained excellent results in the use of the following prescription:

℞.—Bismuthi salicyl.	ʃ℥ij.	
Tr. capsici	gtt. xij.	
Spts. ammon. aromat.	ʃ℥iss.	
Pulv. acaciæ	℥ij.	
Aq. cinnamomi	q. s. ad. ʃ℥ij.	M.

Sig.—Teaspoonful every two hours, for a child from three months to one year of age.—*The Polyclinic*, March, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MARCH 31, 1888.

A CÆSAREAN REVOLUTION IN PROGRESS IN THE UNITED STATES.

FOR a number of years prior to December, 1886, which now appears to have marked a turning point for the better, there was a gradual increase in the mortality of both women and children in Cæsarean cases in our country, until the death-rate reached for the three years preceding the above date, 93 per cent. of the former, and 87 per cent. of the latter. In the year 1884, there were six operations, without the saving of a woman or child; in 1885, there were five, saving one woman and one child; and in eleven months of 1886, four, with one child saved; the entire year, saving one woman and two children. Under fifteen operations, fourteen women and thirteen children were lost.

Prior to December, 1886, there were nine Cæsarean operations in American hospitals, under which not one woman was saved; seven of the children were extracted alive, of which one lived thirty-two hours; another, a few days: a third, thirteen days: and a fourth and fifth, a year each. The initial hospital operation was performed at Bellevue, New York, in 1860, by Prof. Fordyce Barker, upon a woman who had been two days in labor; was affected with pelvic exostosis, and bore the marks of syphilis. The child only was saved; grew to be a fine healthy girl, and may possibly be still living. Not one of the nine hospital cases can be said to have been in a *favorable* condition at the time of the operation, and one was actually moribund. The Sänger method of closing the uterine wound was adopted in three operations, but the cases succumbed notwithstanding, in consequence of their unfavorable character; one being the subject of cancer; another, much exhausted by a long labor; and the third, weak and anæmic from ante-partum hemorrhage.

With hospital case No. 10, December 16, 1886, commenced a new era in our maternity Cæsarean deliveries, as the operation was elective, early performed, and saved both mother and child, who were reported as alive and in good health on March 8, 1888. The woman had been three times delivered by craniotomy, and being anxious to have a living child, willingly entered the Huron Street Hospital, of Cleveland, Ohio, for the purpose of saving the fourth, by the Cæsarean section. Here she was operated upon according to the Sänger method, after a labor of twelve hours, and before the membranes were ruptured, by Prof. H. T. Biggar, who employed sixteen uterine sutures. The patient was a dwarf, of four feet high and sixty-five pounds weight, who belonged to Columbiana County, in which there were two successful Cæsarean sections, in 1833 and 1834.

Hospital operations 11, 12, and 13, were all performed in 1887, in Bellevue, by Prof. W. T. Lusk, saving all of the women and two of the children; the third child dying of tetanus in thirty-six hours, due probably to a head injury, from long uterine pressure; all were Sänger operations. Case 11 has been reported, the others have not been. Cases 11 and 12 were in labor but a short time; but case 13 was in the sixth day of her suffering when received. She made a slow and remarkable recovery, with several almost fatal drawbacks, as will be seen when the case is reported. Prof. Lusk gives great credit for his final success to the Sänger method, and its careful technique.

Hospital operation 14 was less fortunate in its results, as only the child was saved. The woman was of African blood, and twenty years old, and was under the care of Dr. L. Ernest Neale, in the Lying-in Hospital of the University of Maryland, Baltimore. Attempts were made to deliver her by the Tarnier forceps as modified by Prof. W. T. Howard, by which the fœtal head was very seriously wounded. After a labor of fourteen and a quarter hours, during which a trial of over an hour was made with the forceps, the operation was performed as by the original method of Sänger, muscular resection and

separating the peritoneum being found necessary to secure symperitoneal closure. The patient never rallied, and died of shock in forty-four hours. Wounds ununited; that of the uterus unhealthy in appearance. In attempting to avoid the use of the knife, the case was made unfavorable for success.

Hospital case 15 was operated upon in good season, at the Maternity of Blackwell's Island, New York, in February, 1888, by Prof. Henry J. Garrigues, with entire success to mother and child. Six deep and eight symperitoneal sutures were used. The particulars of the case will shortly be given by the operator. This was his second operation, the first having been performed in October, 1882, upon a woman prostrated by ante-partum hemorrhage, and bearing a recently dead fœtus. We heartily congratulate him upon having had this time a favorable case for the operation, and for his success in its management.

Besides the six hospital cases related, there were five in private houses, making eleven, in a period of fifteen months, eight of which were in 1887. All of the operations were by the method of Sänger but one, although in some the technique was not rigidly adhered to. Six women and eight children were saved, or $54\frac{6}{11}$ and $72\frac{8}{11}$ per cent. respectively. Of the five cases operated on in private practice, only one recovered, although three children were saved. This is reversing the experience of the past, where all cases saved were private, and all in hospitals died. To show that the change for the better in the last fifteen months is a remarkable one, we have only to go back over our record prior to December, 1886, until we find six operations that were not fatal, and we will note the fact that we have passed over a list of thirty cases in chronological order, covering eight years, under which only nine children were saved, or one more than out of the last eleven.

We are now beginning to realize practically the benefits of *early operating*, as in contrast with the dangers of *delay*, so fully demonstrated in the past. The adoption of the Sänger method, with the use of the Esmarch tubing, and asepsis, failed, until with them were associated the avoidance of futile attempts at delivery, and a recognition of the importance of prompt action in the use of the knife. We pointed out the dangers of continued uterine action long before the Sänger method was introduced, and we are more than ever convinced that the early union of the uterine wound will depend very much upon the sound or unsound condition of the muscular tissue and endometrium, to preserve which in their integrity there should be a moderate degree only of contractile action, no internal manipulation or use of extracting instruments, and the child should be vigorously alive. We admit that women do recover after long labor, the use of instruments, version, craniotomy, and the presence of a putrid fœtus *in utero;* but, on the average, an early elective operation will be much the safer, and be followed by the most rapid recovery. "*Shock and exhaustion*," so often recorded as the cause of death, really begin in a condition which exists prior to the operation, and is exhibited by an elevated temperature, rapid pulse, and great bodily weakness. In fact, the woman is worn out by muscular effort and the endurance of suffering, and the prognosis of her case, in view of a severe abdominal operation, must be unfavorable. A case regarded as a "favorable" one at the time when a Cæsarean operation is undertaken, will sometimes die; but such are much less likely to do so than "unfavorable" ones are to recover.

The fear of a fatal result under gastro-hysterotomy has had much to do with making the result fatal. But for this the operation would have been much more frequently early and elective, instead of late and compulsory. We have been too much influenced by English writers and statistics, which are antagonistic to the Cæsar-cut, and favor craniotomy. German successes have at last created a feeling in favor of the former and against the latter in our country, the fruits of which are seen in the saving of four women in succession in New York in a period of eleven months. We are now enabled by the results in our own hospital cases, to show what may and ought to be done, with equal credit, in private practice, particularly in the open country and smaller towns, where, in our early days, the least mortality occurred.

What is wanted now is a better acquaintance with pelvimetry, and the steps of the improved operation, as it is performed in Leipzig, Dresden, and New York. The coming reports of Zinke, of Cincinnati, and Lusk and Garrigues, of New York, will furnish valuable practical instruction to those who ought to be fully informed upon this important abdominal operation, so as to be ready in a case of emergency, to meet its requirements with skill and promptness. When the record of the first hundred Sänger operations is published, many readers will be astonished at its marvellous results, particularly in Germany,

and at its low rate of mortality as compared with the Porro-Cæsarean section. Thus far the United States count fifteen cases, with nine deaths and ten children saved; not a very creditable record as compared with that of Continental Europe; but we have commenced to improve it, and hope to continue in the future.

VACCINATION AGAINST TYPHOID FEVER.

Chantemesse and Vidal communicated to the Société de Biologie, at the meeting held March 3d, some interesting observations on vaccination against typhoid fever. They claim that in mice inoculated with cultures of typhoid bacilli a disease is produced, with lesions the same as in human typhoid fever. Mice inoculated with bouillon in which colonies have lived, but which no longer contain the bacilli, resist subsequent inoculation with the most intense typhoid virus. From the large number of observations, this would seem to be well established. On the other hand, mice inoculated with bouillon in which indifferent microbes had grown, such as the bacillus subtilis, did not resist, and were not in the slightest degree protected against the typhoid virus. The saturation of the organism with the soluble chemical substance produced by the typhoid bacillus granted immunity from the effects of the fresh virus. The observations are of value as illustrating the influence of organic substances produced by the growth of bacilli, and they indicate, too, the direction in which we may hope for practical results from bacteriological work.

THE NEW SURGEON-GENERAL OF THE NAVY.

The President has nominated Dr. John M. Browne to be Surgeon-General of the Navy, to succeed Dr. F. M. Gunnell, whose four years term in that office expired on March 26th. Dr. Browne is a native of New Hampshire, entered the Medical Corps of the Navy in 1853, and received his commission as Medical Director in 1878. He was the surgeon of the "Kearsage" during her memorable fight with the "Alabama," and his description of the battle, published in *The Century*, is a very graphic bit of war literature. After the war he was for several years on duty on the Pacific Coast. Since 1879 he has been on duty in Washington. He organized the Naval Museum of Hygiene, and was in charge of it for the first five years of its existence, and he was the delegate from the Medical Department of the Navy to the International Medical Congresses of London and of Copenhagen. The Medical Department of the Navy is to be congratulated upon his appointment, for he is a skilled executive, an accomplished medical officer, and a cultivated gentleman.

The roll of graduates in medicine has been increased during the past fortnight by the following additions: University of Louisville, 100; Baltimore Medical College, 17; and College of Physicians and Surgeons, Baltimore, 77.

The leading physicians of Massachusetts have just sent a remonstrance to the State legislature against the passage of any law allowing the manufacture of illuminating gas containing more than ten per cent. of carbonic oxide, as the intensely poisonous properties of that element of gas are well known, and are dangerous to health and life.

Commissioner Bayles, of the New York Board of Health, in an official communication, warmly praises several of the medical members of his staff, who were not deterred, even by the weather of that terrible Monday (March 12) from attending to their duties. One of them, especially, who has to deal with contagious diseases, is referred to enthusiastically by the Commissioner as a hero, both physically and morally, for the energetic and oftentimes ingenious work performed by that inspector in going to remote places for cases of smallpox, and removing them to the hospital, under difficulties that seemed almost insurmountable. There were others of the medical inspectors who did not spare themselves, even during the highest stress of the blizzard, while looking after their cases of contagious disease. Acts of devotion to duty, less than these, would in some countries be promptly recognized by the award of some form of medal or decoration, here they are taken for granted and presently forgotten.

A committee, representing the undergraduates, the Hospital staff, and the Faculty of the Medical Department of the University of Pennsylvania, has been formed to arrange for a celebration of the fiftieth anniversary of Prof. D. Hayes Agnew's graduation in medicine. It is proposed to have, on Tuesday, April 24th, a jubilee meeting of the Alumni, Faculty, and students in the chapel of the University; subsequently a supper will be served in the college building. A handsomely bound volume of the autographs of those subscribing will be given

to Dr. Agnew, together with some other souvenir of the occasion. All the Alumni are invited to participate. The subscription has been fixed at three dollars, payable by check or otherwise to Dr. James Tyson, at the University, not later than April 10th.

THE New York Academy of Medicine has issued an appeal to the profession and to the public for contributions toward the erection of a fire-proof building, which is an immediate necessity for the accommodation of the Academy and its growing library. The Academy owns its present building free from debt, and has $100,000 in its building fund. It is estimated that in addition $250,000 are requisite to enable the Academy to erect such a building as it requires, and a large committee of professionals and laymen has been formed to solicit this amount.

DR. WHARTON SINKLER has been elected Visiting Neurologist, and Dr. Edward P. Davis Visiting Obstetrician, to the Philadelphia Hospital, Blockley.

THE Annual Address before the Alumni Association of the Jefferson Medical College, Philadelphia, will be delivered by Professor Austin Flint, of New York, in the lecture-room of the College Hospital, on Monday evening next, at 8 o'clock. Subject, "The American Medical Student."

AT the annual meeting of the Association of the Alumni of the Long Island College Hospital, held March 7, 1888, the following officers were elected:

President.—Charles E. de la Vergne, M.D., '78.

Vice-President.—F. H. Colton, M.D., '64.

Secretary.—H. Messenger Ayres, M.D., '80.

Cor. Secretary.—Robert L. Dickinson, M.D., '82.

Treasurer.—Charles N. Dixon Jones, M.D., '82.

The Alumni Prize of one hundred dollars was awarded to A. H. Buckmaster, M.D., '83, for an essay entitled "The Galvanic Treatment of Fibromyomata: An Experimental Research." Honorable mention was made of the essay by Charles N. Dixon Jones, M.D., '82, entitled, "Etiology and Pathology of Rachitic Deformities, with Report of One Hundred Osteotomies without Suppuration."

REVIEWS.

THE YEAR-BOOK OF TREATMENT FOR 1887. 12mo, pp. 340. Philadelphia: Lea Brothers & Co., 1888.

THIS is a most valuable review of current medicine for English-speaking practitioners. It surpasses the majority of books of its kind in that it is a critical review in which the element of criticism is of practical value. Its list of reviewers contains the names of many English medical men well known in America, whose names are a promise of good material.

The objections raised against manuals and summaries we do not think apply in this case; the book is not intended as a text-book, and it is not a labor-saving device for the benefit of students; but it is such a survey of the field of medicine that each reader cannot but find matter of value in his especial field of study. The mass of medical literature which is current is so despairingly great that to have the gist of it, with a reference to the original, and a thoroughly competent review as an indication of its value, is an unspeakable blessing to one who has the ambition to keep up with what the world is learning in medicine.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, March 5, 1888.

THE PRESIDENT, C. L. DANA, M.D., IN THE CHAIR.

DR. DANA presented the report of a case of

THOMSEN'S DISEASE,

with specimen of muscle, in some respects a typical case. The patient was a male, thirty-five years of age, single. He had been delicate as a child and at fifteen or sixteen had masturbated, but not to excess. At fourteen years he had developed talipes varus in the left leg, but tenotomy had been performed with cure. The symptoms of the disease in question had not appeared until the twentieth year, when the patient had commenced to notice stiffness of the hands and difficulty in opening the hands when closed; also stiffness of the leg and of the muscles of mastication. The patient tired easily, especially in the arms. Until recently he had had a high-pitched child's voice and a child's larynx. Erections were incomplete, and there was mental difficulty in concentrating his thoughts. The muscle development was good. Measurement around the biceps gave ten inches in both arms. The dynamometer showed forty degrees in the right hand, and thirty-eight in the left, the normal measurement by the reader's dynamometer being forty-five to fifty. There were tonic contractions of the calf muscles and of the pillars of the fauces. Striking the muscles of the arm or forearm caused tonic contractions in these muscles. Striking the biceps with the percussion hammer would cause a welt and a myoid tumor as well. There was no increase of irritability to mechanical stimulation in the nerves. By galvanism Erb's reaction was obtained. There was increased muscular irritability and a closure tonic contraction which persisted as long as the current continued to be passed. There was closure tetanus both to the cathode and the anode. There was no opening contraction to either pole. A peculiarity of the reaction to faradism was that in the arm the contractions persisted after the current ceased to be passed. There was no ankle clonus, no increase of the reflexes, and no spastic condition. In the eye the fundus was normal, but there was a fibrillary contraction of the

muscles of the lid. There was vasomotor weakness, the hands and feet were red, and easily became cold.

A piece of the supinator longus had been removed, and for comparison a piece of the same muscle from the reader's own arm. These specimens had been placed in weak alcohol and stained with picro-carmine and bismarck-brown. The specimen taken from the patient showed increase of the nuclei of the sarcolemma, an increased number of fibres, and in addition a dichotomous division of the fibres, such as was found in the muscle of the heart. This was characteristic of Thomsen's disease, and was supposed to indicate reversion to an earlier type. The tonic contractures of this disease, too, were characteristic of unstriped muscle fibre.

Dr. George W. Jacoby had examined the specimens and compared them with the specimens from his own case. He did not consider this the typical case which Erb's monograph had described. Erb had excluded all of the published cases but eight. Erb's typical case showed no disease of the central nervous system. In Dr. Dana's case there was at least a suspicion of such disease. The reactions of the muscles, too, were incomplete or failed to comply with the requirements as given by Erb. The speaker did not, however, believe in Erb's lines. He thought they are too close. While this case did not come under the heading as limited by Erb, it did come under the name as understood by others. Erb's theory is that of a disorder of the muscles themselves, a congenital malformation of the muscular system. If the fissuring of the muscles and the increase of nuclei in the case under discussion were dependent upon a central affection, this alone was an interesting fact. It would demonstrate that microscopically alone, a diagnosis of myotomia congenita could not be made. Our knowledge of primary muscle affection is not yet on a solid basis. It was possible that there was first trouble in the central nervous system from which the other proceeds.

Dr. C. Heitzmann had examined the specimens with a low power, and had been impressed with the belief that this was not a genuine case of Thomsen's disease. In the typical case the nuclei of the muscles were augmented. The reader of the paper had made Erb's mistake when he spoke of the nuclei of the sarcolemma. The sarcolemma is a structureless membrane. There was also augmentation of the sarcoblasts or muscle corpuscles. There was too much muscle substance from the earliest period. Hence, the name myotomia congenita. Dr. Dana's case, on the contrary, could not be called congenital, as the disease had not developed until the twentieth year. Second, the muscle fibres were not distinctly augmented in size. If compared with those in Dr. Jacoby's case the difference was marked. Third, the fissuring was not prominent. For these three reasons he was loath to accept the diagnosis. He was, on the other hand, unable to tell what else the condition could be.

Dr. Emmerson had examined the eyes. There was no insufficiency of the muscles, and the pupils had reacted properly.

Dr. Starr realized that we could not yet lay down any positive deductions in regard to electrical reactions. In degeneration we got the pure reaction of degeneration, an intermediate reaction of degeneration, and the normal muscle reaction. Erb had given the reactions for three cases only. Other cases might not substantiate their results. He considered Dr. Dana's case valuable, and one to be put on record. For reliable data a large number of cases are required. Even Dr. Heitzmann's objection of muscular anomalies is not fatal to the theory of its being a case of Thomsen's disease.

Dr. Dana explained that he had not called the case one of myomotomia congenita, but an atypical case of Thomsen's disease. It remained to be proved whether myomotomia is always congenital. He had recently seen a case which commenced at the eighth or tenth year. Since Erb's book, four additional cases have been reported besides his. He agreed with Dr. Heitzmann that the enlargement of the fibres was not positive. He had, with a stage micrometer, measured the fibres in the specimen from Dr. Jacoby's case, in that from the case under discussion, and in that from his own arm. He had found the fibres in the first $\frac{1}{400}$ to $\frac{1}{300}$ of an inch broad; in the second, $\frac{1}{250}$ to $\frac{1}{400}$; and in his own, $\frac{1}{450}$ of an inch. Thus, in the case under discussion, some of the fibres were larger and some smaller than the normal. The increase of the nuclei, however, was, in some of the specimens, shown typically as in Erb's plate. He acknowledged that the fissuring might have been produced artificially by tearing. Electrically there was greatly increased irritability of the muscles, both to galvanism and faradism. The contractions were tonic, with closure tetanus. There was normal excitability of the nerves. Clinically, the patient presented the phenomena of Thomsen's disease. It remained to be proved whether the phenomena of Thomsen's disease could be produced by disorders in which the central nervous system was involved.

Dr. Starr presented a specimen of

TUMOR OF THE BRAIN.

The patient was a woman, at the time of her death fifty-six years of age, who for two years had presented the general symptoms of tumor of the brain—vertigo, projectile vomiting, dulness of the mental faculties, and optic neuritis. During the last five months she had been carefully observed, but without obtaining any evidence which would locate the tumor, if one occasion were excepted, when, during an attack of vertigo, she fell forward and to the right. This was not a permanent symptom, and was the only evidence pointing to cerebellar disease. The tumor was of the size of a hen's egg. It was found on the under surface of the tentorium, simply resting upon and compressing one lobe of the cerebellum. There were no adhesions, and it was unfortunate that no symptoms had pointed to its location, as it might have been easily removed. In 1878, Nothnagel had remarked that tumors of the lateral lobes of the cerebellum did not give rise to the symptoms of incoördination common to other cerebellar tumors.

Dr. J. West Roosevelt presented the report of a case of

BASEDOW'S DISEASE, WITH AUTOPSY.

The case was one of negative interest. The patient had been admitted to the wards of Roosevelt Hospital, May 25, 1887. The patient was a female, widowed, forty-seven years of age, a housekeeper. Both the personal and family history were good. Two years before admission, the patient had commenced to complain of palpitation, dyspnœa upon exertion, and swelling of the throat, which was largest upon the right side. The patient could not lie upon the right side. In the course

of a year the eyes commenced to protrude, and at the time of entering the hospital she had a profuse watery diarrhœa.

The pupils were found to be equal, the reaction to light and accommodation good. The lids did not follow the eyeballs. The neck measured thirteen inches around the lower thyroid region, and ten and a half inches around the upper thyroid region. There was dysphagia to solid food. The pulse was 100 to 120, and the respiration 38. The apex beat was found in the fifth space, mammary line. There was epigastric pulsation, and the area of dulness was slightly increased. There was a short systolic murmur at the apex. There was a systolic thrill over the jugulars, and a continuous venous hum. The pulmonary resonance was exaggerated. The veins of the retina pulsated, the arteries did not. There was no tension. The patient lived until May 31st. She suffered from a watery diarrhœa and restlessness, but was not otherwise sick. In walking to the bath-room, one evening, she fell dead. Autopsy showed the thyroid reduced in size, but still moderately enlarged, and of a pink color. The kidneys showed a trace of fibrous tissue, but otherwise the organs were normal. There was apparently nothing abnormal in the medulla, nor in the sympathetic or vagus nerves. Microscopic examination of these parts also showed nothing.

Dr. W. O. Moore had seen twelve cases, all females, average age forty years, the youngest thirty-one and the oldest forty-five years. Ophthalmic examination had showed simply enlargement and tortuosity of the blood-vessels. Great relaxation of the bowels had been present in one of the cases, having as many as ten evacuations in the day, which it was impossible to control. Electricity had been of no avail in these cases. All had presented the three characteristic symptoms—exophthalmos, thyroid enlargement, and rapid heart action. All had the symptom to which von Gräfe first called attention, namely, a disturbance of the usual coördination of the movements of the eyeball and the upper lid, so that when the patient looks downward below the horizontal meridian, the lid no longer follows the eyeball in its motion, but halts in its course. This fault in the action of the lid was supposed to be due to some defect in the orbicularis, and was not present in cases having prominent eyes from other causes. Occasionally the prominence was so great as to cause the eye to be exposed at all times, both when waking and asleep. In one case in his experience, suppuration had occurred, and the eye had been lost.

The patient, a female, aged forty-five years, stated that when a child she had lost the sight of the right eye through an accident, that one year before coming under observation she had noticed commencing enlargement of the neck, dyspnœa upon exertion, and prominence of the left eye. Six months later, vision for near objects commenced to fail, and four weeks before coming under notice the left eye had become painful and inflamed. Examination, December 13, 1886, showed in the right eye phthisis of the bulb, total corneal leucoma, and exophthalmos so marked that although the eyeball was atrophied the lids were as full as in the usual healthy state. The eyelids on this side covered the globe fully when shut. In the left eye the exophthalmos was so great that the lids were retracted to their full extent, and the eyeball was dislocated through the commissure of the lids. The ocular conjunctiva was chemotic, and the cornea was cloudy through its whole extent. At the upper border of the cornea was a serpiginous ulcer. In other words, there was present a keratitis from loss of nutrition and exposure to the air. The pulse was irregular at 110. The patient was admitted to the Post Graduate Hospital, the outer canthus was cut, hot water applications were made, and the parts were protected by lanolin. In spite of treatment, perforation took place, with escape of the vitreous and lens. The eye began to recede, and phthisis bulbi developed.

Had this case been seen earlier, the writer would have united the upper and lower lids, thus covering the eyeball. At the end of a few weeks the lids would have been reopened, when, as a rule, the exophthalmos would be found improved, and the corneal trouble removed. For constitutional treatment, the patient should receive digitalis, ergot, and tonics. This case was remarkable from the fact that an eye was lost by suppuration, and that this loss was associated with phthisis in the other eye. The loss of an eye from exposure is so rare that the writer knew of but ten reported cases in this country, while Wells reports only one case.

Dr. Starr had been interested in the report of Dr. Roosevelt's case. The fact that no lesion had been found in the sympathetic in this case, did not, of course, prove anything conclusive. Ross had reported eight cases in which such lesion had been found out of twelve cases, as far back as 1882. The pathology, however, was not clear. It was difficult to understand how any one lesion could produce all of the phenomena of this disease. The hypothesis accepted by Gowers was that of lesion of the vagus nucleus in the medulla. The rapid pulse would be accounted for by the loss of the inhibitory power of the vagus. It was known, too, that vasomotor disturbances were produced by irritation of the medulla in this region. The speaker had some time ago collected twenty-one cases of lesion of the medulla, in eight of which the lesion was in its upper part, in the region of the nucleus of the tenth nerve. In all these cases there were subjective flushings and objective increase of perspiration; while in the thirteen in which the lesion was in the lower part of the medulla there were no vasomotor symptoms whatever, thus substantiating the hypothesis of physiologists that there is a vasomotor centre in the medulla, and that this centre is in the neighborhood of the nucleus of the tenth nerve.

He had personally observed seven cases, five in the female and two in the male. In all but one, palpitation of the heart had been the first symptom. This disproved the theory that the goitre was primary, and that the other symptoms were due to the pressure of the tumor upon the pneumogastric nerve. The pulse had ranged between 90 and 155. In all but one the eyes had been prominent. In six there had been nerve symptoms, in four tremors, in four von Gräfe's symptom, in six flushes. Mental disturbance had been present in one case, in which there had been delirium every night for several months, and subacute mania for several weeks. The first symptom in this case had been insomnia, which resisted treatment. The reader supposed it to have had its origin in a condition of the vessels of the brain similar to that in the back of the eye and the thyroid gland. Digitalis had done no good in his experience. Ergot and bromide had quieted the tremor, but no drug which he had tried had reduced the heart.

He had used electricity according to Benedict's recommendation, but without result. He had himself when in Vienna, watched the treatment of three cases in which Benedict had given a good prognosis, but had failed to find any reduction of the pulse while galvanism was being used. In his own cases he had tried every method described as galvanization of the sympathetic; he had placed the poles upon either side in front of the sterno-cleido-mastoid, behind the sterno-cleido-mastoid, and at the back of the neck and epigastrium, carrying the current as high as nine milliampères, which was as strong as could be borne with a small electrode, and he had never been able to obtain any retardation of the pulse. Dr. Janeway expressed himself as having had the same experience.

Dr. Rockwell had met about thirty cases of this disease, and in nine cases he had obtained an approximate cure. He had employed diet, galvanism, and very full doses of digitalis, bromide of zinc, ergot, and iron. He had authentic records of his results. He believed that the cases not benefited by treatment were organic and that those benefited were functional in origin. Those having all of the cardinal symptoms were more often responsive to treatment than those in which the symptoms were more incomplete. He recalled a case in which there was a pulse of 110 reduced to 80. There was puffiness of the eyelids in this case. In the galvanic application one pole had been placed over the eyelid and the other behind the sterno-cleido-mastoid muscle at its upper third. In another case, presenting the three symptoms for several years, the pulse had ranged from 130 to 150. There were dilatation of both pupils and a pulsating swelling over the solar plexus. This patient was placed upon a milk diet and persistently treated for many months, when the pulse had fallen to below 100 and the swelling of the thyroid and the exophthalmos had become less.

Dr. Starr asked whether Dr. Rockwell had obtained reduction of the number of heart beats while the current was being used; also whether he had ever obtained paling of the face and dilatation of the pupils, phenomena which follow galvanization of the sympathetic when needles are used.

Dr. Rockwell replied that he had not made his observations during the application, but that subsequently such slowing had been demonstrated. Lowering of the pulse is also a very common result of general faradization.

Dr. George W. Jacoby considered exophthalmic goitre a rare disease. For eight or nine years he had seen in his dispensary from 600 to 700 neurological cases a year. Not more than a dozen of these had been cases of exophthalmic goitre. The patients had been regular in attendance, and treatment had been persistent, but he had tried every means heralded without result. Subaural galvanism had been without effect upon the color or the pulse. He considered the disease a hopeless condition. Bodily and mental rest furnished about all which could be done. He had tried faradism according to the recommendation of Vigouroux, but also without result.

He thought the exophthalmos the least constant symptom. Where goitre is present one side of the neck is usually larger than the other. Some say that the right is always the larger. This he could contradict, as in a case which he had recently seen with Dr. Birdsall, the enlargement had been equal upon both sides. Von Gräfe's symptom is not always present. Tremor is often the first symptom. In one case in his experience tremors had existed for a year before the development of the other symptoms. At the end of the second year these had become well-developed and bronzing of the skin also was present.

Vigouroux has stated that the electric resistance is diminished in all cases and even in the commencement of the disease. This, if true, would be an important diagnostic point. In 20 cases published by Wolfenden this lowered electrical resistance was present. Two of these cases are published in full. In one of the latter the resistance was only 300 ohms. It was mentioned that there was profuse sweating in this case. In the second the resistance was 200 ohms. Of this case it was said that there was clamminess of the surface and sweating. In the other eighteen cases the resistance was from 500 to 1300 ohms. The speaker said that the standard of resistance, however, varied according to the method used. It had been given as high as 300,000 to 400,000 ohms by Jolly. Gärtner gave it as 30,000 to 40,000 and here we estimated it as at 1000 to 3000 or 1000 to 4000; he had recently tested the resistance in three cases, his method having been to place the body in the circuit, the electrodes being equal in size, and wet. When the galvanometer needle ceased being deflected the body was taken out of the circuit and a resistance coil inserted until the deflection of the needle was again brought to the same point. The amount required equalled the resistance of the body. Comparative observations were at the same time taken upon himself. The first case was that of a female twenty-eight years of age with exophthalmos, palpitation, and sweats. The resistances obtained were as follows:

Through the palms, patient . .	6000 ohms.
" " self . .	8000 "
" the goitre, patient . .	1200 "
" " self . .	2400 "
Through the posterior part of the neck, patient	1400 "
Through the posterior part of the neck, self	2400 "

The second case, a patient of Dr. Birdsall, presented goitre with palpitations and exophthalmos, and the comparative observations were taken upon Dr. Birdsall and himself. The resistances obtained were as follows:

Patient through the hands . .	5000 ohms.
" " the goitre . .	800 "
Patient through the posterior part of the neck	1000 "

The measurements in his own case were respectively 5500, 2400, and 2000 ohms; and in Dr. Birdsall's case, 8000, 1000, and 1000 ohms.

The third case:

Patient through hands . . .	5000 ohms.
" " goitre . . .	1000 "
" " neck, anterior post.	1500 "
Control subjects (two), hands .	11,000 and 10,000 ohms.
" " " thyroid	4,000 and 3,000 "
" " " neck .	3,000 and 3,000 "

The reduction was thus scarcely one-quarter, certainly not one-half, and not more than would be accounted for

by the maceration of the skin due to the abundant perspiration in these cases, or as in the goitre to the influx of blood. The speaker failed to see how any importance could be attached to the test as a symptom.

Dr. Dana was surprised to hear that there was any dispute in regard to the possibility of lowering the pulse by galvanism. In a case of Basedow's disease in Bellevue Hospital, a pulse of 140 would be found lowered 15 or 20 beats after the current had been applied. The sedative effect of galvanism is generally admitted, though we cannot say whether it is produced through the pneumogastric or the sympathetic nerve. Dr. Starr's theory he thought incorrect. Lesion of the nucleus of the pneumogastric should give the same symptoms as division of its trunk, and this never gives rise to the phenomena of Basedow's disease. It might perhaps be said that this disease is due to lesion of the nucleus of the pneumogastric and neighboring parts. The speaker thought that the resistance was diminished in these cases, at least slightly, perhaps 1200 ohms. In testing, he placed one electrode in the region of the seventh vertebra and the other on the sternum.

Dr. Roosevelt has had the same experience as Drs. Starr and Jacoby. He has used both strong currents and weak currents without any influence on the sympathetic nerve. He was surprised to hear digitalis recommended. He believed that digitalis is without value for heart failure except from organic disease. He had had five cases of exophthalmic goitre under observation. Two of these had improved, but both were cases of young anæmic girls. The measurement of electric resistance he thought a difficult problem, because the factors vary.

PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, February 27, 1888.

The Vice-President, Charles K. Mills, M.D., in the Chair.

Dr. J. Madison Taylor exhibited a

new form of percussion hammer

devised to serve as nearly as possible all ends for which a hammer is likely to be called into use by clinicians. This feature at least would, he thought, commend it. In shape it is a cone flattened on the opposite sides, with apex and base carefully bevelled or rounded, of about the thickness throughout of the human index-finger. The material is moderately soft rubber. It is held by an encircling band of metal midway between the apex and base transversely, and from it, on the edge, depends the straight handle. The handle is rigid though light, it being Dr. Taylor's opinion that this had better be under the full control of the wielder. If elastic, as recommended by some, an element of uncertainty enters in the degree of force used in the blow. The special feature of this hammer is that the shape of the striking surface is like the outer aspect of the extended hand, palm downward, which is most often used in obtaining tendon jerk. The rounded apex end is adapted to reach the biceps tendon at the bend of the arm. This last has become important in diagnosis. In fact, in the light of recent investigations, the study of the tendon jerks of knee, biceps, and Achilles tendons, of the jaw jerk as discovered by Dr. Morris Lewis, has become a valuable addition to our means of unravelling the causes of nerve maladies. The matter is even now engaging much of the attention of the foremost writers—Jendrássik, Weir Mitchell, Lewis, Lombard, and others. Especially is this true now that the field is immensely widened by the corroborative symptom of reinforcement.

This little tool will also well serve to elicit chest sounds, to percuss the abdomen, and, in fact, is useful whenever an elastic hammer is needed. The material being of soft rubber, the blow does not hurt the intercepting fingers as does the hammer usually employed to strike the tendons and muscles. It is made by Snowden, of Philadelphia.

Dr. Charles A. Oliver made

a further demonstration of wernicke's hemiopic pupillary reaction.

It was his intention to present a patient with well-marked left homonymous hemianopsia, in whom the hemiopic pupillary reaction of Seguin could be beautifully seen, but this was not possible. He gave a rough demonstration upon the blackboard of a few observations worthy of notice. The case was seen a few weeks ago in consultation with Drs. Mills and Turnbull. The fields, which were carefully taken for form, yellow, blue, red, and green, showed the distinctive and typical limitation of hemianopsia, in which the appearance of a double bow-like curve—the smaller one sweeping around and avoiding the point of macular fixation, and the second continuing irregularly both above and below to the outside in the left field and to the inside in the right field, was plainly visible; the sequence of the fields following the order of the colors just noted. Both of the remaining fields were regularly contracted, without indentations or scotomata; the series on the left side being but one-half of the size of those on the right side, although the intensity and brightness of the colors seen in and around the macular fixation region of the left side were more vivid and pronounced. Vision for form was reduced in each eye, but slightly more so in the right: this was partially accounted for by marked astigmatism with a low degree of hypermetropia, which, upon being excluded by proper lenses, showed that its vision almost equalled that of its fellow. With or without the correcting lenses, the pupil of the right eye did not respond to light stimulus so freely as the left when equal amounts of light were projected into the interior of the organs from the different portions of the existent field areas. The pupillary reactions, which were pursued in the ordinary method of concentration of narrow, yet strong beams of artificial or natural light from various directions upon the pupil, whilst the organ was feebly illuminated to a sufficient degree to observe the actions of the irides, were not only typical of the hemiopic type, but were peculiar in the fact that in nearly all of the experiments there seemed to be an absolute ratio established between the amount of pupillary reaction and the degree of color saturation seen; this being true both in monocular action and consensual; this was plainly shown by the amount of reaction in the left iris being at least one and a half millimetres greater upon exposure of its own arc, than when its fellow arc—that of the right eye—was similarly stimulated.

Another instance which beautifully illustrates the same point, was seen in a case of brain-tumor which he ex-

amined in consultation with Drs. Keen and Mitchell, in June of 1887. There were unequal pupils corresponding in direct ratio with unequal amounts of hemianopsia, in which the greater percentage of lost color manifested itself in the smaller field; there was at least one and a half to two millimetres greater response in one or both irides when the arc holding the better color-conception was stimulated: this condition has been carefully studied, and will be combined in a forthcoming report of the case.

This observation, therefore, is of value in adding another partially objective factor to the various means employed in gaining better information in reference to the now all important question of cerebral localization, as it distinctly shows which arc has the greater amount of destructive or irritative lesion, and thus becomes an additional sign of special and distinctive usefulness.

Dr. J. Lloyd presented

Specimens from a case of probable alcoholic multiple neuritis, with brain involvement.

M. L. W., white, thirty-seven years of age, a dressmaker by occupation, was brought into the hospital February 21, 1888, in a delirious state. When first seen she was unable to move her left leg, but moved the right one with some difficulty. The day following both legs were rigidly extended, and she was apparently unable to move either. She complained of severe pains in the calves upon passive motion. The muscles of the face kept twitching all the time. The arms were constantly thrown about, the hands flexed, and the thumbs turned inward. On the night of the 22d, she became very violent, raving constantly. She would catch hold of the attendants and beg them piteously to keep her from falling. She was given, during the night, ninety grains of potassium bromide and twenty grains of chloral. The next morning she was very much depressed. She had retention of urine; about one pint was obtained by catheterization in twenty-four hours. The urine was dark colored and filled with urates, but no albumen or sugar. On account of the small quantity of urine passed, one-fourth of a grain of pilocarpine was administered hypodermatically. The abdomen was much distended with flatus. After the administration of the pilocarpine she became rather weak, and digitalis and whiskey were then given. The pulse rate became better, falling from 135 to 90 per minute. Hyoscine was then administered with the intention of securing sleep: $\frac{1}{120}$th of a grain was given at 9 P.M., $\frac{1}{210}$th at midnight. At 8 P.M. of the 24th $\frac{1}{120}$th of a grain was again given. On the morning of the 24th she seemed much more rational and quiet, the hyoscine having had the desired effect, but toward noon the pulse rate again became very rapid—from 135 to 160 per minute. The lungs quickly became œdematous, and she died at 1.45 P.M. of the same day. The left pupil was perceptibly larger than the right. There was little rise in temperature, the highest being about 101.6° F. During her illness she retained very little food or medicine, vomiting it as soon as it had been administered. Her bowels were constantly moving involuntarily. The heart sounds were normal but very feeble. Her family could give no account of her at all, as they had not seen her for years; they surmised that she had been leading an immoral life for a long time. She died in about twenty-four hours after she was first seen by Dr. Lloyd.

At the post-mortem examination very few gross changes of any kind were found. There was some congestion of the pia mater, particularly along the longitudinal sinus. In addition there was marked adhesion of the dura mater.

The peripheral symptoms simulated those of multiple neuritis, and she had, in addition, a maniacal and delirious condition. She had cutaneous hyperæsthesia and muscular tenderness. She had paralysis of the extensors, which is characteristic of multiple neuritis. Dr. Lloyd's opinion was that the case was one of alcoholism and not of epidemic cerebro-spinal meningitis, some cases of which latter disease have recently occurred in this city.

Dr. Charles K. Mills made the following remarks on

The probable occurrence of multiple neuritis in epidemic cerebro-spinal meningitis.

Recently a number of cases of cerebro-spinal meningitis have appeared in Philadelphia, of which he had seen several in consultation, three quite recently, two with Dr. Cahall, of the Falls of Schuylkill, and one with Dr. Dick. They had some of the typical symptoms described by authors. The particular point to which he wished to call attention was that in two of these cases markedly, and in the third to some extent, there were symptoms which seemed to point to multiple neuritis, or, at least, to neuritis involving certain portions of the body. In one case the most decided complaint of the patient was pain and soreness in his legs. He found soreness over the nerve trunks; and also, in addition, muscular and cutaneous hyperæsthesia. He also had the appearance of the legs often seen in multiple neuritis, the equino-varus position of the foot. The knee-jerk was diminished. In another case, outside of the mental condition, the pain and tenderness in the leg were the most distinct symptom. The conditions were exactly those which are regarded as diagnostic of multiple neuritis—that is, tenderness over the nerve-trunks, and pain in the muscles with tenderness on pressure. In going over the literature of multiple neuritis lately, Dr. Mills found that this affection had been associated with or caused by nearly all the infectious diseases, but no cases were reported in connection with so-called cerebro-spinal fever. In this disease we have a true meningitis, and he thought we might also have a perineuritis, or a neuritis. In some cases the multiple neuritis might alone be present. In this way certain irregular cases might be accounted for. Stillé and others refer to a neuralgic form of cerebro-spinal meningitis. The point which he wished to make was that true diffused neuritis, either alone or in connection with other conditions, probably occurred as a result of the infection.

Dr. W. Osler had recently had an interesting case of cerebro-spinal meningitis, which proved fatal. The patient, a young girl, when admitted to the hospital was thought by the resident to be hysterical. She was nervous and twitched on attempting the slightest movement. He thought at first that it was a case of subacute rheumatism. She subsequently developed well-marked symptoms of cerebro-spinal meningitis. The case proved fatal, and the autopsy showed the characteristic lesions of the disease. There was extensive recent exudation down the whole posterior surface of the cord. In the brain it was limited to small patches on either side of the pons, but there was the most intense congestion of the cortex. It is remarkable in Dr. Mills's cases, if they be instances

of multiple neuritis, that, unlike other examples of this complication of specific fevers, the symptoms have appeared early in the course of the disease. In other affections, as typhoid fever, phthisis, and diphtheria, the neuritis appears as a late complication.

He would like to make one remark with reference to central nerve irritation producing symptoms of cerebro-spinal meningitis. There are cases of typhoid fever with marked meningeal symptoms, and he has known such cases to be diagnosed by careless observers as cerebro-spinal fever, and the autopsy had shown the specific lesion of the intestine, and only congestion of the spinal and cerebral meninges. The diagnosis of meningitis, either in the brain or the cord, may be extremely difficult. Unless the nerves at the base are involved, it may be impossible to say whether or not there is exudation. This is well illustrated in the meningitis of pneumonia, which may produce an ever-deepening coma, not to be distinguished from that which accompanies cases with intense cerebral congestion, unless pressure on one of the nerve-roots gives the clew; and this led to the diagnosis in one of the eight cases of the most intense meningitis in this disease, which were observed in the Montreal General Hospital between 1876 and 1884.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, March 14, 1888.

The Vice-President, W. W. Keen, M.D., in the Chair.

Dr. J. Madison Taylor read a paper

ON THE EARLY RECOGNITION OF EXOPHTHALMIC GOITRE (GRAVES'S DISEASE).

In which he called attention to the importance of early recognizing a disorder which often eludes detection, pointed out certain features which should enable us to do so, and offered in illustration, very briefly, the salient points in half a score of cases.

Exophthalmic goitre, or Graves's disease, is not a rare malady. At first it is merely a disorder, but frequently becomes a serious disease, and is known to cause death. More often it unfits its victim for active usefulness, or, at least, limits this and sadly disfigures him. Like certain other ailments the outcome of irregular nervous discharge, what in its incipiency is a very manageable complaint, produces in time a disastrous effect upon the tissues, and forms a practically unconquerable disease.

In reviewing a large number of cases in the search for a complete symptomatic picture, he found that the most constant early feature is sudden and marked evidence of loss of nervous equilibrium. The vasomotor nerves seem quite unstrung. Hence arise flushing, sweating, and other skin changes, diarrhœa and transient albuminuria. If at this time a careful watch be kept, we should find irregularities in the action of the pupil. The skin usually loses its healthy hue, grows sallow or dark, and becomes greasy to sight and touch. This oily look was present in most of the cases he had seen, though he had not seen it mentioned elsewhere. Begbie recounts one case of pigmentation, or bronzing, of the skin; Reynaud calls attention to vitiligo; and Edward Squire, to a discoloration in an isolated instance. The oleaginous appearance seems to him quite constant on the face and body. This grows less when salt sponging and belladonna form part of the treatment.

Gowers calls attention to muscular tremor. He had seen this rarely. In two of his cases there was a tremulousness in the voice, which he ascribed to nervousness, yet it is constant. The emotions become often so overwrought that various mental peculiarities excite apprehension. Or a wiser person may regard the case as one of pronounced hysteria; and, indeed, all through the malady hysteria remains present, more or less, leaving one not seldom in grave doubt. Frequently delusions occur, and these so closely in unison with the ordinary habits and thoughts of the individual as to render them most difficult of detection.

Dr. Hilton Fagge warns us to be on the lookout for "slight cases in which one or two of the cardinal symptoms may be absent throughout." Trousseau also insisted on this point. Von Gräfe expresses the opinion that among women it is not rare to find instances of this malady where the only symptoms are disordered action of the heart, not accompanied by valvular trouble or hypertrophy, nor the faulty action of the lid as described by him.

Heart disturbance most often leads the sufferer first to seek medical advice. The pulse is always quick and irritable, usually intermittent. The heart-beats, as a rule, bear surprising relationships to the pulse. Overaction of the heart is well known to be a frequent feature of anæmia and chlorosis. Ross regards the anæmia, which is usually present, as rather a result. Throughout the whole vascular system there is a manifest lack of *tone*. So constant is this that it may yet be found competent to explain the causation of the disorder. Certainly the graver features bear causal relation to this state. The vasomotor nerves seem all out of balance; nor can it be confined to one part, though the cervical sympathetic is most prominently involved. There are cases where limited areas not governed by the upper ganglia show derangement, as in a woman now under the care of Dr. E. T. Bruen, where one side sweats from shoulder to toe, and the opposite eye is prominent. Arterial tension varies rapidly, and unaccountably; hence the oft complained of noises in the head, amounting at times to terrific roarings. This may explain the maniacal attacks, as well as blood-spitting, thirst, and transient albuminuria.

The heart itself is rarely diseased. The overaction in time brings on hypertrophy; more commonly, dilatation. It also suffers from the general malnutrition, which is noticeable throughout the circulatory system. The small amount of structural damage which this viscus sustains is a matter for remark, however, when the profound functional disturbance is considered. Systolic bruits are commonly heard, even over the auricles and the great vessels of the neck. Dyspnœa is distressing. This, at times, even early in the history, alarms one who feels naught else to complain of.

The thyroid enlargement is liable to appear long before the eyes become prominent, but readily escapes attention. It may happen that a sense of constriction is felt when swallowing, especially in men who wear tightly fitting collars. Both lobes are, as a rule, enlarged; but if one only, it is generally the right. When recovery takes place, this badge remains to chronicle the victory.

The eye prominence is late to appear, as a rule, and it would seem to mark the height of the disorder. Before

the exophthalmos, there may generally be noted the sign asserted by von Gräfe to be pathognomic, a belated action of the lid in following the downward movement of the ball. Sometimes the lower lid is tardy in following an up glance. This obtrusion of the eyeball is the most picturesque feature, but happily it is not constant, and is often very late. It is of both eyes, mostly, but if of one only, again the right suffers. Sight is seldom affected, except where the outstanding, unprotected cornea suffers hurt or irritation; then opacities may result. If errors of accommodation exist, this correction, in his opinion, greatly aids in reducing the exophthalmos. Fundus lesions are not characteristic; though pulsation of retinal vessels may serve to confirm suspicions.

Knee-jerks are rarely abnormal; often in slight excess.

Electrical examination has been, very recently, shown by Charcot, and confirmed by Vigoroux and Norris Wolfenden, to aid greatly in foretelling the onset of this trouble, the bodily resistance being greatly lessened most peculiarly in this disease. This may prove a valuable aid in diagnosis.

Dr. Taylor then gave the notes of eight cases which had been under his observation.

The subject of treatment he hoped to discuss on another occasion. It consists mainly of rest, judicious feeding, tonics, and carefully selected sedative measures. Appropriate glasses, too, are essential; at times sharp counter-irritation, especially diuretic remedies and attention to the emunctories. Galvanism, too, has immense value in some instances, but requires judgment in selection of cases. In brief, whatever measures tend to repair the tone of the vascular system and allay nervous excitability will best bring about gratifying results.

Dr. S. D. Risley asked whether there is any indication by which the development of exophthalmos can be expected in cases in which it has not yet appeared.

Dr. J. B. Roberts believed that the great ocular deformity, which is so unpleasant to the patient, and attracts so much attention, can be remedied by a very simple operation: merely putting a stitch at the outer canthus, after freshening the edges of the lids, to diminish the optic commissure after the case has made such progress that it is reasonably certain there is to be no further diminution of the prominence of the eyeballs. The patient can be made more comfortable and less conspicuous.

Dr. Edward Jackson said that the procedure suggested by Dr. Roberts might be resorted to for other than cosmetic reasons. He recently saw a case of this disease, with very great exophthalmos, in which one eye had been lost through sloughing of the cornea due to exposure; and he afterward learned that the second eye had been lost in the same way. Such an accident might be prevented by narrowing the fissure of the lids.

Dr. A. V. Meigs knew of one person who has completely recovered from the disease, a woman who had a very severe attack many years ago, under the care of his father. The prominence of the eyes, which was very great, is now hardly noticeable, and yet no operation was ever done. He did not think much would be gained by sewing up the canthus, for while the disease is in its acute stage, it is hardly likely the operation would afford much relief, and later, if the patient recovers at all, the difficulty cures itself. He thought he knew the case Dr. Roberts had in his mind when he spoke, and Dr. de Schweinitz, who has seen the woman in question, will probably agree with him that nothing would be gained by an operation. One thing he had learned of recent years, and it is that it is not necessary in all cases to put the patient to bed. He could mention three or four cases he had successfully treated with tonics and proper regimen, without its becoming necessary to have rest in bed; the cases, to be sure, were not severe. He did not see how a positive diagnosis can be made until we have at least two of the features of the disease present, namely, the cardiac palpitation, and some thyroid enlargement; the prominence of the eyes occasionally does not manifest itself, but a diagnosis can undoubtedly be made in its absence.

Dr. G. de Schweinitz had examined the case that Dr. Meigs referred to, and he saw nothing to be gained by surgery. The eyes were at first very prominent, but they were then receding, and now the normal relation of lids to eyeballs is restored. Inasmuch as there is considerable myopia, and hence not uncommon prominence of myopic eyes to begin with, they will always be more or less conspicuous.

Dr. S. Solis Cohen agreed with Dr. Taylor that vasomotor paresis plays an important part in the development, if not in the genesis, of this disease. The only case he had seen in the male subject occurred in a young man subject to frequent attacks of flushing of the face, sometimes accompanied with high temperature, in whom the rapidity of the heart's action had led to a diagnosis of hypertrophy of the heart, not warranted by physical exploration. The eyes were not involved at the last time he saw the patient, nor was thyroid enlargement sufficient to attract attention without special examination. He had now under his care in private practice a young lady not at all hysterical, subject to similar attacks of flushing, which sometimes leave behind for a short time wheals like those of urticaria, who has also had two attacks of sudden transient blindness, after which all that could be detected in the fundus was moderate congestion; and whose cardiac action, rapid and irregular at these times, is at other times perfectly normal. No organic lesion of any kind has been detected either by him or by more competent observers. It is possible that this may be an early stage of Graves's disease. Improvement has taken place under minute doses of picrotoxin, a drug which Dr. Bartholow has prescribed in cases of exophthalmic goitre, at the hospital, with very good results. One case especially he recalled which was associated with purpura. He would like to know whether Dr. Taylor has met with this association. A very interesting case of acute exophthalmic goitre presented at the Jefferson Hospital clinic; an anæmic young girl affected from childhood with nystagmus, in whom goitre and exophthalmos were asserted to have developed within a short time after a fall from a ladder. She was unable to button her collar, which friends had opened in attending to her after the accident.

Dr. J. C. Wilson briefly narrated two cases of Graves's disease, recently seen in his private practice, in which the symptoms developed rapidly after mental shock. The patients were young women. The first, a servant, aged twenty-four, engaged to be married to a young man who was by occupation the driver of an ice cart. Within a day or two of a visit to her, he was accidentally killed, and her first knowledge of his death came through the newspapers. Cardiac overaction at once developed, and within a month thyroid enlargement, and slight exoph-

thalmos. Under rest and large doses of Fowler's solution complete recovery took place in a year. The second case was that of a lady, aged twenty, who rapidly developed the characteristic symptoms of Graves's disease after the shock and grief occasioned by the disappearance of a near and loved relative, and the discovery that he was a defaulter to a very large extent. The prominence of the eyeballs was in this case very slight; the other symptoms were characteristic. Under treatment by rest and arsenic decided improvement took place.

Dr. Taylor, in reply to Dr. Risley's query, Does any sign clearly foreshadow the exophthalmos? could only say that he knew none, nor did he see anything in the literature of the subject to aid us. It usually marks the height of the disorder, though this may be the first feature noticed, especially when it arises suddenly, as from a shock or overwrought emotion. In reply to Dr. Meigs's objection that the three classical symptoms can alone and in conjunction constitute the disease, he said that it seemed to him readily possible to recognize in the peculiar vasomotor disturbances, the extreme and unaccountable nervous excitability, the appearance of the skin, etc., the early stages of this disorder. In fact, the object of his paper was to call attention to this very possibility, so that a quietus might be placed upon it at the very beginning if possible.

In the use of galvanism we have a valuable aid in diagnosis, as Charcot and Vigoroux have pointed out, but in the treatment it has not been of greater use than some other measures, though it should always be used in the severer cases.

In his endeavor to be brief he did not intend to say much on plans of treatment, leaving that for consideration elsewhere, but rather to speak of early recognition and *early* treatment, which should consist of rest, carefully regulated living, food, and tonics.

Dr. Charles B. Nancrede read a paper

ON THE IMPORTANCE OF PRIMARY SUTURE OF DIVIDED NERVES, WITH AN ILLUSTRATIVE CASE OF SUCCESSFUL SUTURE OF THE MEDIAN AND ULNAR NERVES.

The aim of this brief note is merely to call the attention of general practitioners in whose hands many of these cases will fall, to the *duty* of suturing divided nerves as a routine practice, just as we would tie arteries, and to describe a simple, effective method of carrying out the indication.

A critical examination of the histories of nearly all excisions of nerves where reproduction has occurred, will show that they were removed either from a bony canal or from an intermuscular space in which they normally lay, *with the minimum* of injury to the surrounding tissues. Moreover, even when their ends have been turned back and sutured in position, or even buried in the surrounding tissues, they have been so secured in the same intermuscular space which the nerve normally traverses. In other words, the bony canals and the intermuscular spaces likewise act as moulds which direct the course of the reparative material from the proximal to the distal end of the severed nerve. In extensive wounds, however, this condition does not obtain. Intermuscular spaces are dislocated, large masses of scar tissue are formed, so that instead of the new nerve-tissue being *compelled* to grow in only one, and that the right direction, it has too often an insuperable barrier interposed, and union fails.

In the case which he exhibited,[1] the proximal ends of the ulnar and median nerves were directed at right angles to their intermuscular space, and would have been infallibly fixed between the ends of the torn muscles in a dense mass of scar tissue, resulting in permanent loss of power of the member. In the seventh month after suture—*i. e.*, the usual period required for the degeneration and regeneration of a nerve—first sensation, and then motion returned, until now, although the functions of the member are not perfect, the boy can earn his living, and do nearly all that can be effected by a normal hand and forearm.

Finally, how should the sutures be passed, and what should their material be? Fine aseptic catgut passed by means of an ordinary sewing needle is to be preferred, but fine aseptic silk can be used. Should the nerve be *very* much lacerated and frayed out, it may, perhaps, be sometimes proper to cut off a portion to gain a clean surface, but this is rarely desirable. The needle should be passed from below upward through the promixal end of the nerve at one border, across, and then passed from above downward near the opposite border, entering the needle from an eighth to a quarter of an inch from the cut end, according to the size of the nerve. The needle must now be passed from below upward through the distal portion of the nerve at the border corresponding to the last passage of the needle through the proximal end, across, and made to pierce the nerve from above downward, when the suture will be found to correspond to the free end of the thread in the proximal piece of nerve.

Gentle traction, with an appropriate position of the member will, by the tying of one knot, accurately approximate the nerve ends; in a word, by this simple method all the advantages of the two separate sutures commonly recommended are obtained with a far greater degree of security. The strictest asepsis should be secured, which is easy enough provided the wounded part, the surgeon's hands and his instruments be strictly cleansed, and the wound be freely irrigated with the bichloride and tartaric acid solution. If the surgeon gets an uncontaminated wound, it is his own fault if he has suppuration, and even with the ordinary run of accidental wounds, if he will thoroughly scrub his hands with a nail brush and hot water, and likewise treat the parts surrounding the wound, pour boiling water over his instruments, without any further antisepsis, in most cases healing without suppuration can be secured, while the omission of these details will mar results with gallons of mercuric solution flowing over the wound.

Dr. H. R. Wharton asked whether we should attempt secondary suture of the nerves when this has been omitted in the first place? He is very decidedly of the opinion that this procedure should be adopted, for a number of cases have been reported of this character, in which the results have been, at least, good enough to make one feel that secondary suture should be attempted when there is

[1] In this patient the brachial artery was also torn through, leaving only a bridge of muscle and skin through which collateral circulation could be carried on. The deficient blood supply possibly explains the failure of the recovery of power in the interossei muscles, although other of the intrinsic muscles of the hand which are supplied by the ulnar nerve contract well.

any probability of restoration of the use of the injured part.

Dr. John B. Roberts said the only case of nerve-suture he remembered at present is one in his wards, in which the work had very properly been done by the resident immediately on the admission of the patient. It was a rather extensive incised wound of the leg, involving the musculo-cutaneous and anterior tibial nerves. The muscles and nerves were sutured and dressed antiseptically, and the results were good; though he did not follow the case after discharge so as to make an accurate report as to sensation. Dr. Nancrede has incidentally touched upon a point of great importance, that of tenosuture. It had been his misfortune to meet with quite a number of cases in which this had been neglected by the attendant called at the time of the accident. One of these recently seen was that of a man wounded in the forearm just above the wrist, and in the ring finger. There was loss of flexion of the finger, but it was hard to tell which of the wounds to reopen in order to come upon and suture the divided tendon. The family physician believed it to be the wrist; but after cutting down, the speaker found the tendon here flaccid and intact. He then opened the finger-wound, and here found the tendon retracted into the sheath. He sutured, but did not get a good result, probably from the extent of dissection necessary to get at the tendon in the sheath, and the great mass of cicatricial tissue. However, he never hesitated to reopen healed or partially healed wounds to suture tendons when this very important measure had been neglected.

He was glad to hear Dr. Nancrede say that with cleanliness of person and of instruments asepsis can be secured without chemical solutions. This is in marked contrast to a surgeon of prominence, who thinks that the employment of solutions renders care as to cleanliness unnecessary.

Dr. J. William White did not know whether Dr. Nancrede spoke of the resection of the crushed and bruised ends of the nerves. The general principles of nerve-suture are admitted by all surgeons, but the question of resecting lacerated or contused ends before suturing, or of allowing them to remain, is one that should be carefully considered in each case. On the one hand, by resection of any considerable portion we increase longitudinal tension, and make greater strain on the sutures; on the other, we run the risk of including in the stitches tissue too much damaged to recover itself. There is some difference of opinion as to the particular suture to be employed. He should think that the one proposed by Dr. Nancrede would be open to objection, if it interposes a foreign substance, the catgut thread, between the ends of the nerve; this, if not absorbed, as is sometimes the case even with the best catgut, is liable to be a constant source of irritation, and to prevent union. He preferred and employed a suture passing quite through the nerve above and below the point of union. Evidence, either clinical, or pathological, or experimental, as to the relative advantages of different sutures is desirable, but he did not know of any, and did not understand Dr. Nancrede to say there was such evidence.

Dr. W. W. Keen cited two cases from his own experience in connection with the subject:

1. A case of primary nerve suture in a boy two years of age, with perfect recovery of motion and sensation. The case occurred ten years ago. The child, carrying a glass bottle, fell, and a fragment of glass divided the ulnar nerve and artery about an inch and a half above the wrist. The mother made compression with her thumb until he arrived, very soon after the accident. After ligaturing the artery, he examined the nerve and found that it had been divided. He had only his pocket-case containing coarse white silk and an ordinary needle. Not wishing to leave the coarse silk in the wound, particularly not in the nerve tissues, he debated as to the method of suture, and devised one which proved eminently satisfactory. Drawing the ends together closely with forceps, he passed a surgical pin obliquely through the two divisions, threw a loop of silk around the point of the pin (as in Simpson's method of acupressure), drew out the thread, passed it around the head of the pin, where it was secured. At the end of forty-eight hours the pin was removed. The thread was thus loosened and removed. Perfect union of the wound took place in a few days. There was no wasting of muscles, and motion was present after twenty-four hours. While the age of the child prevented exact observation as to the time at which sensation returned, at the end of forty-eight hours there was an exclamation of pain on pricking the little finger with a pin. He saw the father of the boy about a year ago, who told him that his son had perfect use of hand and fingers.

2. Extensive tendo-suture, with quick union. A recent case shows the value of even a brief suture of tendons. A man twenty-five years of age was admitted into St. Mary's Hospital with complete severance of all the tendons of the forearm and of the sheath above the wrist. The resident sewed each tendon carefully. He had only Kocher catgut, which does not remain more than three to five days, and then closed the external wound and placed the hand in flexion on a splint. The man left without permission after a few days, and it seems removed the splint and tore out the sutures in the skin. He returned later with a gaping wound in the forearm, but on testing the fingers separately each finger and each joint was found to have perfect motion, showing that even this temporary apposition of the divided tendons had a perfect result. He should prefer for the purpose, however, either very fine silk, or, better, the ordinary chromicized catgut.

Dr. Nancrede said that Dr. White had misunderstood him. There is nothing between the divided ends of the nerve. The nerve is securely and accurately coaptated by the suture. He had no distinct recollection of resecting the injured ends in this case, in fact, he was nearly certain that he did not. In some cases it *might* be desirable, but he is dubious about it. He made it a rule to suture nerves and tendons in every case, and generally obtained fair results.

CORRESPONDENCE.

THE CUTANEOUS EXCRESCENCES FOLLOWING UNSUCCESSFUL VACCINATIONS.

To the Editor of The Medical News,

Sir: Your correspondent, A. J. Comstock, M.D., in The Medical News of March 10, 1888, gives his opinion of the cause of the excrescence which sometimes follows an unsuccessful vaccination. As my experience

differs from his, it may be well to record it, trusting that the true cause may, through the experiences of many, be ultimately determined.

In the early years of my practice, I collected the virus from the eighth-day vesicles of healthy infants, on quills which I had scraped just before applying them to the punctured vesicle, in order to secure their cleanliness. I was particular not to take the lymph when I had pricked the tissues and drawn blood, but applied the quill directly to the drops of lymph as they escaped from the punctures in the vesicle, and seldom touched it to the surrounding skin. If, on the eighth day, the pock had assumed a pustular character, and the surrounding skin began to inflame, I did not collect the matter, as it was not considered safe to use it.

I never saw the excrescences until I commenced vaccination with bovine virus. Since then I have probably used as many ivory points as quills. I have never scraped a quill charged with vaccine matter, and put it on the scarification. I think the excrescence has appeared as often after the use of the ivory point as after the quill, which would disprove the hypothesis of quill-grafting.

My explanation to those who have witnessed the appearance, and have been alarmed by it, has been that the skin of the calf was ingrafted with the vaccination. I give it as an opinion, undemonstrated. The fungous character may be due to the number of cells thus ingrafted, or to the stimulus of scarification to the normal skin. If viable cells are mixed with active vaccine, their viability may be destroyed in all successful vaccinations: hence, their appearance only when the vaccination is ineffectual.

I have had manifold more failures with bovine virus than with the humanized vaccine when I cultivated it for my own use. I hope the culturists of bovine virus will inform the medical profession whether or not they observe as much caution in collecting the matter, avoiding the blood and irritated tissues of the heifer, as I was taught to do, more than thirty years ago, when collecting from the healthy infant; and further, whether they collect the matter when it appears purulent, or after the inflammation has surrounded the pock.

Respectfully, N. W. Leighton, M.D.

148 Taylor St., Brooklyn, N. Y.,
March 19, 1888.

OBITUARY.

WILLIAM BENJAMIN GOLDSMITH, M.D.

William Benjamin Goldsmith, M.D., Superintendent of the Butler Hospital for the Insane, at Providence, R. I., died at that place, March 21st, in the thirty-fifth year of his age. The fatal disease was acute pneumonia of seven days duration.

Dr. Goldsmith was born at Bellona, Yates Co., N. Y. He graduated in the Arts from Amherst College, Massachusetts, in 1874. The next year he spent at the Willard Asylum for the Insane, as a medical student, under the special instruction of Dr. John B. Chapin. He then took a course in general medicine at the College of Physicians and Surgeons, N. Y., for two years, graduating in 1877, and ranking among the first ten in his class. After a brief service at the Presbyterian Hospital in N. Y., he became second assistant at the Bloomingdale Insane Asylum, where he remained two and a half years. The next year he spent abroad, pursuing the study of his specialty at the West Riding and Royal Edinburgh Asylums. In October, 1880, he returned to Bloomingdale as First Assistant, and in March, 1881, when twenty-eight years old, was appointed Superintendent of the Insane Asylum at Danvers, Mass. At the end of three years he resigned intending to go abroad. His resignation, however, was not accepted, but a year's absence was granted him instead, which was spent in Germany. After one year more at Danvers he was, in February, 1886, called to the Butler Hospital, Providence, R. I., to succeed, as Superintendent, Dr. John W. Sawyer, deceased.

Dr. Goldsmith came to the Superintendency of the Butler Asylum in the enjoyment of a high reputation, and upon the earnest recommendation of Dr. Nichols, of Bloomingdale Asylum, and the work he subsequently performed only served to indicate more fully the kind of man he was. Without losing complete harmony with the methods of Dr. Sawyer, he developed a system of treatment and government whose excellence will surely be perpetuated. A friend who knew him intimately has thus written of him, "He was born to command, and what it took others long years to acquire he seemed to grasp without effort, and yet he was always deliberate, careful, and methodical in all which was brought to his attention, but once having acquired it he never lost its possession, so that he was ever gaining and broadening without any retrogression. He entered upon his duties at Danvers with the firm and quiet dignity of a man of years of experience, and so conducted the affairs of that great institution as to command the respect and love of all who were in any way connected with it. His yea was yea, and his nay was nay; and yet there was no sense of fear or dread in his rule. He was a kingly man whose rule, though firm, was the rule of duty and love."

His creed, though short, was all comprehensive, viz., "Love to God and love to his fellow-man."

Dr. Goldsmith was a Fellow of the Rhode Island Medical Society. He was unmarried. A widowed mother and a sister survive him. In his death the medical profession loses one of its most earnest, most useful, and most promising followers.

NEWS ITEMS.

Surgeon-General Gunnell.—A Washington special to the *New York Times* states that the impression prevails among naval officers that Secretary Whitney has been unjust to Medical Director F. M. Gunnell in not reappointing him Surgeon-General of the Navy, and thereby enabling him to retire with the relative rank of Commodore. The Secretary hesitated for some time over this appointment, and it was only after he was convinced that no injustice would be done Dr. Gunnell that he concluded to appoint Medical Director Browne. There is a law not generally known, it seems, that gives staff officers retiring at the age of sixty-two, after forty years of faithful service, the relative rank of Commodore. Dr. Gunnell will have been over forty years in the service at the date of his retirement, and therefore will retire with the rank of Commodore. This provision is contained in Section 1481 of the Revised Statutes, and it was reading that

section which determined the Secretary to supersede Dr. Gunnell.

Philadelphia Polyclinic Course of Lectures.—The remaining evening lectures in the Polyclinic course will be given on the following dates at the Polyclinic Building, Broad and Lombard Streets:

April 3, Prof. Charles H. Burnett: Excision of the Membrana Tympani in Chronic Ear Diseases.

April 10, Prof. Arthur Van Harlingen: The Management of Eczema in Old People.

April 20, Prof. J. Henry C. Simes: The Treatment of the Primary Lesions in Syphilis.

April 24, Prof. Edward Jackson: The Character and Significance of the Retinal Lesions associated with Bright's Disease.

May 1, Prof. Alexander W. Mac Coy: Observations on the Pharyngeal Tonsil.

May 11, Prof. H. Augustus Wilson: Treatment of Lateral Spinal Curvature.

May 22, Prof. Solomon S. Cohen: Respiratory Therapeutics.

All lectures begin at 8 P.M.

A Warning.—The *Lancet*, in a recent issue, offers the following timely warning against the indiscriminate use of antipyrin: The public attention given to the latest remedy for sea-sickness and many other affections to which flesh is heir has its percentage of evil as well as good. Every medicament is not an unmixed advantage, and to suppose that antipyrin may be taken recklessly any more than chloral is to adopt a position of a dangerous kind. Antipyrin has on several occasions been administered with unexpected results. It is a drug which has undoubtedly powerful effects on the nervous system, especially as tending to produce a lowering action. We must strongly protest against its indiscriminate employment without the supervision of a medical man.

A Practical Test of the Cremation of Garbage.—The *Sanitary News* of March 10, 1888, describes a recent test of the garbage crematory at Chicago, as follows:

As yet the men who have charge of the crematory are inexperienced, the masonry is in a moist, if not a wet condition, and on the day of the test the garbage arrived late, yet, from 9 o'clock in the morning until noon, about sixty-seven double wagon loads of garbage had been incinerated. Speaking of the garbage, it was really more of a curiosity than the works, inasmuch as everything conceivable, fire-proof or inflammable, combustible or non-combustible, from a broken tooth-pick to a barrel of solid ice, was there to be burnt. During one slow, but sweeping and satisfactory glance on the refuse of a great and mighty city, we missed nothing, positively nothing—that is, over, on, or under the earth.

The furnaces and buildings surrounding them, in fact, the crematory, complete, cost but $7000, and when one takes into consideration the great amount of teaming the work will dispense with, not to speak of the incalculable value, from a sanitary point of view, it will soon pay for itself, if it proves the success it is expected to. Garbage will be hauled to this crematory from a radius of one and one-half miles, and after it has proved successful, others will be built, probably five in all. Thirty-six wagons are now being made for the special purpose of hauling the garbage. The capacity of the furnaces has not, as yet, been tested, but the inventor claims that they will burn anything put into them, and that a great deal can be put into them. While at the crematory we were treated to a cat and dog burning exhibition, which was very fine—that is, the ashes, as one of the party said. The furnaces have an excellent draught, and the little smoke that arose from the tall chimney was shot straight into the air, for several feet, before being carried away by the rather stiff breeze, high over the buildings in the vicinity. There was no odor perceptible, except such as arose from the garbage before it went into the furnace, which smell can be enjoyed at home, in the alley, in the back yard, or even on the sidewalk.

Ancient Anatomical Figures.—Le Blant, of Rome, describes figures discovered in Rome recently, without head or limbs, but with an open thorax, showing the location and relation of the viscera. The latest discovery of this sort was the finding near the temple of Æsculapius upon an island in the Tiber, more of these figures excellently modelled and colored. The God is said to have performed miraculous cures at the spot where these were found.—*Gazette des Hopitaux.*

The Cause of Dental Caries.—The *Popular Science Monthly* for April, 1888, writes that to the question, Why do teeth decay so rapidly? Dr. Julius Pohlman answers, because we do not use them enough—showing that as a rule, "those people who are least acquainted with the so-called hygiene of the teeth are the happy possessors of the soundest dentition"—like the negroes who chew sugar-cane; the German peasants, who are famous for their brilliant "Schwartz-brot-Zähne," or "rye-meal-bread teeth," polished but not worn out by daily mastication of dry, hard, black loaves, and the few old people left among us who persist in eating bread-crusts. Our weak and effeminate teeth are not used to hard work, and like other organs that are not exercised, tend to atrophy. "The foundation for bad teeth," says this author, "is generally laid in early childhood; for numberless mothers and nurses very carefully soften the food or remove the crust from the bread before giving it to the little folks, because it may otherwise 'hurt their teeth,' and so the child grows up with a set of unused organs in its mouth; and when we have finally succeeded by the creation of artificial conditions in producing weak organs, then we wonder why the poor child has such bad teeth, and why it is so often suffering with toothache, and why the dentist's bill is so high. Teeth are organs specialized to perform the work of mastication; they are subject to the same laws that govern other organs, and their strength is determined by their use. Understanding this, we are obliged to admit that, if we ever become a toothless race, it will be our own fault."

Nitrite of Amyl in Warfare.—Weston, an electrician, concludes from his studies of projectiles, that the common form of offensive and defensive weapon at present is something that will throw a solid or an explosive metal projectile—a solid shot, a shell, or a torpedo. Explosive bullets for small arms are tabooed under the laws of war, because they do unnecessary damage, that is, they kill after striking, when the wounds they first cause would

be sufficient. It follows that if one could overpower his enemy without either killing or wounding him, that plan would be preferable to any now existing. That is what he believes can be done. It is well known that the nitrite of amyl possesses the power of causing insensibility very quickly in a human being breathing its fumes. The effect is equivalent, temporarily, to a paralytic stroke. Now, nitrite of amyl is very cheap and plentiful. He proposes to fire shells filled with this chemical instead of gunpowder. It will not be necessary to penetrate a ship. A few gallons of this nitrite dashed on the deck of a war ship would soon render her crew helpless. The most powerful ironclads would be even more vulnerable than the light cruisers, for they would be sucking down great draughts of air through their artificial ventilators, and the odor would thus rapidly permeate the whole ship. The whole crew being rendered helpless for an hour or two, the ship could, of course, be towed into a safe spot, while the captors ventilated her and removed the insensible men.—*American Analyst*, Feb. 15, 1888.

Poisoning by Castor-oil Bean.—EDSON reports in the *Brooklyn Medical Journal* for February, 1888, the following instance of poisoning from the castor bean:

In October, 1887, fifteen children under six years of age, and one female nurse twenty years old, all inmates of the Home for Destitute Children in this city, indulged in a repast of raw beans taken from a castor-oil plant growing in the yard of the institution. The effect upon them all was to cause severe vomiting and prostration. The vomiting was persistent and seemed but little amenable to treatment. Various measures were tried to afford relief, but none was satisfactory. The nausea and retching recurred at short intervals in many of the cases, for at least forty-eight hours after the seeds were eaten, varying in duration and severity with the number eaten, the amount of food contained in the stomach at the time, and the susceptibility of the individual children.

The number of beans eaten could not be well ascertained, but it is believed that no child ate more than three or four.

The nurse, who even yet maintains that she ate but a single one, was so affected that for over sixty hours she could not assume the upright position without the recurrence of the nausea and vomiting. She was so prostrated that she was under treatment in the hospital of the institution for ten days before she was able to resume her work. Extreme prostration was a feature of all these cases.

The remarkable feature in *all* these cases was, that *in not a single instance was there any catharsis.*

This is not in accordance with what we have been led to expect.

Congo Paper.—The following description of this recently introduced test for acids is of interest, in view of its application to the diagnosis of gastric diseases.

The *American Druggist* for March, 1888, gives the following formula:

Congo-red	1 part.
Alcohol	7500 parts.
Distilled water	2500 parts.

Dissolve the Congo-red in the mixed liquids, and impregnate paper with the solution.

Limit of sensitiveness: 1 : 3000 toward sulphuric acid; 1 : 2500 toward hydrochloric acid.

According to this, Congo-red appears to be an exception to other indicators, as it is less sensitive to hydrochloric than sulphuric acid.

Congo-red was proposed about two years ago as a good indicator for acids and alkalies. At first it was proposed as an indicator for free acids in the presence of alum. It is turned *blue* by acids, and *red* by alkalies, just the reverse of litmus. Though its sensitiveness is not very great, it may yet be used to advantage in some cases, where the result obtained with litmus paper remains doubtful, owing to the specific color of the liquid to be tested.

Congo-red is a name given by the "Aktiengesellschaft für Anilinfabrikation," in Berlin, to a product discovered by Paul Boettger, and patented by him on February 27, 1884. It is prepared from tetraazodiphenylchloride and naphthionic acid. It has the remarkable property of dyeing cotton without requiring a mordant, and has become the starting-point of a large number of new colors of similar properties.

Opium Poisoning in England.—The *Popular Science Monthly* writes that it is said that forty per cent. of all the deaths from poison in Great Britain are due to opium; and this rate of mortality, according to Dr. Wynter Blythe, "arises in a great measure from the pernicious practice, both of hard-working English mothers and the baby-farmer, of giving infants 'soothing-syrups,' 'infants' friends,' and the like, to allay restlessness and keep them asleep during the greater part of their existence." It has been calculated that one preparation alone is the undoubted cause of death of 150,000 children every year.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM MARCH 20 TO MARCH 26, 1888.

SPENCER, WILLIAM C., *Major and Surgeon.*—Died, March 22, 1888, at Fort Trumbull, Connecticut.

FORWOOD, W. H., *Major and Surgeon.*—Granted one month's leave—*S. O. 20, Department of Dakota*, March 10, 1888.

BROWN, H. E., *Major and Surgeon.*—Assigned to temporary duty at Fort Barrancas, Florida, during the absence on leave of Assistant Surgeon M. C. Wyeth. On the return to duty of Captain Wyeth, Major Brown will rejoin his proper station.—*S. O. 65, A. G. O.*, March 20, 1888.

ORIGINAL LECTURES.

THE CARTWRIGHT LECTURES. ON THE GENERAL PATHOLOGY OF FEVER.

Delivered before the Association of the Alumni of the College of Physicians and Surgeons, New York, March 29, 1888.

BY WILLIAM H. WELCH, M.D.,

PROFESSOR OF PATHOLOGY, JOHNS HOPKINS UNIVERSITY, BALTIMORE.

LECTURE I.

THE NATURE OF FEVER.

THERE is no subject in medicine of more general and varied interest than fever. The practitioner in every department of medicine, the pathologist and the physiologist are equally interested in the investigation of the nature and effects of fever. Even the physicist and the chemist, who are not directly concerned with medical science, have lent their aid to the study of animal heat and its disorders. The history of opinion regarding fever is in great part the history of medicine itself, for no feature of the great systems of medicine from Hippocrates and Galen to the present century so characterizes these systems as the views held concerning the nature of fever. In consequence of the importance of the subject and of the number and ability of those engaged in its investigation, it might be supposed that no chapter in medical science would be better understood than that pertaining to fever. That such is not the case is due to the fact which is becoming more and more evident that the reaction of the animal system which we call fever is dependent upon the most fundamental and essential properties of protoplasm and of nerve energy. In proportion as our knowledge of these properties increases and becomes more accurate, we gain a clearer insight into the complicated processes involved in the production of fever.

I should hardly have selected for this course of lectures a subject where so many problems remain unsolved and which must necessarily be presented in so fragmentary a form, were it not that in all ages the opinions held concerning the nature of fever have controlled measures employed in its treatment. In proof of this, one need not go back to the time when fever was regarded as an almost conscious struggle of an anima with a noxious principle, in which struggle the physician was to interfere as little as possible, or to the time when fever was supposed to result from morbid humors which the physician should aim to eliminate by the production of a critical discharge, or to the period when the treatment hinged upon the belief either in the sthenic or the asthenic nature of fever. In our own time the treatment of fever is intimately connected with the answers variously given to such questions as whether fever aids in the elimination or destruction of infectious agents concerned in its production; whether increased waste of tissue is a constant condition and a source of danger in fever; what part is played by infection and what part by elevation of temperature in causing the grave symptoms of fever; what in addition to lowering of temperature are the effects of so-called antipyretic measures of treatment?

I need hardly say that the subject of these lectures relates to fever as a condition common to all febrile diseases. Some writers understand by the term fever used in this sense merely abnormal elevation of temperature, others elevation of temperature and the symptoms directly caused by this, and still others a complex of symptoms of which increased temperature is the most prominent but not necessarily the cause of the others. In considering the general pathology of fever it is convenient to adopt the last meaning, although it would doubtless be less confusing if the word fever were applied only to abnormal elevation of temperature.

Increased temperature being the dominant and essential symptom of fever, all discussions as to the nature of fever centre around the question, How is the febrile rise of temperature produced? It is to the consideration of this question that I first invite your attention. As there are other aspects of fever which I wish to discuss, it will be necessary to present the matter belonging to this division of the subject in as succinct a form as is compatible with clearness. Twelve years ago Burdon-Sanderson[1] brought together in an admirable critical review the results of investigations upon this subject up to that period. Since that time important additions have been made to our knowledge of the mode of production of fever.

In the wonderful preservation of a nearly constant temperature which characterizes in health the warm-blooded animals three factors are concerned, viz., the production of heat within the body, the loss of heat from the body, and the regulating mechanism by which the varying heat production and heat loss are so balanced that the internal temperature remains practically constant. It is theoretically possible that the rise of temperature in fever may be due to the disturbance of any one or more of these factors. It becomes necessary, therefore, to consider the behavior of heat production, of heat loss, and of the regulating mechanism in fever.

We will begin with the consideration of the production of heat in fever. The amount of heat produced by the body is estimated by two methods, one known as direct calorimetry, the other as indirect calorimetry. In the method of direct calorimetry the animal is placed in a closed ventilated box surrounded on all sides by a compartment containing water or air, and the amount of heat discharged from the body is determined by the quantity of heat imparted to the surrounding water or air. If the temperature of the animal remain unchanged during the period of observation, the heat production is equal to the heat loss; if the temperature rise or fall, the amount of heat corresponding to this change

[1] Burdon-Sanderson: The Practitioner, 1876.

of temperature—an amount determined by multiplying the weight of the animal by its specific heat and by the number of degrees of altered temperature—is added to or subtracted from the quantity of heat imparted to the calorimeter. Time will not permit me to enter into experimental details in this connection; it must suffice to say that the method of direct calorimetry necessitates the introduction of a number of corrections which cannot be determined with absolute accuracy, so that the results obtained are of relative rather than of absolute value.

Hitherto the estimation of heat production in fever by determining the entire amount of heat liberated from the body has been made only upon animals in which fever has been artificially produced. The most elaborate researches of this nature are those of Senator[1] and of Wood.[2] The experiments of Wood are of the greater value because he extended his observations over longer periods of time.

In four of the seven calorimetrical experiments of Wood on different fevered dogs comparison can be made of the amount of heat produced hourly in fever with that produced by the same animal when fed and when in a state of hunger. During the period of fever the animal was also in a condition of hunger. I have computed from Wood's tables that the average hourly heat production during seven days described as first and second fever days, is a little over 23 per cent. greater than that of the healthy animal during a state of hunger, the minimum excess being 1 per cent. and the maximum 55.5 per cent.[3] If a comparison be made of different periods during the existence of fever there are found to be even greater fluctuations in the amount of heat production than these figures would indicate, this amount being sometimes more than double that in hunger and sometimes considerably less than the average production in hunger. Moreover, these experiments show no definite relation between the height of the temperature and the amount of heat produced, nor is it possible to deduce from them any relation between heat production and the different stages of fever, such as the more recent calorimetrical experiments of Wood, Reichert, and Hare[4] appear to show and which will be described later. An important outcome of these as well as of all similar calorimetrical experiments is that, although the heat production of an animal in fever is greater than that under like conditions of nourishment, it is, as a rule, less than that of the same animal upon a full diet.

There are many reasons which make it important to control the experimental results obtained from animals in fever by corresponding observations of human beings. The agents used in producing experimental fever have been generally putrid fluids or pus, the injection of which causes sometimes diminution instead of elevation of temperature. When fever is thus produced, it is usually of short duration and of only moderate intensity, the rise of temperature being rarely more than four degrees, and sometimes not more than one degree Fahrenheit. Moreover, a large part of the important role played by the skin in the regulation of the bodily temperature in man is assumed by the lungs in these animals.

Complete calorimetrical observations of human beings in fever encounter difficulties which have not yet been overcome. The imperfect or incomplete methods employed by Liebermeister[1] and by Leyden[2] in determining the heat production of human beings in fever justify the inference that this production is increased, and, apparently, as a rule, to a greater extent than in animals, but they do not warrant positive conclusions as to the quantity of heat produced.

We turn now to the results regarding febrile production of heat obtained by what has sometimes been called indirect calorimetry. Inasmuch as the heat energy of the body is the result of chemical changes of its proteids, fats, and carbohydrates, it is evident that if we know the kind and the amount and the heat value of the substances consumed in a given time within the body, we can compute their heat production.[3] These chemical changes, so far as their final products are concerned, are processes of oxidation. The heat values of the substances consumed in the body were determined first by Frankland and more recently with accuracy by von Rechenberg, Danilewsky, and Rubner. The investigations of Pettenkofer and Voit have shown that in hunger almost exclusively fats and proteids are oxidized, and that in this condition by determining the amount of oxygen absorbed and of nitrogen and of carbon excreted, we can estimate the quantity of fat and of proteid substances oxidized during the period of observation.

Physicians of past centuries regarded increased consumption of the material of the body in fever as so evident that it needed no especial demonstration, and after Lavoisier made apparent the sources of animal heat, it was accepted almost unquestioningly until the last quarter of a century that fever is essentially a process of increased combustion or oxidation. The immense historical importance of the promulgation in 1863 of Traube's theory, which denied the dependence of fever upon increased production of heat, is that this theory has led to a careful inquiry into the grounds of beliefs hitherto generally accepted, and to the demonstration of the unsatisfactory nature of the evidence hitherto thought to be conclusive.

The striking loss of weight of most fever patients is, as is well known, a fact of great clinical importance. Weber and Finkler have demonstrated that animals in fever lose weight more rapidly than healthy animals in hunger, and although observations on human beings with reference to this point are not concordant in their results, there can be little doubt that the tendency of fever is to cause a greater loss of weight than can be explained simply by insufficient nutriment. This tendency, however, may be masked by the retention of water within the body as the investigations of Leyden and others have

[3] The energy resulting from these chemical changes appears partly in the form of heat and partly in mechanical work. As practically all of the internal mechanical work is transformed within the body into heat energy, it is only the external mechanical work which is to be considered in estimating the actual heat production. The influence of this factor in fever will be spoken of later.

shown. While, therefore, the studies of the loss of weight in fever leave no doubt that there is increased destruction of tissue in this condition, we cannot consider this loss as an accurate measure of the increased destruction, nor, without further knowledge, as an indication of increased oxidation, still less as proof of excessive production of heat.

It was for a long time believed that the excessive excretion of urea in fever afforded satisfactory evidence of increased oxidation and of greater production of heat. We now know, especially from the researches of A. Fränkel,[1] that this is so far from being true that we could explain the excessive elimination of urea better upon the assumption of diminished than of increased oxidation of tissue. In certain pathological conditions, notably phosphorus poisoning, the amount of urea excreted may be increased more than threefold, nothwithstanding, or, as Fränkel believes, in consequence of diminished absorption of oxygen and elimination of carbonic acid. It can, moreover, be computed that even without any diminution of the respiratory gases the discharge of urea may be increased without greater production of heat. While, therefore, the enormous increase in the discharge of urea in fever sheds valuable light upon a most obscure subject, the nature of febrile metabolism, it does not, regarded by itself, afford us any information as to the production of heat.

Failing to find satisfactory proof of increased oxidation in the loss of weight of the body, or the excessive excretion of urea in fever, attention was then directed to the elimination of carbonic acid, an excretory product which bears a much closer relation to the production of heat than does urea. Immense importance has been justly attached to the determination of the amount of carbonic acid excreted by an individual in fever. No point in the whole battle-ground of fever pathology has been more hotly contested than whether increased production of carbonic acid is an essential part of the febrile process. The first investigators of this question, Leyden, Liebermeister, Senator, contented themselves with the determination of the amount of carbonic acid eliminated by an individual in fever and in apyrexia. There are several considerations which greatly diminish the value to be attached to the mere estimation of carbonic acid excreted without simultaneous determination of the amount of oxygen absorbed. As has been urged by Senator, and with especial clearness by Pflüger, increased discharge of carbonic acid does not necessarily imply increased production of the same. The discharge of carbonic acid varies, independently of its production, with the rhythm and depth of respiration, and with the temperature and the alkalinity of the blood, all factors which are altered in fever in such a manner as to favor increased liberation of carbonic acid. It is true that the influence of these factors would cause increased discharge of carbonic acid out of proportion to its production only for a limited period, and that the prolonged increase in the amount of carbonic acid discharged in fever, which has been found by several observers, can hardly be interpreted otherwise than in favor of increased production. There is another point which detracts still further from the value of exclusive determinations of the quantity of carbonic acid discharged, and this is that it makes a great difference, so far as the production of heat is concerned, whether the carbonic acid is the result of oxidation of carbohydrates, of fats, or of proteids, a difference amounting, according to Rubner,[1] to 29.5 per cent.; or, if only the proteids and fats be considered, to over 20 per cent. In investigations of nutrition it is now known to be of the utmost importance to determine the so-called respiratory quotient—that is, the ratio between the amount of carbonic acid discharged and that of oxygen absorbed. This quotient varies in a definite way with the kind of material oxidized in the body, and an accurate knowledge of it would enable us to draw conclusions as to the substances consumed in fever.

The investigations which have been published within the last few years upon the absorption of oxygen, as well as the discharge of carbonic acid in fever, are to be ranked as most valuable contributions to our knowledge of the subject. The first determination by trustworthy methods of the amount of oxygen absorbed and of carbonic acid excreted in fever was made in Pflüger's laboratory by Colasanti upon a guinea-pig, and was published in 1877. Since that time two careful and elaborate researches upon this subject have been made, the one by Finkler, and the other by Lilienfeld.[2]

These experimenters found that in fever there is increase of the amount, both of oxygen absorbed and of carbonic acid excreted. Making comparison with healthy animals under the same conditions of nutrition, Colasanti found that the increase in the absorption of oxygen amounted to 18 per cent, and in the excretion of carbonic acid to 24 per cent.; Finkler, whose experiments were made also upon guinea-pigs, found, under varying conditions of external temperature, the average febrile increase of oxygen to be 13.8 per cent., and of carbonic acid 15.3 per cent., and Lilienfeld, who experimented on rabbits, found the average increase of oxygen to be 13.9 per cent. The statement of these averages gives an incomplete conception of the oxidation in fever, as they are derived from all stages of fever, and varying elevations of temperature. No constant proportion was found to exist between the height of the temperature and the amount of oxidation. On the other hand, a relation was observed between the oxidation and the stages of fever, viz., the initial stage with rising temperature, the acme with constant high temperature, and the defervescence with falling temperature. During the period of rising temperature oxidation was increased, and in this stage Finkler found the highest percentages, amounting to 36.6 per cent. in the increase of oxygen, and 37.6 of carbonic acid. There were, however, marked fluctuations in this stage, both in the temperature and the amount of oxidation. In the stage of constant high temperature such high percentages were not noticed, and the fluctuations were less marked. The processes of oxidation, according to Lilienfeld, are increased, on the average, less in the acme than in the initial stage of fever.[3] During defervescence of fever the increased oxidation falls, and may sink below the normal. Taking a broad view of these stages, we may say, therefore, that the periods of rising,

[1] Fränkel: Virchow's Archiv, Bd. 67.

[1] Rubner: Zeitschrift f. Biologie, Bd. xxi.

[2] Colasanti, Pflüger's Archiv, Bd. xiv. Finkler, Ibid., Bd. xxix. Lilienfeld, Ibid., Bd. xxxii.

[3] In the period of rising temperature there was an increase of oxygen absorbed of 27 per cent., in the acme of 14.9 per cent.

constant, and falling temperatures in fever, correspond to periods of rising, constant, and falling oxidation, but we must bear in mind that the fluctuations in oxidation are much greater than, and bear no constant relation to, those of temperature; so that, in each period, there are times when oxidation may rise or fall most decidedly without corresponding changes of temperature.

Inasmuch as these experiments have shown that the increased excretion of carbonic acid in fever is accompanied by increased absorption of oxygen, and, as will be explained presently, that the respiratory quotient, if it changes at all, sinks, it is evident that we need not discard experiments in which only the amount of carbonic acid excreted has been estimated by good methods. The most accurate of these experiments are those of Leyden and Fränkel upon fevered dogs.[1] They found that, without exception, carbonic acid is excreted in larger amount in fever than in health under the same nutritive conditions, the excess amounting sometimes to 70 per cent., and in general being larger than in the experiments which have been previously considered. The earlier and meritorious experiments of Senator upon this point did not give uniform results, and he felt justified in concluding that there is no evidence of increased production of carbonic acid in fever. Subsequent experiments with far more accurate methods have demonstrated the incorrectness of Senator's conclusions. It may be well to call to mind that Burdon-Sanderson's deductions, which have naturally had great influence among physicians here and abroad, were based, in great part, upon the data derived from Senator's experiments.

Hitherto, the methods employed in studying the respiratory gases of human beings in fever have not approached in accuracy those used in the experiments described. If the discordant results of Wertheim, which were obtained by methods manifestly very inaccurate, be discarded, all other investigators have observed augmented discharge of carbonic acid in fever of human beings. Leyden found an excess of 50 per cent. in the febrile discharge of carbonic acid; and Liebermeister, whose observations were made chiefly on cases of intermittent fever, found an excess of 30 to 40 per cent. in the period with rising temperature, and of 19 to 31 per cent. in the acme of the fever. During the defervescence of the fever the excess of carbonic acid discharged diminished, and sometimes wholly disappeared. In one instance, in which the determination was made during the rigor of intermittent fever, the carbonic acid excreted was two and a half times the normal amount; an excess so enormous that it was undoubtedly due, in great part, to the muscular movements which attended the chill.

Although we cannot consider these figures as absolutely accurate, they indicate clearly that in human beings, as well as in animals, fever is characterized by increased oxidation, and apparently that, as a rule, in man the excess of oxidation is greater than in the experimental fever of animals. This was to be expected, as it is difficult to produce experimentally in animals anything approaching in intensity the well-marked fevers of human beings.

As the result of these laborious researches we may consider it established that increased oxidation is a part of the fever process. It has been claimed that this augmented oxidation is simply the result of the elevation of temperature, but it can be proven that this is not true. Pflüger has demonstrated that the processes of oxidation are more active at high than at low temperatures of the body, and he has also established the increment of oxidation which corresponds to each degree of rise of temperature. By means of these data Finkler has computed that in guinea-pigs the febrile elevation of temperature of 1° C. could cause an increase of the absorption of oxygen of only 3.3 per cent. Moreover, Lilienfeld found decided increase in the processes of oxidation before there is any marked elevation of temperature, and all the experiments have rendered it quite evident that there is no such relation in fever between the height of the temperature and the energy of oxidation, as would be expected if the augmented oxidation were merely the result of the increased temperature.

There is no reasonable doubt that the more energetic oxidation which we find to be an essential part of the process of fever indicates increased production of heat. Exactly what amount of heat production corresponds to the increased oxidation we cannot know until the kind and the quantity of substances oxidized in fever have been determined. It is to be regretted that no experiments have been made in which the amount of nitrogen excreted has been determined at the same time with the estimation of the oxygen absorbed, and of the carbonic acid discharged. These data would enable us to form some estimate, although not an accurate one, of the amount of heat production corresponding to the oxygen absorbed, unless very different laws from those in health control the oxidation processes of fever.

Mention has already been made of the importance of determining in fever the respiratory quotient, or the ratio between the carbonic acid discharged and the oxygen consumed. A few words will make this clear. It is well known that under ordinary circumstances in health not all of the oxygen consumed reappears in the carbonic acid discharged. This indicates that a part of the oxygen absorbed is used in other oxidations than those resulting in the production of carbonic acid. According to the extent of these other oxidations, therefore, the respiratory quotient must vary. It is probable that these oxidations, of which carbonic acid is not a product, result at least in part, in the formation of water, which is, therefore, one of the excretory products of the body, as has been urged especially by Austin Flint. The influence of various circumstances upon the respiratory quotient has been studied, but what especially concerns us here is that in hunger this quotient sinks, which is to be expected from the fact that in this condition almost exclusively fats and proteids are oxidized. We evidently possess in the determination of the ratio of carbonic acid discharged to the oxygen consumed a means of reaching a conclusion as to a cardinal point in the pathology of fever, viz., whether the processes of oxidation in fever conform to the laws which govern them in health, and particularly whether, as has been often asserted, unusual or incomplete products of oxidation are formed to any considerable extent in fever. Colasanti and Lilienfeld found that the respiratory quotient in their fevered animals did not vary from that of healthy animals under similar nutritive conditions. Finkler observed that the respiratory quotient fell in fever somewhat more rapidly than in hunger, and this he explains by the more active oxidation in fever.

[1] Leyden and Fränkel, Virchow's Archiv, Bd. 76.

All three experimenters reached the conclusion that the substances oxidized are the same in fever as in health, and that other than the normal products of combustion are not formed in fever in any considerable amount. That the metabolism in fever does differ in at least one important respect from that in hunger, is evident from the excessive amount of urea excreted in fever, but considerable variations in the disintegration of albuminous material may occur without much change in the respiratory quotient.

The only determinations of the febrile consumption of oxygen and discharge of carbonic acid in man are those of Wertheim and of Regnard. Both investigators found a decided diminution of the respiratory quotient. The method employed by Wertheim was so defective that no confidence can be placed in his results. The experiments of Regnard[1] are presented with great neatness, but his results on other points differ so much from those obtained by trustworthy physiologists and by better methods, that we cannot accept his conclusions as to the respiratory quotient in fever without confirmation. Regnard found in all fevers which he studied a most marked diminution of the respiratory quotient. If this were true it would follow that in fever a much larger part than in health of the oxygen consumed is employed in other oxidations than those yielding carbonic acid. This would confirm the widely accepted belief that water and products of incomplete oxidation are formed in excessive amount in fever.

From the unfortunate discrepancy of these results it is evident that the knowledge which we now possess of the processes of oxidation in fever is not sufficient to enable us to form from them an accurate estimate of the heat production. In hunger, from one-fourth to one-third of the absorbed oxygen is available for combination with hydrogen to form water, the remainder uniting with carbon to form carbonic acid (Regnault and Reiset). If in fever the same ratio exists, then the excess of heat production would be proportionate to the excess of oxygen absorbed, assuming that the substances oxidized are the same in both conditions; if, however, as Regnard's experiments indicate, a larger proportion of oxygen is available in fever for the oxidation of hydrogen, then the increment of heat production would be still greater, for the same amount of oxygen produces more heat when employed in the oxidation of hydrogen than in that of carbon. It is also to be considered that the same quantities of hydrogen and of carbon in their oxidation yield varying amounts of heat according to the chemical compounds in which they are contained, and we cannot say positively whether the compounds oxidized are the same in fever as in health under like conditions of nutrition. Upon the whole the weight of evidence is in favor of the view that the excess of heat production in fever is approximately proportionate to the increase in the consumption of oxygen, but it would be rash to assert this positively. It is evident that in fever ordinarily a much smaller amount than in health of the energy resulting from chemical processes is transformed into external mechanical work, so that relatively more remains in the form of heat.

In connection with this discussion of the possibility of unusual sources of heat in fever may be mentioned an hypothesis which has been advanced with much ingenuity by Dr. Ord.[1] This hypothesis is based upon the assumption, which is probable enough, that there are in the body chemical processes in which heat energy is transformed or rendered latent. These processes are thought to be chiefly those concerned in the building up of tissue. It is argued that inasmuch as the construction of tissue is manifestly in abeyance in fever, the amount of heat in the body may be increased not only by disintegrative processes, but also by "the persistence in the form of heat of energy which should have taken another form." That these building up processes influence decidedly the amount of heat produced in the developing ovum has been demonstrated by d'Arsonval's calorimetrical determination that the egg during incubation absorbs heat, notwithstanding the consumption of oxygen and the excretion of carbonic acid. This fact, which might have been predicted, certainly does not justify us in refusing to attach any calorimetrical value to the determination of the respiratory gases and the urinary nitrogen. From the little we know of these constructive processes in human beings we should infer that the amount of energy in the form of heat which they appropriate bears only a very small ratio to the total heat energy set free by heat-producing processes, so that their cessation would not bring a large increment to the heat of the body. Moreover, these constructive processes are also in abeyance, although doubtless to a less extent, in starvation, with which experimental fever is usually contrasted as regards heat production and heat loss. It is not probable that any extraordinary difference in the behavior of the processes of tissue-building in fever and in starvation can occur without affecting the respiratory quotient. For the present, therefore, we cannot attach any great importance, so far as the increase of heat energy in fever is concerned to the inactivity of heat-absorbing processes.

We have gone over now the evidence which, in my judgment, establishes the fact that there is increased production of heat in fever. The same conclusion is reached also by the study of the loss of heat from the body in fever. That fever is accompanied by increased production of heat and by more active combustion, has been in all ages the belief of the majority of physicians. This belief, however, has been rather instinctive than based upon actual demonstration. It has been contested by investigators of great ability, and on the ground of scientific observation. For these reasons, and on account of the importance of the subject, it has seemed to me desirable to present to you the exact evidence, although many of its details, I fear, may have wearied you. We have learned, moreover, certain facts concerning febrile thermogenesis which the mere observation of fever patients does not render so apparent. We have found that there is no definite relation between heat production and the height of the temperature, so that we may have excessive thermogenesis with low as well as with high temperatures. There appears to be, however, a relation between the stages of fever and heat production, this being in spite of remarkable fluctuations greatest in the initial stage, and least in defervescence.

Although for reasons which have been mentioned, and others might have been adduced, we can attach hardly an approximative value to figures which purport to give

[1] Regnard: Recherches Exp. sur les Variations Pathologiques des Combustions Respiratoires. Paris, 1878.

[1] Ord: British Medical Journal, 1885, vol. ii.

the actual heat production in fever, still, unless far more serious errors than seems possible inhere in the methods of direct and of indirect calorimetry, we can draw one important conclusion. This is that while an individual in fever produces more heat than he would in health under similar conditions as to food and muscular movements, he does not produce necessarily in fever more heat than he would in health on a full diet. And it is certain that he usually produces far less heat in fever than he often does under circumstances which normally increase heat production, such as a cool environment and muscular exercise. That one in health, with little or no change of temperature, may produce twice or more the quantity of heat which he produces in fever, makes it plain that it is impossible to explain febrile rise of temperature simply on the basis of increased thermogenesis, or what probably comes to the same thing, of increased oxidation. That in health vastly increased heat production may occur with comparatively little change of temperature is, of course, due to the fact that the dissipation of heat is proportionately increased. It is self-evident, and, so far as I know, has never been disputed that in fever the equilibrium is so disturbed that heat loss does not correspond to heat production as it should in health. This disturbance of equilibrium can be brought about in various ways, and it is only by the determination of the actual heat production and heat loss in fever that we can say in what direction the balance is disturbed.

We have found that the production of heat is increased in fever when the comparison is made with like conditions of nourishment and of environment. It is obvious that the total loss of heat cannot equal the total production of heat during the period of febrile rise of temperature.

As is well known, most of the heat of the body is liberated from the skin and from the lungs; from the former by radiation and conduction and by the evaporation of moisture, and from the latter by evaporation of moisture and warming the respired air. It has been estimated that in man about eighty per cent. of the total heat dissipation is from the skin.

The method of direct calorimetry, already described, has been applied only to animals for the determination of the total heat loss in fever. Here Wood's experiments are the best which we possess. Leyden and Liebermeister have furnished calorimetrical data which, although unsatisfactory in many respects, indicate the general direction of febrile heat loss in human beings. All of these experiments show that more heat is dissipated in fever than under like conditions in health. The fluctuations of heat loss during a febrile paroxysm are so great that the statement of an average for the entire period has little significance. Such an average, according to Wood's results on fevered dogs, would fall between twenty to thirty per cent. excess of heat loss as compared with the loss in health under like conditions of food. The dissipation of heat in fever, however, may be at times more than double the normal amount, and again may sink below the norm. We have not sufficiently accurate estimates either of the total amount of heat produced or of that dissipated during a febrile attack to enable us to strike a balance between the two. Some persons have been so impressed with the large amount of heat lost during certain periods of fever, that they have concluded that there must be far greater excess of heat production than previous investigations have shown to be probable. They suggest that there are sources of febrile heat of which at present we have no idea. Such conclusions seem to me quite unwarranted, when we consider the behavior of heat-loss, not for a limited time but throughout the different stages of a paroxysm of fever. We have already seen that we obtain no satisfactory conception of febrile production of heat unless we follow it during the stages of fever, and this is no less true of heat dissipation. The observation of the condition of the skin as regards temperature and moisture must in all ages have afforded an insight into the general behavior of heat dissipation during the different periods of fever. It does not require any instruments of precision to make plain the fact that a cold, dry skin, such as we observe during a febrile chill, liberates less heat than normal, or that a hot, moist skin, such as we are likely to find at the defervescence, loses more heat than normal. Not quite so evident is the direction of heat loss during the hot stage or acme of a febrile paroxysm or fastigium of a continued fever. Here the skin usually appears hot and dry. The ordinary impression that more heat than normal is dissipated during this stage is supported by calorimetrical experiments. There can be no doubt that the elevation of the cutaneous temperature which we observe in the hot stage of fever causes an increase in the amount of heat lost by radiation and conduction. Similar elevations of cutaneous temperature in health, such as those caused by muscular exercise, are accompanied by increased moisture of the surface. Not only is visible perspiration usually absent during the hot stage of fever, but the invisible perspiration is, as a rule, relatively although not absolutely diminished, as Leyden has shown. The dryness of the skin, therefore, is a factor which in the hot stage of a fever tends to lessen heat dissipation. Clinical observation, however, shows that fevers differ markedly from each other as regards perspiration during the hot stage, the skin being sometimes bathed in perspiration without any depression of temperature. It would undoubtedly be of great interest to possess trustworthy data as to the exact loss of water from the surface of the body in different fevers and at different stages of fever. We cannot place much reliance upon the indications afforded by Weyrich's hygrometer, which has been repeatedly used for this purpose. More is to be expected from the method employed by Peiper[1] in studying insensible perspiration under physiological conditions.

The general impressions regarding febrile loss of heat derived from clinical observations, are supported by calorimetrical experiments. The dissipation of heat is least during the initial stage of fever, and greatest during the period of defervescence. During the hot stage or fastigium heat dissipation exceeds the normal, but usually, on account of the dryness of the skin, not so much as one might infer simply from the impression of heat received by the hand when placed upon the skin.

During the initial period the loss of heat, although on the average less than in the following stages, is usually greater than normal. If, however, the rise of temperature be rapid the heat loss falls below the normal amount. As there is now increased production of heat, there is evidently a glaring disproportion between the two factors, heat production and heat loss, and under these circumstances the febrile attack is likely to be ushered in by a chill.

[1] Peiper: Zeitschr. f. klin. Med., Bd. 12.

During the febrile chill all the efforts of nature combine to produce in the shortest time the greatest possible elevation of temperature. Not only is heat loss reduced to a minimum, but heat production is excited to the utmost.

During the period of defervescence, on the other hand, the relation between heat loss and heat production is reversed. This is, of course, most apparent when the fever terminates by crisis with rapid fall of temperature. Then the loss of heat is excessive, being sometimes threefold that in the normal state, and the production is relatively and often absolutely diminished.

It is of importance to remember that there are continual and irregular fluctuations in the dissipation of heat during the different stages of fever. These fluctuations bear no definite relation either to the momentary production of heat, or to the height of the internal temperature. We deal in ordinary life so much more with units of temperature than with units of heat that it is difficult for us to keep constantly in mind the fact that no inference can be drawn as to the height of the internal temperature from the knowledge of the momentary heat production and heat loss. If the heat loss fall behind heat production the temperature of the body rises, and it can remain at this elevated point with either diminished or increased heat production so long as the heat loss equals heat production.

No correct conception of the condition of the heat-regulating mechanism in fever can be obtained without taking into consideration these irregular variations in the discharge of heat, and it is a merit of Senator and his pupils to have emphasized particularly this point. These variations are made apparent not only by calorimetric measurements and direct observation, but also by the studies which have been made of the cutaneous temperature in comparison with the internal temperature in fever. Hankel's law that the difference between the temperature in the axilla and that of the surface of the body in the febrile condition is less than in the normal condition manifestly does not hold for the chill, in which it has been proven that the superficial temperature falls while the internal temperature rises. Jacobson, Wegscheider, Schülein,[1] find that there constantly occur in the course of most fevers changes of the superficial temperature, which stand in no relation whatever to alterations of the internal temperature. Schülein thinks that he has discovered some facts in this regard which are available in diagnosis. However this may be, these observations indicate that contraction and dilatation of the cutaneous vessels are constantly occurring, and without any regularity, in fever. These irregular variations in the calibre of the bloodvessels are also apparent to the eye in the vessels of the rabbit's ear during fever. When it is considered, furthermore, that these irregularities of cutaneous circulation vary decidedly in different situations, no further proof is needed that the mechanism which regulates the discharge of heat from the surface of the body is profoundly disturbed in fever.

These alterations in cutaneous circulation are such striking phenomena that it is perhaps not surprising that two great medical authorities should have based upon them exclusively theories of fever, Traube assuming excitation and Marey paralysis of vaso-motor nerves as the primal element in fever. We need not discuss these theories, now generally abandoned in their exclusive form. From what has been said concerning the loss of heat in fever, it is evident that we cannot explain febrile rise of temperature solely by the behavior of heat dissipation any more than we can explain it solely on the basis of increased heat production. In rejecting Traube's theory that fever is the result solely of retention of heat we must still recognize the fact that decrease in the dissipation of heat, at times absolute, at other periods relative, is a factor of the utmost importance in the febrile process.

From whatever point of view we consider the question we cannot avoid the conclusion that it is the mechanism which controls the relation of heat production to heat loss, which is disturbed in fever.

Heat production is increased in fever, but if the regulating mechanism were normal, then the discharge of heat would be proportionately increased and the temperature would not be materially affected. Nor would the force of this argument be changed if febrile thermogenesis were twice as energetic as we suppose it to be.

The loss of heat is increased in fever, so that on this ground alone we should be obliged to assume increased heat production. But, even if it were proven that heat dissipation is diminished, as has been recently claimed again by Rosenthal,[1] and that fever is the result of heat retention alone, it would still be necessary to admit that the regulating mechanism is at fault, for Pflüger has demonstrated that when this is normal, changes in the temperature of the skin are attended by such changes in heat production that the internal temperature remains within wide limits unaltered.

I repeat then that the conclusion is forced upon us that the fever-producing agents must act either directly or indirectly upon the mechanism regulating the harmonious relation of heat loss to heat production.

(To be concluded.)

A CASE OF RADICAL CURE OF HYDROCELE BY EXCISION OF THE TUNICA VAGINALIS TESTIS.[2]

By W. W. KEEN, M.D.,

PROFESSOR OF SURGERY IN THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA, SURGEON TO ST. MARY'S HOSPITAL, ETC.

A man, æt. sixty-three, was admitted to St. Mary's Hospital, December 17, 1887, with a hydrocele of three years' standing. The tumor was as large as a good-sized orange. For the following notes of the case I am indebted to Dr. J. C. Heisler, surgical interne.

December 20, 1887. An incision was made the whole length of the tumor. The hemorrhage from the scrotum was quite free, but was easily controlled by hemostatic forceps, and eventually no vessel required ligation. The sac was then incised, when its liquid contents at once escaped, and the edges of the sac were seized on each side by hemostatic forceps. By means of the fingers and the closed points

[1] Rosenthal: Deutsche med. Wochenschrift, 1888.

[2] Read before the Philadelphia Academy of Surgery, March 5, 1888.

of a probe-pointed pair of scissors, the tunica vaginalis was then dissected from the surrounding tissues of the scrotum, until its attachment to the cord and testis was reached. The loose tunica vaginalis was then cut off close to the testis and cord, and the wound was accurately closed by five sutures, horsehair drainage being provided. No hemorrhage of importance occurred from the sac or during its dissection.

Strict antiseptic precautions were used (but no spray), carbolic acid 1 : 24 for the instruments, and bichloride of mercury, 1 : 1000, for the hands, sponges, etc. A sublimate gauze dressing was then applied and retained by a broad T-bandage, the abdomino-scrotal portion being triangular in shape, with an aperture for the penis.

At 7 P. M. of the same day, five hours after the operation, the patient's temperature was normal, his pulse was 58, and he was suffering some pain. The temperature rose on the following evening to 100.2° F., which was the highest point attained, and from which it gradually declined, to reach the normal standard on the fifth day after the operation.

The dressings were changed on the first day after the operation, and were nearly saturated and stiff from the oozing of bloody serum.

On the third day, at the second dressing, three of the five sutures were removed, as was also the horsehair used for drainage.

On the seventh day the two remaining sutures were taken out, the dressing discontinued, and the patient allowed to get up with the scrotum in a sling. Beyond the slight pain on the evening after the operation, the patient suffered no inconvenience, except that incident to confinement to bed. He was entirely well on the 31st, but for other reasons did not actually leave the hospital till January 7th.

Remarks.—Until recently various methods of injection, especially by iodine or carbolic acid, have been the chief and almost the only means employed in the treatment of hydrocele. They have the great advantage that but few deaths can be laid to the use of iodine, and none, I believe, to carbolic acid. But they have several disadvantages.

First, that of recurrence. In over eight per cent. of the cases treated by iodine, recurrence takes place, and this misfortune sometimes even occurs a second time. Carbolic acid has been much less widely used, but its promise as to freedom from recurrence is much better than iodine, and if injection be the method chosen, this would seem to be the preferable one.

Secondly. In a large number of cases additional lesions are found besides the hydrocele, lesions which in the majority of cases cannot be cured by any injection. In 123 cases reported by Juillard and Senzmer (The Medical News, May 3, 1884) cysts were found in 43, enlargement of the testicle and epididymis in 23, thickening of the tunica vaginalis in 54, false membranes in 26, and free or attached foreign bodies in 3.

Thirdly. There is generally great pain.

Fourthly. Not seldom severe inflammation and swelling, sometimes suppuration, and occasionally even gangrene of the scrotum occurs.

Fifthly. Even if no such untoward results occur there are great induration, weight, and tenderness in the scrotum, such that the patient is usually laid up for three weeks, and sometimes longer.

Three somewhat different methods of open antiseptic incision have been proposed as substitutes for injection, and especially with a view to a more permanent radical cure. Volkmann incises the sac, and after syringing it out with a three per cent. solution of carbolic acid, unites the edges of the tunica vaginalis to the skin, and, after drainage, dresses the wound with an antiseptic compressing gauze and bandage.

Juillard took a step further. After incision of the sac, and removal of all pathological products by the scissors or spoon from the sac, cord, or testicle, he then resects the superfluous tunic, leaving only enough to cover the cord and testis. The edges of the tunica vaginalis are then sutured with catgut and the external wound closed independently, drainage and antiseptic gauze completing the dressing.

Bergmann (reported by Bramann, *Berlin. klin. Wochenschr.*, April 6, 1885, p. 209) went a step further, and proposed the total extirpation of the free part of the tunica vaginalis, only leaving that portion attached to the cord and testis. Of course, any other concomitant lesions are appropriately treated at the same time. Bramann reports twenty cases, with rapid cure in eleven days, without fever or suppuration. Bull has reported two cases (hydrocele of the cord) thus operated on, one of which had been twice injected with carbolic acid, and the other once with iodine. Both rapidly recovered. Southam (*Lancet*, September 10, 1887) reports four cases, one of which had recurred after carbolic acid injection, cured with an equally speedy and happy result.

To these twenty-six cases I add but one, but it is an excellent illustration of the slight reaction following the operation, and of the quickness of the cure.

It would seem, *first*, to be almost an impossibility that recurrence should take place, for practically none of the sac is left, and in so far it would be *à priori* the ideal radical operation.

Secondly. This method facilitates the proper treatment of any additional lesion above described as not uncommon.

Thirdly. As is usual after antiseptic wounds, there was little or no pain.

Fourthly. As again is the rule in wounds so treated, there was little inflammation, practically no fever, not a drop of pus, and no seeming possibility of gangrene.

Fifthly. There were only moderate induration,

weight, and tenderness, so that the patient was up and about on the seventh day, and was ready for discharge on the eleventh day entirely cured and comfortable.

Sixthly. Although a more radical operation than that of Volkmann, it is less painful and less dangerous. In 254 cases collected by the writer in The Medical News (*supra*) recurrence is noted in three, and two died of septicæmia and pyæmia, while abscess, sloughing, and orchitis have all occurred. Induration, weight, and tenderness have persisted from three to four weeks. The conditions after resection of the entire tunica vaginalis and immediate closure of the wound, with drainage, and antiseptic dressing are such as to favor the speediest and safest recovery, without any of the dangers above noted as following antiseptic incision.

The case is also a good illustration of "the conditions conducive to the *earliest possible* healing of operation wounds," to which I have called attention in a paper with the above title, read before the Surgical Section of the New York Academy of Medicine (*Medical Record*, January 28. 1888), especially the method of drainage by horsehair instead of rubber, glass, or bone tubing, as is suited best to so small a wound, and the change of dressing on the day after the operation, recovery being complete in seven days.

SALICYLATE OF SODA IN POLYURIA.

By J. N. RANDALL, M.D.,
of Decatur, Illinois.

On June 23, 1887, Mrs. L. brought to my office her daughter, aged eleven years. The child was of large frame for her years, but pale and flabby, and though the weather was warm she complained much of cold hands and feet. The mother informed me that the child was voiding too much urine. They were requested to return after a lapse of twenty-four hours, during which the mother was to determine accurately the measure of the urine. This was found to be nine and a half pints (milk measure). Urine was found to contain no sugar. Fluid extract of valerian in half drachm doses three times daily was given for ten days to no purpose. Thirst during this time was insatiable. The child was directed at the first visit to quit her attempts to learn music, to do as little work or play as possible.

Ergot and tannic acid were given next for ten days; the former in half drachm doses three times daily, and five grains of the latter, to be given alternately. They did no good.

It was now near the middle of July; the thirst was difficult to appease, the quantity of urine was as great as before, and the child was weaker and further reduced in weight to seventy-nine pounds. The urine was found, as before, to be free from glucose.

She was now given eight grains of salicylate of soda in aqueous solution after each meal; her meals were small. In ten days there was an appreciable amendment; she had more solicitude about her food; she felt stronger. The treatment from this time forward, consisted of nothing else than the salicylate of soda; the dose of eight grains was increased to ten, but so much complaint of headache was excited that I was obliged to suspend dosing for a few days. No restriction was imposed upon the choice of food.

The amount of urine diminished slowly but steadily until, in November, the daily discharge was two and a half pints. In the meantime her color returned, there was no longer complaint of lassitude and of inability to breathe easily. Her weight was increased to eighty-seven pounds. She was sent to school, and has manifested no illness of any sort since. The remedy was discontinued early in December.

I am aware that little importance is to be attached to a single result of this sort, and regret that further opportunity has not been mine to test the efficacy of this remedy; but cases of polydipsia are not of common occurrence, and, rather than wait until time shall bring to me chances to test the value of this remedy, I submit this report for what it is worth. I regret that I am unable to state the duration of this affection prior to my first acquaintance with the case. The mother was aware that the child had been obliged for weeks to rise repeatedly during the night to void her urine, but was astonished at its volume when she measured it. It is scarcely necessary to add that the mother's attention had been excited by the consuming thirst for weeks before she took any measures for its relief, or before she deemed any explanation necessary.

NOTES ON THE PAST AND PRESENT MORTALITY AND TREATMENT OF PNEUMONIA.[1]

By HENRY HARTSHORNE, M.D.,
of Philadelphia.

Observation and experience, beginning more than forty years ago, along with such attention as has been within my power to current medical literature, have made me acquainted with a process of transition going on in medical practice, especially in regard to the treatment of acute inflammatory affections, of which pneumonia may be considered as a type. Between 1845 and 1855, the accepted treatment of pneumonia was what was then called moderately antiphlogistic; including early and moderate abstraction of blood in patients of good strength and not over middle age, early purgation with some active cathartic medicine, and then the use of agents, chiefly mineral salts, to promote and maintain the action of the skin, kidneys, and bowels; very little use of opium being made, unless at a late stage, and quinine being reserved for that period as a tonic; alcoholic stimulation being resorted to only in cases of exceptional prostration, as in aged patients, or in

[1] Abstract of a paper read before the College of Physicians of Philadelphia, February 1, 1888.

those of enfeebled constitution, or when a severe and prolonged attack brought on decided exhaustion.

Under this treatment, in private practice, patients with uncomplicated pneumonia and pleuro-pneumonia very generally recovered; and in hospitals their mortality was hardly more than one death in ten cases; often considerably less than in that proportion. In Suffolk Hospital, England, in 1835, it was only one death in fifty cases.

Between 1855 and 1860 a movement of reaction went on against bloodletting, in which Dr. J. Hughes Bennett was one of the most conspicuous leaders. This was shortly followed, in part, indeed, accompanied, by the introduction, under the leadership of Dr. R. Bentley Todd, of the early and free use of alcohol in pneumonia and other acute inflammatory diseases. Next came the era which still continues, of physiological rationalism in therapeutics; characterized by a general abandonment of previously approved principles and methods, and the substitution for them of the use of potent agents upon special indications in regard to functional actions and conditions, these agents being first tried in the laboratory upon animals, either in a state of health or in various conditions of traumatism. Prominent among the agencies thus lately much used in practice are those designed, as "apyretics," directly to lower the temperature of the body when it is abnormally elevated in disease.

The "working theories" of practice in acute inflammatory diseases have thus, with very little appearance of distinct formulation, undergone a gradual, but very positive change. To-day the predominant method of treatment of pneumonia may be said to be characterized by the following features: 1, the practically universal omission of venesection, and the very rare local abstraction of blood; 2, the general disuse of active cathartic medicines in the early stage; 3, by many, perhaps a majority of physicians, the early and continued use of alcohol, to the extent of from 2 to 12 or more fluidounces in 24 hours; quinine, mostly in 10 or 20 grain doses, once or twice daily; opium, or morphia, from the start or near it, averaging perhaps sulphate of morphia gr. $\frac{1}{12}$ to gr. $\frac{1}{8}$, every 3 or 4 hours: with deviations from this general plan, or additions to it, by the use of antipyrin, antifebrin, aconite, digitalis, etc.; and warm applications, as poultices, or cotton batting to the chest, or counter-irritation with turpentine, etc. These last may be said to be common to the old and the new methods of treatment.

For definite information sustaining this account of now predominant practice, I refer to Hospital Notes, published last year, of hospitals in New York, Boston, and Philadelphia; also, memoranda furnished me during last year by a resident physician in one of our largest and best hospitals; and the *dicta* concerning treatment, of Dr. A. L. Loomis, in his article on "Croupous Pneumonia," in vol. iii. of the *American System of Practical Medicine*.

It is entirely legitimate to apply to these old and new, different, and in some respects opposed, methods of practice, careful *reasoning* as to the principles upon which they are based. Considerable attention is given to this kind of comparison in the paper of which this is an abstract. Yet it is also appropriate, and is more nearly decisive in importance, to bring to bear upon them the testimony of *facts* concerning the *results* of the different modes of treatment which are compared. It is true that an absolute demonstration of therapeutical conclusions by means of statistics is not often practicable. My opinions on this subject have not been founded upon statistics, but upon direct personal experience. But, when evidence of that kind, of a marked character and considerable in amount, can be adduced, it is manifestly worthy of careful attention, even when the conclusions to which it points are different from those which, in practice if not in theory, are in vogue, and which are approved by highly respected authorities, at the present time. Such evidence it is the principal purpose of my paper to bring forward, and to apply to the question, how we ought to treat acute, uncomplicated pneumonia, in patients of ordinarily good constitution, not over middle age.

From sources and authorities which will be admitted to be reliable, and which are referred to in full in the paper of which this is an abstract, I have obtained and analyzed statistics, of which I will now give a summary account. I will say that, throughout my analysis of these statistics, I have made liberal allowance in favor of that construction of the facts which is most opposed to the conclusion which my judgment approves. On behalf of the latter, a much stronger case might be made out, if my aim were anything other than the actual truth.

First, a comparison is made of the results of different modes of treatment of pneumonia, within a few years prior to 1858, reported by between forty and fifty physicians, of 11,627 cases in Great Britain and Ireland and on the continent of Europe. Of these, 2751 cases were treated with bleeding, and 8876 without it. Among the latter, however, 452 cases had exceptional modes of medication in the use of chloroform, lead, copper, or iron. Deducting these, the comparison rests between 2751 cases treated with, and 8424 cases without bleeding. The figures, in summary, are these:

With bleeding, either often, a few times, or once, with or without tartar emetic, altogether, 1 death in 11.1 cases.

Without bleeding, under all treatments except with opium—except, also, with chloroform, copper, or iron, as before said—1 death in 9.7 cases.

Large and repeated bleedings, alone, 1 death in 11.6 cases.

Bleeding a few times, or moderately, alone, 1 death in 12.3 cases.

Bleeding and tartar emetic, 1 death in 12.56 cases.

Tartar emetic, no bleeding, no opium, 1 death in 11.3 cases.

Opium, without bleeding, 1 death in 3.3 cases.

Tartar emetic and opium, without bleeding, 1 death in 3.8 cases. I would call attention especially to these last figures, for the greatest mortality obtained under any method was that under the opium treatment of pneumonia.

Next, I present a comparison of mortality from pneumonia in the United States Army, at two periods: one before the anti-bloodletting movement had fairly set in, and the other, when it had begun to make a decided impression upon general practice. Between 1840 and 1854 there were, in the United States Army, 1416 cases of pneumonia, with 127 deaths—1 in 11.15: between 1855 and 1859, 657 cases, with 97 deaths—1 in 6.67: an increase of more than one-third in the proportion of deaths.

The testimony of Dr. George B. Wood, in the first edition of his *Practice*, published in 1847, was decided as to the favorable prognosis of uncomplicated pneumonia, especially in early life. Dr. Lewis P. Gebhard, of Philadelphia, whose practice began near the beginning of this century, and was extensive for many years, told me, near the end of his life, that he had never lost a case of simple pneumonia.

Examining the records of the Pennsylvania Hospital, as a representative institution, with a medical staff excelled by none in reputation and ability, I have found the results to be as follows: in the three years, 1845, '46, and '47, from pneumonia and pleuro-pneumonia, 1 death in 16 cases—6¼ per cent.; in the years 1865, '66, and '67, 1 in $5\frac{4}{10}$th, or 18½ per cent.; in 1884, '85, and '86, 1 in 3.2, or more than 31 per cent. To make sure the avoidance of the error of confounding cases of acute tuberculosis with pneumonia, in this comparison, I invariably took only those fatal cases in which the diagnosis of pneumonia was entered at the time of the *death* of the patient. In collating some other statistics of the same hospital, which were cited in the discussion upon my paper in the Philadelphia College of Physicians, I believe this precaution was not taken; and hence a greater mortality was inferred, throughout the time investigated.

Dr. A. L. Loomis, in his article on "Croupous Pneumonia" in the *American System of Practical Medicine*, states that the average ratio of deaths from pneumonia to those from all diseases together, in New York, was 15.2 per cent. greater between 1859 and 1877 than between 1840 and 1858.

Other figures are given more fully, with references to their authorities, in my paper. The figures may be altogether summarized thus: first, all prior to, or not later than, 1858:

Skoda estimated the average mortality of pneumonia, about 1841, as 1 death in 8 cases. Balfour, near the same time, reported his observation in a homœopathic hospital under Fleischmann (treatment probably *nil*), of a mortality of 1 death in 6⅓ cases; Dietl, with diet only, no bleeding nor medication, 1 death in 13.5 cases; in the British army, at home and in various stations, average of all together, 1 death in 20.66 cases; hospitals in a number of different cities in Europe, from 1822 to 1856, average 1 in 9 54: United States Army, as already said, from 1840 to 1854, 1 in 11.15; Pennsylvania Hospital, as before mentioned, 1845, '46, '47, 1 in 16. Taking all these together, it is safe and fair to estimate the average mortality of pneumonia, during the second quarter of this century, as not more than 1 death in 12 cases, or 8.33 per cent.

Coming now to the recent and present mortality of the same disease, we find it editorially stated in The Medical News of December 11, 1886, that "the rate of mortality" of pneumonia "in the large general hospitals in this country is rarely below, more often above, 25 per cent., which represents about the average death-rate from this disease in the Northern and Southern armies during the Civil War." It is added, that "in this country extensive statistics of pneumonia in private practice are not available; but in the recent returns of the Collective Investigation Committee of the British Medical Association, the mortality was 18 per cent." This last ratio, it will be perceived, is considerably more than double the carefully computed mortality of pneumonia before 1858, namely, 8.33 per cent. We have thus, I think, a *demonstration* of the large increase in the proportion of deaths from that disease in recent times, over what it was thirty, forty, and fifty years ago.

How is this increase of mortality to be accounted for? Three hypotheses are conceivable.

1. The records may be supposed to have undergone modification through improved methods of diagnosis. There is no ground for this supposition. The physical signs, as well as the symptomatology, of pneumonia, were well understood forty and more years ago, by those physicians whose reports have furnished materials for the statistics which have been cited. The use of percussion, in aid of diagnosis, dates with Auenbrugger, 1761: auscultation began with Laennec, about 1818.

2. "Change of type" of the disease may be asserted; or a general change in the constitutions of men, affecting the character of all diseases. Reasons are given in my paper for believing that neither of these hypothetical assumptions has such support in facts as at all to meet the requirements of the case. While, at all periods, it may be sometimes sthenic and sometimes asthenic or typhoid, pneumonia is practically the same disease that it was forty or fifty years ago.

Lastly, therefore, we are brought to dwell upon the coincidence between this great increase in the mortality of pneumonia and a marked change in prevailing methods of treatment.

What has brought this change of treatment about? Is it a better knowledge of the pathology of pneumonia? No. Autopsic and microscopic investigations have cleared up certain minutiæ, as to the distinction, for example, between croupous and catarrhal pneumonia. But we still have, as ever, the first stage, of congestion; and, the second, of red hepatization of the lung; in other words, primary *stasis*, with interrupted nutrition, at the focus of inflammation; concentric hyperæmia there, and general vascular excitement of the system; then exudation, whose changes chiefly determine the result, as least so far as the lung is concerned. The increased vascular tension following a local obstruction to the circulation, gave the indication for measures of relief in the older practice; and that *indication* still remains, in the presence of the most advanced researches as to either the crass or the minute morbid anatomy of pneumonia.

Attention is given in my paper, at length, to the opinion now entertained by some pathologists, that pneumonia is a systemic fever, with lung changes as merely its local manifestations; especially in connection with the theory of the microbic causation of the disorder. Jaccoud, in France, and Dr. H. B. Baker, in Michigan, are cited as having not long since[1] given *demonstrative* evidence that the essential, necessary cause of pneumonia *cannot* be microbic; dry cold having the most to do with its production, in at least much the larger number of cases; while the bacilli and micrococci often found present may, no doubt, exercise a morbific action, affecting the character of the disease. If, however, it were even proven that pneumonia depends upon microbes for its causation, that would not decide the question of its treatment, while we are not in possession of direct and certain microbicidal measures of therapeutics.

By all these considerations we are led at last to the conclusion, that the change in practice that has been referred to, has no other origin than a fluctuation of opinion, not justified by facts or reasoning, concerning certain principles in therapeutics. This fluctuation involves:

1. A depreciation of the value of the early abstraction of a moderate amount of blood, locally or by venesection, for the relief of active inflammation, in persons of good previous health, and not advanced in age.

2. A like depreciation of the utility of early catharsis, especially as an eliminative agency, to prevent the accumulation in the system of the products of regressive metamorphosis of the tissues.

3. The same want exists of due valuation of salines, formerly called refrigerant medicines, for lowering blood-pressure and promoting the functional activity of the skin and kidneys, as well as the bowels.

4. An erroneous, exaggerated estimate prevails of the beneficial influence of large doses of quinine, employed for the reduction of temperature. Testimony is accumulating as to the failure of the use of quinine in antipyretic doses in the treatment of pneumonia. Drs. Bartholow and Osler, in Philadelphia; Drs. Kinnicutt, Ripley, Putnam Jacobi, Castle, Billington, and Emmett Holt, in New York; and Drs. Shattuck and Minot, of Boston, are among those who dissent from the now common approval of this point of practice.

5. An especially injurious error consists in the administration of opium and morphia at an early stage of pulmonary inflammation. The tendency of opiates to *diminish bronchial secretion* stands right in the way of their utility in pneumonia. I may here recall the statistical fact, mentioned a little while ago, that in the reports of results of different modes of treatment before 1858, the worst record of all was attached to the opium treatment of pneumonia.

6. An experimental administration is now being carried on of antipyrin, antifebrin, etc., as antipyretics, whose results do not correspond with what is desired of them as remedies for acute organic inflammation. They have another rôle, as neurotic medicines, in which they possess much value. I may remark incidentally, as an example, that in Dr. Pepper's interesting case, reported in the *Medical and Surgical Reporter* early in last year, it appears to me probable that it was the *neurotic* element in the case—the strongly marked tendency to convulsions—that received benefit from the antipyrin used rather than the pneumonia itself.

7. The practical ignoring must be noticed, in recent therapeutics, of the important difference between the debility of *oppression* in the early period of severe attacks of acute disease, and the *exhaustion* which belongs to a later stage of the same, or which is produced by other causes and conditions. The *treatment* of these two states, as was long ago recognized, is properly quite different.

8. Connected with this, the early and free use of alcohol is now common. In my judgment, except in previously enfeebled patients or those otherwise exceptionally prostrate, this is an injurious medication in pneumonia. Heart-failure during the early stage, in patients of previously good health, may be best averted by so lightening the burden of oppression imposed upon the heart, as to make it possible for it to carry its load without exhaustion. It is under a prevailing so-called "supporting" treatment that

[1] Jaccoud's paper was communicated to the Académie des Sciences, and was reported May 7, 1887, in La France Médicale. Dr. Baker's investigations have been made public in several places within a year or two.

not a few men in the prime of life have, within a few years, dropped off under less than a week's illness with pneumonia.

The relief often afforded by bleeding, without consequent exhaustion, even at a somewhat late stage, to the condition characterized by distention of the right heart (this being a practice approved even by many physicians who are otherwise opposed to bloodletting) should be remembered and set over against the excessive fear entertained by some of the production of debility by early bleeding.

I conclude, then, that there is reason for the judgment that the now current "working theory" of the treatment of pneumonia and allied affections, by early and continued stimulation and narcotism, is not supported by the facts concerning the results of that treatment, as compared with those of the *moderate, early*, sedative and eliminative practice of forty and fifty years ago.

I do not assert that venesection is called for in nearly all cases; but I believe that early local depletion will do good in the majority, in patients not old, and who were previously in good health; and that early active catharsis, with diaphoretics and diuretics afterward, are rightly in place: quinine as a tonic, and alcohol as a stimulant, being indicated only exceptionally at the beginning, in persons of low vitality or bad habits, or old age; more often, when real exhaustion is imminent, at a late stage.

There is more room for question, on the basis of experience, between the older practice and pure expectancy, nursing the patient in bed without medication, than there is between the therapeutic methods now current, in regard to acute inflammatory affections, and those of the early part of this century. We want no return to any Sangrado extreme; but only to replace in their position of confidence, lost for a time, some of those measures of practice which have been abundantly tested and commended by the experience of ages.

MEDICAL PROGRESS.

The Pulse in Children.—Jacobi, in the *Brooklyn Medical Journal* for March, 1888, writes as follows on this point:

The pulse of the infant and child offers a great many differences from that of the adult, both in frequency and volume. As already stated, the pulse of the fœtus varies from 124 to 144 or 150 or more. Immediately after birth it is very much less frequent. Within an hour it assumes a certain regularity, and still the figures furnished by a large number of competent authors appear to prove the greatest difficulties in obtaining uniform results. From what I have observed, J. L. Smith is correct in fixing the number of heart-beats in a minute at 126, his lowest figure being 96, his highest 164. According to some, the average figure rises during the second half of the first month, and then proceeds slowly to decrease. From the first to the sixth month the pulse is 120 during sleep, 130 to 135 while awake. It is 100 at six years, 88 at thirteen, 72 in the adult. Tall children exhibit less frequency than short ones; girls, after the fifth year, and more so about puberty, more than boys. The pulse is more rapid in the infant while awake, sitting up, or standing, than while asleep or lying down; more in excitement, exercise, or fever. Thus it is difficult to arrive at a safe estimation of the frequency of the pulse in cases of sickness. In the radial artery it is sometimes impossible to obtain it; the femoral or carotid is often more accessible, the basilar, through the open fontanelle, very much more so. When frequency alone is the object of examination, it is always better not to touch the baby at all. The beats of the fontanelle or the carotid can be distinguished and counted easily, up to a frequency of 240 a minute. But it is not always, or not only the frequency we wish to notice, but the character of the pulse. In the latter respect the young have their peculiarities. The expansion of the artery is very much more perceptible and prolonged than the contraction, and the rhythm is by no means stationary. The pulse is very apt to be irregular, even during the regular respiration of sleep. The slightest deviation from the normal standard of health renders it slightly but perceptibly irregular; anæmia does the same, and either increases or diminishes its frequency. When the latter takes place, the differential diagnosis between anæmia and incipient meningitis, with its pneumogastric irritation, becomes quite difficult.

Quinine Hypodermatically.—De Brurmann and Villejean, in an extended article in the *Bulletin Général de Thérapeutique* of March 15, 1888, report the following formulæ for solutions suitable for the hypodermatic exhibition of quinine.

An aqueous solution:

Quiniæ hydrochlorat.	gr. 15.
Aquæ destillat.	ʒ 3½.
Aquæ lauro-cerasi	ʒ 1.

Dissolve out at gentle heat and filter.

An alcoholic solution:

Quiniæ hydrochlorat.	gr. 15.
Alcohol (60°)	♏ 45.
Aquæ destill.	♏ 90.

A solution in glycerine:

Quiniæ hydrochlorat.	gr. 30.
Aquæ destillat.	ʒ 1.
Glycerin.	ʒ 1.

Dissolve perfectly by warmth.

The Effect of Antipyrin upon the Kidneys.—The *Medical Press* states that at the Société de Thérapeutique M. Huchard recently resumed the discussion on certain indications and counter-indications of antipyrin. If the drug gives incontestable satisfaction in many cases, there are others where it should be employed with precaution, and even rejected entirely. In facial neuralgia, migraine, sciatica, etc., antipyrin is generally very valuable, but it has been proved by recent researches that the quantity of urine is notably diminished under its administration, consequently its counter-indication is evident in certain maladies of the kidneys, and in those affections in which some renal mischief is observed as a concomitant symptom. Again, if in the neuralgic form of

angina pectoris observed in nervous and hysterical persons antipyrin eases the pain, it would be dangerous, on the contrary, to give it in true angina with stenosis of the coronary arteries, collapse of the heart might be the result. However, there is one affection which seems to be greatly benefited by the treatment with antipyrin, and that is polyuria. He had actually under observation a woman who was suffering from meningo-myelitis consecutive to an attack of typhoid fever. This woman drank very large quantities of liquid, so that the urine passed in twenty-four hours exceeded twenty quarts! Antipyrin was given in progressive doses up to two drachms in the twenty-four hours, and the result was a rapid decrease in the amount of urine, until three quarts daily were reached. If he had been so fortunate in this case, M. Huchard said that he had no doubt that his success depended on the fact that his patient was of a very nervous and excitable temperament, with exaggerated reflexes and shooting pains down the vertebral column and along the limbs. The kidneys were in no wise affected.

Dermoid Cyst of the Mediastinum.—At a recent meeting of the Berlin Medical Society, DR. LOEWENMEYER brought forward a tumor of this kind, rather larger than a child's head. It was removed from the body of a man who had been shown to the Society four years previously, his symptoms being then difficult to interpret. Apart from hæmoptysis and a moderate degree of pleuritic effusion on the left side, the attention was chiefly drawn at that time to a projection of the left side of the thorax, with loss of resonance, reaching from the clavicle to the sixth rib. The apex beat could not be felt over the cardiac region, but a thrill was noticed to the right of the sternum, also epigastric pulsation. A precise diagnosis was not made. The patient improved somewhat in hospital, and then went out and worked for a few years regularly, but no symptoms of pressure came on till quite recently, when severe recurring attacks of dyspnœa and cyanosis quickly induced a fatal result. The necropsy revealed a tumor occupying the greater part of the left half of the thorax. Anteriorly it was in contact with the chest wall, having pushed the heart entirely over to the right. Prof. Virchow had examined the tumor, which contained in its interior cysts lined with epithelium and filled with soft substance of gelatinous consistency, but the outer and firmer portion of the tumor was composed of dermoid products, namely, epidermis, hair, fat. Cartilaginous plates were also found. Evidently there had existed abnormality of the chest wall in the embryonal stage of existence of the patient, so that part of the integument had been displaced inward, and part of the respiratory apparatus outward, at the time of closure of the thorax.—*British Medical Journal*, March 17, 1888.

Diabetic Foods.—HARRINGTON, of the Harvard Medical School, publishes in the *Boston Medical and Surgical Journal* of March 22, 1888, the following conclusions, based on an examination of the diabetic foods most commonly sold:

Comparing the estimated figures with the amounts of starch in the two ordinary breads, it is observed that the difference is but slightly in favor of the diabetic breads, whereas, according to the claims made by the manufacturers and retailers, the difference should be overwhelming. But the item of palatability is something to be considered, and the slight difference in the percentage of starch might well be waived in favor of the great difference in taste.

There is another and more serious side to this question of diabetic foods. That they are in the highest degree fraudulent has, I consider, been proved. They are in addition a positive danger, for the diabetic accepting as truth the assertions that they are non-starchy, takes into his system that which even the circulars of the manufacturers admit to be virtually a poison in its effect on the course of the disease, and thus innocently more than counteracts the benefit which he otherwise would derive from his medical adviser. In conclusion, I have to express the hope that every practitioner will do his utmost to discourage the use of these fraudulent and dangerous foods, and to drive them out of the market.

A Pill for Incontinence of Urine.—GRISOLLE prescribes the following:

R.—Ext. nucis vom.	. . . .	gr. 3.
Ferri oxid.	. . . .	gr. 45.
Quassiæ pulv.	. . . .	gr. 45.
Syrup. simpl.	. . . .	q. s.—M.

Ft. pil. 20 in num.

Sig. 1 to 3 pills daily.—*Les Nouveaux Remèdes*, March 8, 1888.

The Treatment of Fissures of the Nipple.—MONTI advises the use of gutta-percha, chloroform, q. s., to dissolve. Excoriations should be covered by a pellicle of the dissolved gutta-percha, which is not removed by nursing.—*Les Nouveaux Remèdes*, No. 4, 1888.

The Practical Use of Haya to Produce Anæsthesia.—The *Medical Press* of March 14, 1888, writes that at a meeting of the Berlin Medical Society KAREWSKI gave an address on the subject. The preparation employed was obtained from Merk, of Darmstadt. Complete anæsthesia was never obtained, but its action was much heightened by the local production of anæmia. Its action was not uniform in all cases. Subcutaneous injection of at least $\frac{1}{25}$ of a grain was necessary to produce analgesia. The analgesic effect of plugging the nares with 0.5 per cent. solution took place after eighteen minutes. It did not act over an area of more than a half an inch above and below the point of injection. The analgesia thus set up sometimes lasted several hours, the length of time being dependent on the size of the dose. The bye effects were very disagreeable, amongst them being violent pain at the point of insertion, coming on in a few minutes afterward, and becoming intolerable and lasting for several days. The results were not encouraging, but in a number of cases of neuralgia some favorable ones were obtained. Two cases of lumbago, one of brachial neuralgia, one of intercostal neuralgia, and one of sciatica, were treated by parenchymatous injections varying from $\frac{1}{150}$ to $\frac{1}{7}$ of a grain. Great pain was produced which lasted for an hour and a half, after which it subsided, and with it the original pain, the latter remaining away twenty-four or more hours, and in some cases permanently.

The Initial Angina of Typhoid Fever.—CADET DE GASSICOURT, in *L'Union Médicale* of March 15, 1888, reports three cases of angina, in whom the quinsy was the first

symptom of typhoid fever. Two of the cases were in children, both were of moderate severity, and terminated in moderately severe typhoid fever; both patients recovered. The third case was a boy, twelve or thirteen years of age, vigorous, and, when first seen, in violent delirium. The pulse was rapid; the skin hot; the submaxillary glands swollen, and the tonsils and soft palate covered with a whitish yellow exudate. While the diagnosis of diphtheria was doubtful, symptoms of typhoid developed, and the patient died on the twenty-fifth day.

The difficulties of diagnosis, especially when the history is unattainable, are very great.

Displacement of the Testicle.—At a recent meeting of the St. Petersburg Society of Russian Practitioners, Prof. Vladimer N. Popoff showed (*Vratch*, No. 4, 1888, p. 75) a unique case of ectopia of the testicle in a patient aged twenty-four. The scrotum was found to be normally developed, with the right testicle in its usual situation; but the left half of the scrotum was empty, while exactly at the root of the penis there was a swelling of the size of a walnut, covered with normal skin, and containing an oval body which measured about four-fifths of the normal testicle, but felt somewhat softer. The patient said the swelling had been there since birth. He had, however, suffered in early childhood from an inguinal hernia, and Prof. Popoff thinks it more likely that the displacement of the testicle developed under the influence of the rupture. The man's sexual power was formerly quite normal, but for about six months he had been impotent. Dr. Popoff could find no similar case in medical literature. Prof. Wenzeslaw L. Gruber, the great Russian anatomist, who takes special interest in anomalies, considered the case unique.—*British Medical Journal*, March 17, 1888.

Ergotin Hypodermatically, for Hemorrhage.—Montard-Martin prescribes the following solution:

Ergotin	gr. 30.
Glycerin.	ʒ 3¾.
Aquæ	ʒ 3¾.

Of this solution from 15 to 25 minims may be injected. —*Les Nouveaux Remèdes*, March 8, 1888.

When should Antipyrin be Given?—The *Medical Press*, of March 14, 1888, furnishes timely information on this point, as follows:

Antipyrin should be administered with or immediately after a meal, otherwise pain, nausea, and discomfort, may result from its contact with the walls of the stomach. The cutaneous manifestations which sometimes follow its ingestion are probably due to vaso-motor disturbances characterized by peripheral dilatation of the arterioles. In certain cases the rash has simulated that of scarlatina, with intense itching. There is every reason to suspect that in consequence of the present great demand for the drug, due care may not be employed in its manufacture, and it is suggested that an analysis should be ordered whenever toxic symptoms are observed. Dr. Dujardin-Beaumetz claims to have detected a mixture of benzine in certain samples, the presence of which would explain many untoward effects. It should be borne in mind, especially by the public, that we have in antipyrin a useful but potent agent, the use of which in unskilled hands may and will in a certain proportion of cases give rise to severe and even fatal symptoms. Manufacturers would also do well to look a little more closely to the purity of the drug, otherwise it may fall into discredit.

***Calycanthus glaucus* (*Carolina Allspice*).**—Eccles writes, in the *Brooklyn Medical Journal* for March, 1888, that the shrub within whose seeds he discovered the alkaloid, was during the late civil war used in decoction of roots, leaves, and bark by the Confederate soldiers for the cure of intermittent fever, and, as claimed, with success. It is still used in domestic practice by the natives of the region where it grows. A fluid extract of an allied species is already upon the market, so that somewhere in the country it is being prescribed for some purpose. If in its crude form it has proven of advantage, this new concentrated form should be still more efficient. The seeds contain nearly two per cent. of this alkaloid, and a smaller amount of probably two others. The odor of the volatile one of these last is distinctly that of pyridine, an alkaloid of tobacco, and as it is unlikely that two should exist having the same smell, we may at present assume it as probably such.

Antifebrin in Epilepsy.—Borosnyoi is quoted by the *Centralblatt für die gesammte Therapie* for March, 1888, in his report of the results obtained by using antifebrin in the treatment of epilepsy. He treated nine epileptics with the remedy in doses ranging from three and a half to thirty grains. It was found necessary to intermit the treatment by pauses. His conclusions are that antifebrin is inferior to the bromides in the treatment of epilepsy; cases of collapse and cyanosis were observed during the treatment. Large doses of antifebrin control epileptic paroxysms, but are too depressing to be continued.

Sulphurous Inhalations for Phthisis.—A series of observations has recently been made on a method of treating pulmonary tuberculosis, which, if not curative, would appear to possess a beneficial power over the progress of this dread malady. The method consists in the systematic inhalation of an atmosphere impregnated with the fumes of sulphurous anhydride (SO_2); and several ingenious plans of obtaining a constant supply of the gas have been devised, the best of which is a lamp constructed to burn bisulphide of carbon. The simple plan of burning flowers of sulphur in a closed room can, however, be resorted to if desired. Under its influence, it is said, the expectoration becomes more liquid, the mucous surfaces are relieved from the irritation caused by the presence of muco-purulent secretions, and the patient is spared the fatigue of violent paroxysms of cough. In a certain number of favorable cases the improvement in the general health which follows, is reported to be sufficient to allow of the cicatrization of cavities, and the subsidence of the more disquieting symptoms. The irritating effects of the vapor may be mitigated to some extent by burning opium and gum benzoin at the same time. Some two hundred observations have already been recorded, and the results have been sufficiently good to warrrant a more general trial. Caution is advisable in the quantity of the gas, which should not exceed a certain proportion, which must be ascertained by close supervision of the patient during its administration.—*British Medical Journal*, March 17, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, APRIL 7, 1888.

THE RELATION OF THE ACIDITY OF THE GASTRIC JUICE TO THE DIAGNOSIS AND TREATMENT OF DISORDERS OF THE STOMACH.

DIFFERENT opinions concerning the nature of the acid to which the gastric juice owes its reaction have prevailed since the days of Blondlot and Bernard. Variously regarded at different periods by men of the highest attainments in chemistry and physiology, as phosphoric, sarcolactic, lactic, and hydrochloric, the discussion is now limited to the two last named substances; and, with reference to these, the latest researches have proved that either may be present alone, or both in combination. During the first half hour of normal digestion, lactic acid is found alone; then follows a stage in which it is in company with hydrochloric; finally comes a period—the longest and most active—in which the latter is the only acid present.

To determine the digestive power of the stomach, its secretion should not be removed for examination until at least three-quarters of an hour after the ingestion of food—that is, during what has been called the hydrochloric acid stage. The object of the examination is to determine, first, the presence or absence of hydrochloric acid; secondly, its amount. The tests employed for this purpose are too numerous to describe at length here. As in examining urine for sugar or albumin, so here each observer comes to rely upon that method with which he has had the greatest experience. The latest test for hydrochloric acid in the gastric secretion is the phloroglucin-vanillin test devised by Günzburg, of Frankfort, of which a full description was given in THE NEWS of January 14, 1888. Concerning this test, Ewald declares that it is the best and most exact of any yet employed, and there is little doubt that with this, and the well-known methyl-violet test, the investigator will be fully equipped.

The practical results that have thus far been derived from these clinical applications of chemistry are interesting and valuable. The first examinations of the contents of the stomach led to the belief that hydrochloric acid was invariably absent in cancer of that organ, and this supposed fact was eagerly welcomed as a sure means of determining or excluding carcinoma. From a careful study of five cases, in which he made 154 examinations of the gastric juice, Riegel concluded that, as a rule, the gastric juice of a cancerous stomach contains no hydrochloric acid, and is devoid of digestive power, and that, on the other hand, when these are present in a specimen, cancer may be excluded in spite of the most positive symptoms of that disease. The case, however, is not so simple, for free hydrochloric acid is not only absent in other non-cancerous forms of dyspepsia, but has been found in several undoubted cases of carcinoma, in one of which (referred to by Petit, *Gazette Hebdomadaire*, February 10, 17, and 24, 1888) it persisted until death. Seé, who has recently studied this question with the aid of Günzburg's test, concludes that the diseases which reduce the hydrochloric acid to a minimum are cancer of the stomach, with or without dilatation; atrophy, and amyloid degeneration of the mucosa; and certain forms of dyspepsia known as mucous, which result from inanition and marasmus. These are, unfortunately, just the conditions that are most apt to simulate cancer, so that the conviction is forced upon us that too great a significance has been attached to the absence of hydrochloric acid in carcinoma of the stomach. It is still, however, justly regarded as a valuable corroborative symptom in latent forms of that disease.

The opposite condition of hypersecretion is a well-recognized morbid entity, and has been already discussed at some length in THE MEDICAL NEWS of October 1, 1887. Physiologists have established the fact that pepsin displays its greatest digestive power in gastric juice containing a certain proportion of hydrochloric acid, about 2 per 1000. When the acid exceeds or falls below this amount, the digestive power of the secretion is impaired, and, apparently,

in equal degree: that is to say, in a neutral, as well as in an excessively acid secretion, digestive power is entirely absent.

Hyperacidity has been frequently observed in pregnant women with repeated vomiting, in diabetes, in certain cases of dilatation of the stomach, and in chlorotic girls. Its presence in the latter class is quite significant, for hyperacidity is known to predispose to gastric ulcer, which had been observed to be common in cases of chlorosis before the state of the gastric secretion in that disease had been investigated.

The practical question with reference to the chemical examination of the stomach contents is whether it has added to our therapeutic resources. This question may be positively answered in the affirmative. Acids and alkalies formerly administered almost at random, may now be prescribed with mathematical certainty. It has been proved by these researches, for example, that dilute hydrochloric acid which has been fitfully prescribed in typhoid fever, meets a real indication; for in febrile conditions this acid is much diminished. In cancer of the stomach the indications for its administration would seem to be equally prominent. Opinions, however, are divided as to its efficacy. Sée considers it absolutely useless in this disease, since the gastric juice is devoid of pepsin as well as of acid. On the other hand, Petit mentions having seen a case of gastric cancer in which all the digestive troubles disappeared after the administration of hydrochloric acid, with consequent improvement in the general nutrition.

The condition of hyperacidity furnishes more decided indications for treatment. The condition once recognized, the exhibition of alkalies follows, as a matter of course, but does not, as a matter of course, succeed. Failure often depends upon the administration of too small a dose. If not, it should be generally known that small doses of an alkali will actually increase the acidity of the gastric juice, and will, therefore, in cases of hyperacidity act the part of fuel to a fire. On the other hand, large doses not only always relieve the immediate symptoms, but will often exert a permanent curative effect.

CONTRAINDICATIONS AND DANGERS OF ANTIPYRIN.

Of the numerous recent additions to our materia medica, antipyrin appears to have come into most general use, and to have a very wide range of usefulness. But its administration appears, upon further study, to be not without contraindications and dangers. Eloy, in the *Revue Générale de Clinique et de Thérapeutique* of March 1, 1888, points out that a large number of ailments are frequently produced by it, particularly if given for any length of time.

He quotes Guttmann, Falkenheim, Alexander, and others, in support of his statement that nausea, vomiting, and gastro-intestinal disorders may result from its use. Beside these symptoms, he records instances where syncope has occurred under its employment, and Bentzeff is quoted as believing that the drug always produces such a tendency. He asserts that, in the opinion of Moncovor, Dujardin-Beaumetz, and several others, the secretion of urine is seriously modified, and one of his references is stated to have put it that "antipyrin closes or shuts up the kidneys."

Going still further, Eloy calls attention to the case of Dr. Barr, which is recorded in the *Lancet* of February 25, 1885, in which collapse and death followed the ingestion of from fifteen to thirty grains of antipyrin in two doses. In a case of puerperal fever, antipyrin caused a fall of over two and a half degrees Centigrade, with vomiting and diarrhœa. Rigors now came on, the extremities became livid, and in thirty-two hours the patient died in syncope. At the autopsy the spleen was found contracted, the kidneys were shrunken, and contained infarcts. A large number of instances were also collected, in which antipyrin has apparently, in the minds of the recorders, produced disorders so varied and so different from one another that it is scarcely possible for them all to be produced by the same drug.

It appears to us that Eloy is not justified by the facts he cites in reaching the conclusions as to the dangers of the drug which he sets forth. In the case of puerperal fever to which he alludes, nothing occurred which warrants the attributing of the fatal termination to the use of antipyrin, and the post-mortem lesions indeed point to the disease itself as the cause of death, without any aid from the drug.

We think it but a fair conclusion that antipyrin is in no sense a dangerous remedy, and that as yet there are no cases in which death can be attributed directly to its use. All untoward symptoms, clearly produced by any drug, should be reported, but at present the tendency seems to exist of reporting any unforeseen turn in a case as the effect of the drug last administered. Undoubtedly the differentiation is at times difficult, as to whether the symptoms are

of the illness or the drug, but every disease runs at times such an irregular course that the careful clinician thinks twice before charging a drug with a change which his own foresight or care might have averted, or at least expected.

WEIL'S DISEASE.

A FEW years ago PROFESSOR WEIL described a new infectious disease characterized by fever, headache, gastric disorder, jaundice, and pains in the muscles. In the *Deutsches Archiv für klin. Medicin* there have been four or five articles on the subject during the past five years, and in the current number Fiedler, of Dresden, records thirteen cases, and discusses fully the general characters and diagnosis of the disease. The onset of the affection is sudden, without prodromata, and often with a chill. The characteristic symptoms are those above mentioned. The fever runs a typical course, and lasts from eight to ten days. The liver and spleen are usually swollen, and the former is tender. Nephritis often occurs, and herpes and erythema have been present. The cases so far have been chiefly in men, and nine of Fiedler's patients were butchers. The prognosis is favorable. The cause of the disease is unknown, but the fact that dealers in meats form such a large proportion of the cases suggests the direction in which the poison is to be sought. Fiedler discusses the diagnosis, particularly from abortive typhoid, and concludes that it is an affection *sui generis*. It is quite possible that the affection may prove to be a form of chronic ptomaine poisoning.

THE Thirty-ninth Annual Meeting of the American Medical Association will be held at Cincinnati, on May 8th, 9th, 10th, and 11th, under the presidency of Dr. A. Y. P. Garnett, of Washington. The Address in Medicine will be delivered by Dr. Roberts Bartholow, of Philadelphia; the Address in Surgery by Dr. E. M. Moore, of Rochester; and the Address in State Medicine by Dr. H. P. Walcott, of Cambridge, Mass.

The general sessions will be held in the Music Hall, and the sectional meetings in adjoining rooms in the same building. The present indications point to a large meeting.

THE next annual meeting of the South Carolina Medical Association will be held in Columbia, S. C., on Wednesday, April 11, 1888, under the presidency of Dr. T. Grange Simons, of Charleston.

DR. ROBERTS BARTHOLOW, of Philadelphia, we learn, has been elected an Honorary Member of the Royal Medical Society of Edinburgh.

DR. JOSEPH TABER JOHNSON, who has heretofore held the position of Professor of Obstetrics and Gynecology in the Medical Department of Georgetown University, having resigned the Professorship of Obstetrics, the chair has been divided into two separate professorships, Dr. Johnson retaining that of Gynecology, and Dr. P. J. Murphy has been appointed Professor of Obstetrics.

DR. OLIVER WENDELL HOLMES has presented his valuable medical library to the Boston Medical Library Association.

THE New York County Medical Society caused the arrest of an Italian shoemaker for practising medicine without a diploma. At his trial the cobbler entered the plea that he had used no medicines, but simply used charms which had been taught him in Italy, to cure people of witchcraft. His deluded countrymen had to pay roundly for his services whenever they went to him to have the spells of witchcraft lifted from them. He was fined fifty dollars, and he said with a sigh that he would hereafter "stick to his last."

DRS. SAYRE and LUSK, of New York, have been proposed as corresponding members of the Academie de Médecine de Paris.

IN an editorial in the *British Medical Journal* of February 25th, on the "Birthplace of Consumption," we find the newly coined verb "to sanitate." The innovation will be welcome to all who have to write upon questions of public hygiene: the evolution of modern civilization makes necessary such additions to our vocabulary.

BUN-POISONING is reported from Belfast, Ireland. A number of children and adults in the workhouse of that town showed symptoms of poisoning after partaking of buns. The medical officer found twenty-three children on the floor vomiting, and some of them screaming. Ten adults had to be removed to the hospital, but all have recovered. An analysis of the remaining buns has been ordered by the authorities.

PROFESSOR NICHOLAS SENN has been appointed Professor of the Principles of Surgery and Surgical Pathology in the Rush Medical College, Chicago.

REVIEWS.

Diseases of the Heart and Circulation in Infancy and Adolescence. By John M. Keating, M.D., and William A. Edwards, M.D. Philadelphia: P. Blakiston, Son, & Co., 1888.

The reprinting of the articles on this subject which have run through the numbers of the *Archives of Pediatrics* for the past year will enable the profession to obtain in book form that which they might otherwise have obtained by a subscription to the journal itself, if this is any advantage.

The work of collecting the cases from the literature of the subject must have been most laborious, but we doubt very much whether the present volume fulfils the want which it is supposed to fill—*i. e.*, the information on this subject which the text-books lack.

The printing is clear and well done, and the photographs which are scattered here and there are well executed but almost entirely useless, rather by reason of the difficulty which always surrounds the photographing of pathological specimens than from any lack of skill on the part of the pathologist or artist. Unless each one of them was labelled, we think it would puzzle the average physician to tell what they are supposed to represent.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, March 5, 1888.

The President, D. Hayes Agnew, M.D., in the Chair.

Dr. De Forrest Willard reported the following case of

SQUAMOUS EPITHELIOMA OF PENIS; AMPUTATION.

A. B., seventy, has had slight burning sensation in the glans penis for nearly two years, but no decided lesion until six months ago, it then ulcerated, and was treated for several month as gonorrhœa and warts, although there had been no sexual congress, other than with his wife.

On examination at first visit to me, a growth nine inches in circumference was found involving the entire glans, which had nearly disappeared. Prepuce not involved, save in the dense induration, which also extended through body of penis almost to the trunk. Whole surface covered with foul pus, and from several points pus was also exuding from corpora cavernosa. Urination painful and difficult. Anterior part of urethra destroyed. No involvement of inguinal or other discernible glands.

Immediate amputation by the knife was performed, close to the trunk, a rubber band controlling all hemorrhage. Arteries tied with catgut, the slit urethra firmly attached to sheath, and skin and parts drawn nicely over the stump. Antiseptic dressings applied, and no catheter used; the parts being thoroughly washed with sublimate solution after each act of urination, and fresh dressings adjusted. Union took place in a few days, and contraction of cicatrix at orifice of the urethra was prevented by use of a silver tube worn while in bed. Subsequently the urine was carried off from the body, when passed, by applying over the stump each time a cylindrical rubber vaginal speculum. The microscope showed the growth to be of the squamous type. Each corpus contained one or two pus cavities.

The growth will probably return, but an offensive mass is removed, and the next deposit may be intra-pelvic, with a less painful and disgusting death.

Dr. William Hunt had seen a good many cases of amputation of the penis, but did not recall an instance in which it was necessary to make use of any contrivance for easier urination, or to prevent adhesions, except during the first part of the treatment. It is possible that trouble may have occurred after the patient left the hospital, but he could not recall one coming back to be treated. Cases of penis amputation for epithelioma are very unlikely to have *local* return of the disease, although this does sometimes happen.

Dr. Gross thought that any surgeon who has operated on many cases of epithelioma of the penis, will find that even if there be no local recurrence, the glands in the groin will, in the majority of cases, be invaded.

The President said that the question then arises as to the proper method of dealing with the inguinal glands in these cases. Would it not be as important to remove these glands in cases of epithelioma of the penis as to remove the axillary glands in cases of carcinoma of the mamma?

Dr. Gross thought that the importance of this is recognized more particularly by the German surgeons, who are certainly more in advance of the surgeons of other nations as regards the extent of operation that should be performed in carcinoma. They remove the glands in the groin. There are many cases, however, in which, although the superficial glands be removed, the deep glands in the pelvis will be found involved. This is more apt to be the case when the glands in the groins form a large mass rather than a distinct enlargement of the separate glands. In many cases the glandular involvement has gone so far that operation is out of the question.

Dr. W. W. Keen read a paper on

THE RADICAL CURE OF HYDROCELE BY EXCISION OF THE TUNICA VAGINALIS TESTIS.

(See page 371.)

Dr. Gross said that he was the author of the article in The Medical News to which Dr. Keen had referred. Since he wrote that paper he had, from time to time, noted some other points in regard to operations for hydrocele, which may be of interest. Some years ago, Dr. Allis made statements to this body which surprised the most of his hearers, concerning the various methods of treatment of hydrocele, and he showed that none was absolutely safe, not even that of the injection of various mixtures and solutions. The records of a larger number of cases show that the conclusion of Dr. Keen with reference to excision is correct.

He might correct him as regards the first excision of the vaginal tunic. The history of the operation is briefly as follows. In 1873 Volkmann resorted to incision of the tunica vaginalis, with drainage and suture of the edges of the tunica vaginalis to the edges of the scrotum. In 1878 he incised the tunica vaginalis, united it with sutures, and also passed deep sutures, bringing the surfaces of the tunica vaginalis together. In 1882 he excised a large portion of the vaginal tunic, sutured the remainder with

gut, and united the scrotum with silk, putting in two drains. He was, therefore, the first to excise, as he was the first to incise. Juillard, of Geneva, in 1883, excised all of the vaginal tunic except a sufficient portion of the parietal layer to bring over the testis and epididymis, and thus shut up the testis in a smaller sac of the tunica vaginalis. He inserted a drain in the scrotal cavity, and united the scrotum with catgut. Nicaise strips off the tunica vaginalis, saving enough to cover in the testis, and uniting this with catgut he puts in a small drain. He then unites the scrotal wound and puts in a second drain. A year or two ago, the speaker himself excised the tunica vaginalis, and then approximated the sides of the scrotum with the figure-of-eight suture of Heppner.

Now a word with reference to statistics. He had collated 540 cases of iodine injection from the records of later years, particularly by German surgeons. There have been no deaths, but there was recurrence in 8.15 per cent., and acute suppuration or gangrene in 1.66 per cent. Of 90 cases of carbolic acid injection, all were successful. In three cases, however, there was suppuration, but in all from one to three drachms of carbolic acid had been used. Still smaller quantities may, moreover, give rise to suppuration. He had seen, in the practice of a colleague, suppuration follow the injection of half a drachm into the left side of the scrotum, and Abbe has had suppuration follow the injection of only twelve minims. The percentage of suppuration after carbolic acid injection, 3.33 per cent., has been greater than after the injection of iodine. In 305 cases of antiseptic incision there was recurrence in 4, and he believed that that was the reason that Volkmann resorted to excision. There were also 4 deaths, 1 from pyæmia, 1 from septicæmia, 1 from tetanus, and one was said to have died of phthisis. It may be remarked that every one of these cases died under the carbolic acid dressing. There has been no death reported, so far as he knew, from incision since the use of corrosive sublimate dressing. As Dr. Keen had remarked, there is frequently in these cases of Volkmann's operation, orchitis, occasionally abscess, and partial sloughing of the edges of the wound. We now come to the 78 excisions; of these one recurred but none died, and there were no subsequent complications, so that in reality the safest and most satisfactory method of treating hydrocele reported up to the present time is excision of the sac. It may be that there has not been a sufficient number of cases, but the fact that there has been only one recurrence and no deaths or accidents, would indicate that in suitable cases this is a proper operation.

In an ordinary hydrocele, he should not at once resort to excision. In the case of a hydrocele containing, for example, eight ounces, he should empty the sac, and when it had refilled one-third, inject some solution, as there would then be less surface to be acted upon. In a case that has never been operated upon he empties the sac and tells the patient to return when it has refilled one-third. He then throws in thirty drops of ninety-five per cent. commercial carbolic acid. If the patient has had injection practised, and particularly if the operation has been repeated several times, he thinks that we should at once proceed to open the sac. In these cases we will find that the vaginal tunic and the fibrous tissue under it have undergone changes. The vaginal coat is not only thickened and ecchymosed in spots, but in places it has undergone cartilaginous degeneration, and is frequently beset with cysts or other abnormal products.

He has great confidence in the treatment of hydrocele with carbolic acid. He has practised it for some years and has never had a failure from it nor has he seen any bad results, although, as he had stated, one of his colleagues had a case in which suppuration followed its use, but this must be attributed to infection by the instrument.

DR. J. EWING MEARS was not aware that the method of treating hydrocele by excision of the tunica vaginalis was so recently instituted. He performed it himself in 1876, not knowing that it had been so rarely undertaken. This was in a case of old hydrocele which had been operated on a number of times. The tunica vaginalis and the subjacent tissue were much thickened, and there was also atrophy of the testicle. He not only removed the tunica vaginalis, but also the atrophied testicle, which was not larger than an almond. The wound was dressed antiseptically, and the patient recovered without a bad symptom.

He thought Dr. Gross had indicated the proper method of treating these cases, and that all are agreed that in simple hydrocele, not previously operated upon, the injection of some fluid—Dr. Gross suggests carbolic acid, he had used iodine with success—is the proper plan. He injects the iodine after the method suggested by the President, evacuating the contents of the hydrocele, then injecting the iodine and allowing it to remain. He has never had any unfavorable symptoms follow its injection in this way, nor the persistence of severe pain, as stated by Dr. Gross. He thought that it is the operation most likely to succeed in simple cases. In old cases of hydrocele with thickening of the tunica vaginalis, there is no doubt that excision is the only remedy that will give a radical cure.

DR. GROSS said that excision is not the only remedy that will bring about a cure when the tunica vaginalis is thickened. The first case in which he did Volkmann's operation was one in which there were patches of cartilage in the vaginal tunic. He did not excise it, but the cartilage reverted to embryonic tissue and disappeared. The only disadvantage was that the cure was protracted. It was about three weeks before the incision had healed. Of course, excision is the best, although not the only operation in these cases.

DR. JAMES M. BARTON referred to a method which he had been using with considerable satisfaction for the past three or four years. He had met with a number of cases of hydrocele which had resisted treatment. It was formerly the method in Jefferson College Hospital to treat these cases with a seton. This was often followed by unpleasant results. Finding that these were, to a large extent, due to insufficient drainage, he began by introducing a drainage tube at the lower opening at the time of operation, subsequently substituting a drainage tube for the seton. This answered well, and he thought was still further improved by making the operation antiseptic. He had treated ten cases in this way with success. The parts are scrubbed with turpentine, water, etc., on the day before the operation, and covered with a piece of cheese-cloth saturated with a solution of the bichloride of mercury. Over this is placed a piece of rubber cloth, a hole being made for the penis, and the dressing held in position by adhesive plaster. The following day the trocar and canula is entered at the lowest possible point, the

sac emptied, and the instrument brought out at the highest point. A drainage tube, somewhat larger than the canula, is carried through, the tube being stretched to reduce its calibre. The parts are then covered with antiseptic gauze. In the course of from two to four days, lymph will appear around the tube, forming a mass about one inch in diameter. At the expiration of the above time the tube is removed, and the patient allowed to go about. He had in most cases succeeded without inducing suppuration. In one or two cases there has been slight suppuration, but the only disadvantage resulting from this has seemed to be the delay in recovery.

Dr. Keen desired to correct one error into which Dr. Gross had fallen. He stated that there had been no deaths since the bichloride of mercury had been introduced. Dr. Bull has reported one case of death from mercuric poisoning after Volkmann's operation. He was glad to see the general impression with reference to the difference in danger between complete excision and the incision of Volkmann. Certain it is that the method by incision is not by any means so radical, so devoid of danger, or so philosophical as the entire removal of the tunica vaginalis, with the exception of that portion covering the testicle and cord. He agreed with those who had spoken that excision is the best treatment for cases of old hydrocele which have been repeatedly operated upon; and from his experience with the methods of injection which are followed by so much of induration, of swelling, of weight, of inflammation, and of pain, he was very decidedly inclined, even in cases of recent hydrocele, to practise extirpation of the tunica vaginalis. It is well known how aseptic and non-inflammatory the course of such wounds is. It seemed to him that we should have much better results in the future than we have had from carbolic acid injections in the past.

Dr. William Hunt asked if there had been any observations with reference to the behavior of the testicle after successful excision of the sac for hydrocele. It has been well established that in the ordinary operation the cure is not due to the adhesion of the two sides of the sac, but to an alterative action exerted by the injected solution upon the membrane. Now, after the sac has gone, does the testicle adhere to the connective tissue, and become restricted in its movements, or is a lubricating surface or pseudo-cyst formed around it?

Dr. Willard asked if the contraction might not destroy the functional activity of the organ?

Dr. Keen was not aware of any observations upon these points. He took it for granted that there would be complete adhesion between the two surfaces. He thought that no contraction would take place, and that the function of the organ would not be interfered with.

Dr. Gross said that, going back to the subject of injections, the reason that he adopted carbolic acid was, because it is followed by so little inconvenience. After throwing in thirty drops of commercial carbolic acid the pain ceases in a minute or two. Tincture of iodine, or any of the preparations of iodine, on the other hand, causes excessive suffering which may last for hours.

Dr. J. Henry C. Simes said that he had used injections of cocaine previous to the injection of iodine, and found it very satisfactory in preventing pain.

Dr. D. Hayes Agnew still adhered to tincture of iodine, but occasionally used carbolic acid. He thought that we cannot tie ourselves down to any one method of treatment. In most cases iodine or carbolic acid will answer. He still preferred tincture of iodine, but where there are extensive changes in the sac it is proper to excise. With reference to the pain following the injection of iodine, his experience does not agree with that of Dr. Gross. The suffering is intense for two or three minutes, certainly not more than five or ten minutes. He keeps the patient quiet for five or six days, after which he is allowed to go about with a suspensory bandage. He thought that we cannot draw conclusions with regard to the value of iodine injections from statistics, because iodine is used in such a variety of ways. Some dilute it, while others allow it to escape immediately. To make a success, pure tincture of iodine must be thrown in (never less than two drachms) and allowed to remain.

Dr. Willard had not seen long-continued pain follow the injection of tincture of iodine. He had seen it continue two hours, but usually not longer than from ten to thirty minutes.

MULTIPLE FRACTURE.

Dr. Hunt wished to refer to a case, and his object in doing so is to put it on record. It is a curious one of multiple fracture. A man, forty-one years of age, came into the Pennsylvania Hospital after falling a distance of ten or fifteen feet striking the cobbles. The injuries were confined to the right arm. There was a fracture through the neck of the humerus and dislocation of the head of the bone, which was reduced; there was a fracture of the olecranon and a Colles's fracture.

Dr. Packard thought that this was an unique case. The man has been in the hospital about two weeks and there is nothing remarkable in the progress of the case. What forces caused the combination of injuries without breaking the shafts of the bones anywhere, is hard to determine. For a man to break the same limb at all three main joints at the same time, is certainly a very rare occurrence.

NEW YORK ACADEMY OF MEDICINE.

Section on Orthopædic Surgery.

Stated Meeting, March 16, 1888.

V. P. Gibney, M.D., in the Chair.

Dr. Samuel Ketch read a paper on

THE PRESENT STATUS OF THE TREATMENT OF ROTARY LATERAL CURVATURE OF THE SPINE.

This condition, he said he felt sure, had given rise to more theories and, as a result of these, more ingenuity in the means devised for the relief of a deformity presenting greater obstacles to success, than any other encountered by the orthopædic surgeon. In speaking of rotary lateral curvature of the spine he wished emphatically to be understood as referring here to only typical cases, and he defined such rotary lateral curvature to be that lateral deviation of a portion or whole of the vertebral column which shows as its most constant factor the rotation, torsion, or twisting of the bodies or segments of bodies of the vertebræ, with accompanying or consecutive alterations in the shape of the thorax. No deformity with which we are brought in contact exhibits in its slow, insidious progression, in its involvement of area, in its secondary effects on important internal organs, so decided alterations of form, and such marked disturb-

ances of function, as this. When it becomes recognized that the condition we have to deal with is but the effect of some cause, some irritation in fact, the exact nature of which is as yet unknown, it will be seen that the problem of treatment embraces something more than the attempt to remove the mechanical results of such cause by the use of opposing mechanical means.

The present treatment of the disease consists principally of two methods, or a combination of the two, viz., by apparatus and by exercises, or by the conjoined use of both. Dr. Ketch did not think it necessary to speak in detail of the treatment by complete recumbency or that by cutting of spinal muscles (tenotomy), although both plans, he thought, might be useful adjuncts at times. He went on to say that at the present day apparatus for the relief of lateral curvature might be described under two varieties, progressive and fixative. He strongly condemned treatment by the constant action of cumbersome and heavy instruments which by their abnormal pressure often give rise to large excoriations, and even sloughs of the skin. In his opinion no lever brace should be used for any other purpose than simply that of retaining the spine in an improved position previously obtained either by appropriate manual exercises or combined manual and gymnastic movements. Such braces should be light, easily removable, to allow of inspection of the parts, and simple enough to be easily applied by those having the home care of the case.

The second class, or fixation apparatus, were originally constructed with the idea of firmly immobilizing the distorted spine in an improved position, obtained by suspending or extending the patient. This original plan has been modified to the extent of opening the brace in front, whether constructed of plaster-of-Paris, poroplastic felt, leather, or other substance, with the object of easy removal, in order to allow proper exercises and give attention to the subjacent parts.

In regard to the matter of exercises he said that he attached most importance to those which have for their object the "unfolding" of the twisted vertebral column. These can be applied with the greatest precision and benefit by means of the surgeon's hands. The importance of manual force has not been overlooked by surgeons in their attempts to relieve deformity, and no appliance can rival the ease, proper application of pressure, and safety which manual exercises afford. Their success, however, depends on detail, and they should be given either by the surgeon himself or a thoroughly trained assistant.

As to what is meant by a cure, Dr. Ketch said that to his mind this would involve not only the restoration of the lateral deviation, with its normal curves, but also the disappearance of that most constant factor of the deformity, the rotation. As generally understood, however, this implies either the prevention of further deformity or an amelioration of the condition as originally observed. In the cases observed by him he has never been able to convince himself of the entire disappearance of rotation, while he believes it to be essential that this symptom should be prevented or removed before a vertebral column can be considered as restored to a perfectly normal state. To the question, Are we able at the present day to remove this rotation? he felt compelled, then, to answer in the negative. He then took up the question, Are there any means by which we can more fully accomplish our ends? In the way of apparatus, he said, there is nothing new, for all apparatus finds its efficiency in the proper application of mechanical laws. In the way of prevention, however, a great deal can be accomplished. It is only by the earliest recognition of the symptoms and an appreciation of their importance that prophylaxis can be accomplished. He then referred to a paper which he read two years ago before the Section on lateral curvature, with special reference to its occurrence in children. It was based on an analysis of 229 cases presenting the typical deformity in question, and he divided these cases into three classes, as follows:

1. Those where the deformity was first observed from the first to the twelfth year, or the age of childhood.

2. Those where the deformity was first observed from the twelfth to the eighteenth year, or the age of puberty.

3. Those where the deformity was first observed from the eighteenth year and upward, or the age of complete development.

During the period of childhood the deformity occurred in 120 cases, or over one-half of the whole number, and among the conclusions at which he had arrived in the paper were the following:

1. Rotary lateral curvature is principally a disease of childhood, and may be either congenital or acquired.

2. The disease should be looked for early in life, and as a factor in early treatment the careful inspection of children's spines becomes most important toward the prevention of the deformity.

He did not mean to say that even were the spines of young children to receive the utmost care, and at the first suspicion of a deformity the child was taken to a surgeon, that we should not have lateral curvatures; but he felt convinced that the inveterate deformities now seen in so large a number would be few and far between.

Dr. A. N. Phelps said that in lateral curvature of the spine, if there were changes in the bone, no apparatus or gymnastic exercises would correct the deformity. It was, however, of advantage to suspend the patient, and, having got him into the best possible position, to secure this permanently by some fixed apparatus. He believed Stillman's brace to be the most satisfactory steel instrument that had been devised; but, so far as his experience went, he had found that the plaster-of-Paris jacket was by far the best appliance at the command of the surgeon. He thought that compensating curves could be maintained which would be of service in mitigating the deformity.

Dr. A. B. Judson believed that mechanical treatment which involved strong lateral pressure on the ribs, would increase, rather than reduce, the rotation and curvature. If we could invade the cavities of the chest and abdomen, and make lateral pressure on the errant vertebral bodies, it would be easy by direct force to correct at one motion both the curvature and the rotation. His views of treatment were based on the importance of placing the patient as often, and for as long a time as practicable, in those positions in which the deformity was diminished or entirely reduced, so that, as the patient's frame developed, the skeleton might grow and harden with as little deformity as may be. As the superincumbent weight is the direct cause of the curvature, and as the deformity disappears in mild cases when the patient lies down, the recumbent position should be maintained at least two or three hours in the middle of the day. And if general debility, or fatigue, or muscular failure is to be

considered the indirect or remote cause of the affection, something might be gained in this direction by the prescribed recumbency as well as by encouraging the patient to avoid fatiguing tasks, and to lie down whenever so disposed. Again, when the patient is lying down he considered it advisable that he should remain on his back, and not only on his back, but in such a position that a lordosis is produced. This was accomplished by placing an air pillow, blown up to its full extent, under the spine. The reason for this is, perhaps, a little theoretical. In the rotation of the spinal column it is clear that the anterior portion of the vertebræ is the most at fault. The same is true in Pott's disease, the disease being located in the anterior portion of the vertebræ, and, therefore, in Pott's disease also, is produced a lordosis, if possible. We remove the pressure from the anterior part of the vertebræ to the posterior.

Another very useful position was that in which the weight of the body is suspended by the upper extremities. It is well known that even in cases in which the deformity is marked the curvature and rotation absolutely disappear when this attitude is taken. He referred to the theory of Dr. Henry G. Davis, who pointed out that in this position the chest is directly and forcibly enlarged by the fixation of the anterior ends of the ribs, which are connected by the fibres of the pectoral muscles with the humerus, while the posterior ends of the ribs are dragged down by the weight of the lower part of the body. Suspension may be practised by the rope and pulley, the suspension bar, the parallel bars, the overhead ladder, or the suspended rings. As much exercise of this kind as is possible should be taken short of fatigue, with the threefold object of maintaining an improved position of the spine, of increasing the capacity of the chest, and thus indirectly combating rotation, which narrows the chest, and of securing the improvement in general health and strength which naturally goes with improved respiration. He did not believe that the cases of extreme deformity, which are so common, could be materially improved in shape, but some cases of moderate severity can be entirely restored to symmetry. He had never seen a case pass from the moderate to the extreme type of deformity.

Dr. Reginald H. Sayre agreed most thoroughly with Dr. Ketch, in saying that preventive rather than curative treatment is what we must aim at in lateral curvature. He also bore out his observations as to occurrence in early life, having seen one case where the curvature is said to have been present at birth, another where it was noticed at six months, and having personally seen a case in a child two months old.

As for getting a perfect restoration to the normal form, he believed it to be possible only in cases where there is but very slight rotation, cases which present considerable rotation and curving of the ribs he believed can never be restored completely to the natural shape. They may, however, be benefited, and he had been surprised to see the amount of improvement attainable in very advanced and, at first sight, apparently hopeless cases.

If possible, he would treat a case by gymnastics and massage alone, with the object of educating the muscles of the patient and enabling him to retain such improvement of position as he could make by manipulation, and exercises, which, being different in various cases, would require too much time to be described here.

If a case is sufficiently distorted to require also mechanical support, or if it is necessary, on account of paralysis, he should use a plaster-of-Paris corset, as he has never seen a case which became worse under this mode of treatment, and he has seen a number of most frightful distortions occur under instruments of various kinds, applied while the deformity was very slight, as attested not only by the testimony of the parents, but by photographs taken at the time of beginning treatment; and as this result has followed instrumental treatment in the hands of various physicians of large experience, with patients whom he has found most obedient in following out instructions, he is forced to conclude that the fault lay in the method.

His patients, who have worn both braces and plaster-of-Paris jackets, all give testimony in favor of the superior comfort of the latter, which would lead him to use this method even were the results no better than those attained by instruments, but where he sees improvement take place in patients who have steadily grown more crooked during years of instrumental treatment, he feels more and more that most of the machines he has seen are worse than nothing.

Dr. Ridlow thought that surgeons are not sufficiently definite as to what is meant by cures and what by exercise for the patient. He was in the habit of dividing the cases which he saw into three classes for prognosis and treatment. In the first class there was little or no rotation, and the spine could be put into what seemed to be the normal position for a brief space of time. In the second class there was more or less rotation and rigidity of two or more segments of the spinal column, and the deformity could not be reduced, but pain and weakness were absent. In the third class there was marked curvature and rigidity; and, in addition, pain and weakness.

In the first class of cases he believed that a cure could be effected; and here he deprecated all use of apparatus in the treatment. In the second class of cases he was inclined to think, with Mr. Bernard Roth, of London, that the spine could be made straight and the rigidity overcome. Gymnastic exercises are of great service, but as to mechanical means, he did not feel sure that they are of any value. In fact, he was convinced that they sometimes do harm, but at the same time he found it advisable to employ them himself in certain instances. Any apparatus made use of should be light and elastic, and made to fit. In the third class the spine could not be straightened or the rigidity overcome, but the patient could be made to carry himself in better form. Here he was accustomed to prescribe certain exercises, and in addition he used a steel apparatus which would act somewhat as the hand of the surgeon in correcting the deformity. It should not be flexible, but he thought it should be changed in its adjustment each day according to circumstances. The osseous curve, in his experience, always remains unchanged. Of course, much can be done by baths, massage, and electricity; but more can be accomplished by the use of suitable gymnastic exercises than by any other means.

He said he was surprised that something more definite in regard to such exercises had not been insisted upon in the present discussion. Sitting upon a stool and twisting the body he thought accomplished as much as anything else in developing the spinal muscles. The patient

should be put in a position nearest the normal that was attainable, and instructed to maintain this to as great an extent as possible. Dr. Ridlow then went on to advocate the system of exercises described by Mr. Roth in Heath's *Dictionary of Surgery*, the "key-note" position (in which the patient is to be exercised) being that position of the trunk and arms in which the greatest improvement in the position of the spine is obtained. A cure was considered by Mr. Roth to have been accomplished when the patient was so educated that the best possible position became an habitual one. This surgeon, he believed, had done more to secure good results in lateral curvature than any one else that he knew of. If we knew just what we could accomplish in any particular case, a definite plan of treatment could be adopted, which is much preferable to the uncertain and slipshod methods hitherto in vogue.

Dr. V. P. Gibney stated that he had not much to add to what Drs. Judson and Ridlow had said. He was now hard at work in practically testing Roth's system of treatment. Among the points which had not been taken up in the discussion was the subject of measurements, and he thought it of the utmost importance that some definite system should be adopted upon which all orthopædic surgeons could agree. In carrying out Roth's methods it is very difficult to get dispensary patients to come to the surgeon every day, and he had recently organized an evening school of gymnastic exercises for young girls afflicted with lateral curvature. Their powers of resistance seemed, as far as he was able to judge, to have developed wonderfully already, and the experiment bade fair to be a very successful one.

In closing the discussion, Dr. Ketch said he thought that it would no doubt be as difficult to maintain the compensating curves spoken of by Dr. Phelps as to remove the lateral curvature and rotation. He could not say that he regarded a rotary lateral curvature cured which had a deformity remaining. Braces will either prevent the deformity from becoming worse, or might tend to produce amelioration. Experience with special kinds of apparatus enabled some surgeons to obtain better results with these than other surgeons could who had not the same facility with them. Thus, Dr. Sayre was no doubt more successful with the plaster-of-Paris jacket than those less familiar with this appliance. A steel brace should have a fixed point for making pressure, which should be oblique, and not directly lateral. In regard to Dr. Judson's remarks, he thought that any analogy between inflammatory disease of the vertebræ and rotary lateral curvature was inadmissible. It seemed to him that Dr. Judson had been especially fortunate in not having met with any of those inveterate cases referred to in the paper and the discussion. There is no deformity so much like that of clubfoot as rotary lateral curvature of the spine. The former condition, however, is usually detected soon after birth, and measures taken to correct it. Hence we met with much fewer cases of inveterate clubfoot than of lateral curvature, since the latter is not, as a rule, treated at a sufficiently early stage. After all, the prevention of deformity was the point on which he desired to lay most stress. He believed that no two cases are alike, and whatever the plan of treatment adopted frequent inspection and the most careful watching are essential on the part of the surgeon.

Section in Pediatrics.

J. Lewis Smith, M.D., Chairman.

Stated Meeting, March 28, 1888.

Dr. A. Jacobi read a paper on

sepsis in the newborn.

Semmelweiss was the first to teach that puerperal fever in women and newborn infants is of traumatic origin, septic material being absorbed through erosions and abrasions of the skin and mucous membranes, the lesions in the newborn being especially those which occur about the head and navel. The changes in such cases are often manifested in the umbilical vein, arteries, and surrounding tissue; and they sometimes occur in cases in which thrombi are, to all appearances, normally formed. Some writers have stated that it is impossible for sepsis to occur through the cut end of the cord, excepting in cases in which the ligature surrounding the stump is insecure, but Budin has seen cases in which pus could be expressed though the ligature was properly applied, and the author had also seen such cases in which the umbilical wound refused to heal.

The question may be asked, Whether sepsis can occur without apparent disturbance of the navel? And the author would reply that this is possible, though it is not of frequent occurrence. Cases undoubtedly occur in which a newborn infant is infected while the mother remains unaffected, the poison being transmitted by the discharges from the mother; or the fœtus may be infected through the medium of the maternal blood. In such cases no wound surface in the maternal tissues may be apparent. Sepsis may also occur, according to some writers, through the mother's milk; but if this is possible it is also true that many infants are so robust that they remain unaffected however contaminated the milk may become. Septic pneumonia and other pulmonary troubles have also been recorded in consequence of the inhalation and aspiration of decomposed or decomposing material. If there are abrasions and erosions of the skin, sepsis may result even though the lesion may apparently be a very slight one. Spontaneous pyæmia has been described by certain authors, and though such a supposition seems irrational, cases occur now and again in which no lesion can be found. Two such cases were recently seen by the author.

Ebstein describes three forms of sepsis in infants which seem to be due to lesions in the mouth: (1) Septic catarrh which may result in hemorrhage and other accidents, (2) croup, and (3) diphtheria. In such cases there are unquestionably lesions of the epithelium of the oral cavity. These lesions may be slight, but are yet sufficient to afford an avenue for the entrance of septic elements. The practical point in this matter is that manipulations about the mouth of the newborn infant should be of the gentlest possible character. Lesions of epithelium in the vagina and anus may also give rise to sepsis.

Pneumonia in the newborn is not of infrequent occurrence, though it occurs more frequently after the third or fourth day of life. It may result from the aspiration of liquor amnii, meconium, etc. Too much stress should not be laid upon the influence of micrococci. They

occur in all parts of the body, and the micrococcus of sepsis is not yet absolutely determined. Much yet remains to be done upon the bacteriology of this subject. Experimental pathology is useful, but it cannot prove everything, and much of it is exceedingly faulty. To the question, Whether sepsis can be transmitted by the air? it may be replied that it can, even without the evidence which is afforded by experimental pathology. The symptoms and localization of this condition are many and varied—for example, dermatitis of varying intensity, syphilis, ulcerations of the scalp and of the umbilical stump. Hemorrhage, which is a very common symptom, may be due to the influence of micrococci, or it may be due to the undeveloped condition of the vessels in the newborn infants which predisposes them to give way from very slight causes. Purulent metastases also occur frequently in different parts of the body, or the inflammatory collection may consist of bloody serum or sero-pus. It must not be forgotten that changes in such patients take place very suddenly, and often with a fatal issue, when no great rise of temperature has suggested a serious condition. Great loss of weight is apt to be noticeable in such cases. If the case becomes chronic, the chances of recovery become more favorable.

Dr. J. Lewis Smith read a paper in which cases were narrated showing

THE MANNER IN WHICH SEPSIS OCCURS IN THE NEWBORN.

He had observed that this is sometimes obscure, but that the poison usually enters the system through the umbilicus, and is usually microbic. The cases which had come under his observation were divided into groups: First, those in which an umbilical phlegmon had resulted from the umbilical ulceration. In some of these cases diphtheritic inflammation was present. This was especially the case in connection with an epidemic which recently occurred at the New York Infant Asylum. In other cases the inflammation of the umbilicus was accompanied with sepsis of moderate intensity. In the epidemic referred to the disease seemed to be due to the poisonous atmosphere of the wards of the hospital. Careful examination of the air revealed the presence of multitudes of disease germs, and even after the wards had been fumigated with sulphur, disease germs could still be found and cultivated. In this group of cases the infection was transmitted mainly through the lymphatics. The pathological investigations upon the cases which were reported were made by Prof. T. Mitchell Prudden.

The second group included cases in which the poison was transmitted through the umbilical vessels, especially the vein. These had not been so numerous as the first group.

The third group included cases which were infected by all other possible channels, as the lungs, the skin, etc. If sepsis is possible through the umbilicus, as seems to be proven, there is great probability that it may also occur, if less frequently, through other channels.

Trosseau has observed that infantile erysipelas is most frequently seen in hospital wards in which puerperal fever is present. Such cases would now-a-days be considered of septic origin. Fortunately, they are more rare than they used to be, and this is probably due to improved methods in obstetrics.

Dr. Andrew F. Currier read a paper entitled

A RÉSUMÉ OF RECENT VIEWS CONCERNING ICTERUS NEONATORUM; AND ITS RELATION TO SEPSIS.

The great size of the liver and its consequent capacity for holding blood: the abolition of the umbilical vein and ductus venosus, the channels by which the placental circulation is maintained, and the degenerative changes which occur in the blood after the ligation of the umbilical cord are facts which enable us to understand why morbid conditions, which are traceable to the liver, occur so frequently during the first few days of life. A review of the various theories which have been advanced to explain the etiology of icterus neonatorum shows great differences of opinion, but the following facts seem to be pretty well established: (1) With the completion of fœtal life and the termination of the placental circulation, extensive changes in the blood of the infant always take place. (2) These changes are degenerative and are much more marked in immature and feeble infants than in those who are robust. (3) The external evidence of these changes appears in the form of icterus, which, in the greater number of cases is of brief duration, and is not accompanied by symptoms indicating serious constitutional disturbance. (4) In those cases in which the icterus is profound and persistent, serious results are to be expected, for the condition is not caused by the ordinary degenerative changes in the blood corpuscles which always follow the ligation of the umbilical cord. (5) Among the causes which are followed by severe or fatal symptoms are (*a*) Non-closure of the *ductus venosus* (Quincke's theory). (*b*) Defects and malformations of the bile ducts. (*c*) Œdema of Glisson's capsule (Birch-Hirschfeld's theory). (*d*) Weakness of the heart, especially its right side, pulmonary atelectasis, insufficient anastomoses of the veins of the umbilicus with the contiguous veins of the abdomen, syphilitic and other new growths, malformations and deformities of the liver, and other causes which lead to insufficient tension in the subdivisions of the portal vein, with consequent stasis, effusion of bile and resorption of the same into the circulation either directly by way of the hepatic veins, or indirectly by way of the lymphatics.

The relation of icterus to sepsis depends largely upon the conception which one has concerning sepsis. If we understand by sepsis the disturbing influence which is produced upon the body and its functions by microbes of decomposition which are conveyed to it from without and through the medium of a wound surface, there are undoubtedly certain cases of icterus in which sepsis plays an important part. The ordinary cases of icterus in which there is no particular disturbance of function are simply the result of hemoglobinæmia, which Silbermann considers physiological within certain limits. There are other cases in which the icterus is more profound, and the evidences of disturbance in the secretions more decided, but nothing which indicates the presence of pus in the system. The umbilicus in such cases has a healthy appearance, and there are none of the ordinary symptoms of phlebitis though the cases may proceed to a fatal issue.

In a third class of cases the skin may or may not be decidedly yellow, there is great constitutional disturbance with high temperature, dry tongue, and tender and swollen belly, there may also be chills and abscesses in the

parenchyma of the liver and elsewhere. The umbilicus is swollen and ulcerated, and pus or blood exudes from the arteries or veins, or both. Birch-Hirschfeld found in the blood of such patients both rod and spherical bacteria. Schüller and Vogel observed that this condition coexists with puerperal fever in the mother, and it is not improbable that the same element of infection is common to both. Between such cases, in which there are manifestly septic elements and conditions with more or less decided jaundice, and those in which the jaundice is due to an excess of hæmoglobin in the blood or to a resorption of bile, a clear and broad distinction can be made. The former are simply cases of septicæmia, the latter are cases of toxæmia, in the sense that the blood either contains a substance which is abnormal to it (the bile), or an excess of a normal element (the hæmoglobin).

CORRESPONDENCE.

COCAINE POISONING AND ITS ANTIDOTE.

To the Editor of THE MEDICAL NEWS,

SIR: I submit to you an interesting example of cocaine poisoning which came to me for treatment last fall. I was called up to attend the following case of cocaine poisoning in the person of a student who had been experimenting on himself by hypodermatic injections of a four per cent. solution of cocaine at regular intervals during the day, but they were not followed by its toxic influence until some four hours after its last exhibition. These were shown principally by irregularity of the circulation accompanied by cerebral excitement.

Patient's attacks came on in paroxysms whose onset were indicated by a steady, constant rise in the pulse accompanied by tinnitus and a sensation as though the head would burst. Capillary circulation somewhat interfered with, the extremities being colorless. At the height of the paroxysm patient grasped the head between the hands and labored under intense excitement lasting from thirty to sixty seconds, when there was a gradual decline in the pulse to normal (and sometimes below) and also of the cerebral symptoms, patient becoming quiet during the interim which lasted from one to two minutes, when the same cycle of symptoms were repeated. Pupils and tactile sensibility normal, respiration not markedly interfered with except at the height of the paroxysm, when it became more superficial and hurried.

Amyl nitrite seemed clearly indicated, and was used by inhalation with immediate relief, followed in a short time by an entire disappearance of all untoward symptoms.

Yours very truly,

F. P. EMERSON.

CHESTER, VERMONT, March 18, 1888.

NEWS ITEMS.

CINCINNATI.

(*From our Special Correspondent.*)

The American Medical Association.—A large attendance is anticipated for the approaching meeting of the American Medical Association at Cincinnati; that it will be of interest and profit to its members is confidently expected. Cincinnati is especially adapted by location and her excellent railroad facilities to the reception of the Association. The city is easy of access from every quarter; and her hotel accommodations are abundant. The Committee on Transportation report that it has secured the customary reduction of fare (full rates to the meetings, and one-third rates returning) over all roads.

The Committee of Arrangements, under the efficient leadership of Dr. W. W. Dawson, has been for some time actively engaged in preparing for the event. The great Music Hall has been selected as the place of meeting, as it affords ample facilities for the holding, not only of the general sessions, but of all the sections as well. It is also easy of access from all the hotels, and by street railways from every part of the city.

As is usually the case, the titles of papers to be read are not promptly reported, and the programme is still very incomplete. It is, therefore, impossible to judge, as yet, of the amount or character of scientific work to be done.

One of the most interesting features of the meeting will be the exhibition of drugs, books, surgical instruments, etc. In this feature the meeting is expected to excel. This is due chiefly to the fact that arrangements have been made to retain many of the exhibits for the Centennial Exhibition of the Ohio Valley and Central States, which begins here on July 4th.

The entire programme for the entertainment of visitors has not yet been made known. It is generally understood, however, that there will be a large reception at the Art Museum, and a grand concert at the Music Hall. Every effort will be made to render the visit of the Association enjoyable, without losing sight of its scientific interest. Nothing is more desired by the profession here than that the coming meeting should strengthen the bonds of friendship between the members of the Association, and it is hoped that the meeting in May will be memorable for the large number of men coming from every quarter of the country who have at heart the well-being of the Association, the interests of the profession, and the advancement of medical science.

Bandage Cases in Switzerland.—Col. Ziegler, physician-in-chief to the Swiss army, has introduced the use of a dressing or bandage case which will be exceedingly useful to the soldier in the field. Captain Secretan has lately given a very interesting lecture on this subject, in which he says: "Col. Ziegler, with the aid of Dr. Kocher, of Berne, has had made some very practical small cases. They contain a muslin bandage, about six feet in length, in a wrapper of parchment paper. There is sufficient gauze to make a provisional antiseptic dressing for wounds of small dimensions; for instance, such as those caused by bullets. This is very important, as every one knows these wounds are less dangerous the sooner they are protected from infection. It was at first intended to distribute these cases to the men, as is done in Germany, where each soldier is provided with a small box of dressing, sewn into the flap of his tunic between the lining and the cloth; but practice has shown the evils of this system. Nine times out of ten, when the dressing was needed, it was found soiled by perspiration and dust, deteriorated by damp, or that the soldier had used it for other purposes. Therefore, these cases will not be distributed to the troops. They will be wrapped up in packets of five in an envelope of waterproof paper

bearing instructions as to their use, in three languages, and they will be kept in the store. The doctors will have them in their cases in reserve, the ambulance corps in their knapsacks, and they can be ultimately distributed to the patrols, to guards, and to isolated detachments where medical care might momentarily fail."

A Double Monster.—The *Madagascar Times* reports that a Malagsy woman in Antanarivo gave birth to a double female child. The child had four eyes, two noses, four ears, four arms, two mouths, and four legs, but only one head and one body. Both parts of the child were female. Both the mouths uttered sounds, but only one suckled the mother. The sight was so strange that the babe was put to death on the second day, and the mother, we are told, is severely ill from fright.

A Lack of Military Surgeons in France.—A recent competitive examination for the French army medical service failed to attract a single candidate.

Gelatine Plaster Casts for Anatomical Specimens.—Some time ago Mr. C. W. Cathcart, M.B. (Edinburgh Infirmary), proposed a new basis for making casts of anatomical specimens. The basis is made as follows: Take of "No. 1" gelatine, say six ounces, soak it till quite soft and swelled, afterward dry it slowly until just pliable. As it has now the minimum of water necessary, melt it in a water bath, and add six ounces (measure) of clear glycerine. When the two are thoroughly mixed, the material is ready. To render it opaque, add while it is still hot, and therefore fluid, small quantities of a thick paint made by rubbing up oxide of zinc in glycerine. When a skin color is wanted, a little vermilion is required to give a warm, life-like hue. Should other things be cast, the prevailing color can be given with water color as required (tubes of moist water color sold at two pence each will be found convenient). Several pounds of this mixture may be made at once, and portions used as required.—*Scientific American*, March 3, 1888.

The Anthropometrical Method of Identifying Criminals.—*Science* of March 30, 1888, writes that the anthropometrical method of identifying criminals, originating in Paris, has been adopted in the prison at Joliet, Ill. In addition to the photograph of the prisoner, accurate measurements of his height, the length and width of his head, the length of the left middle and little finger, of the foot, the forearm, the ear, the stretch of the arms, description of scars, color of the eyes, and so on, are recorded; and it is thus possible to identify prisoners assuming false names with far greater ease than was before possible. It is asserted that, in the two years that the system has been in operation in Paris, eight hundred and twenty-six habitual criminals arrested under assumed names have been identified. Besides the practical utility of the system, it amasses very valuable statistical data contributing toward the natural history of the criminal classes.

Death of Professor Combal.—The recent death of Combal, Professor of Clinical Medicine at Montpellier, is announced.

A Successful Removal of the Larynx.—Perossi reports in a Milan journal, *Caffé*, that there is now living in the vicinity of Indra an Italian, named Nesmini, whose larynx was removed in 1875. This was the first extirpation of the larynx done in Italy, and the fourth in Europe. The patient continues in comfortable health.

The Monopoly of Antipyrin.—The Society of Practical Medicine, of Paris, has discussed the question of the validity of the patent which covers the manufacture of antipyrin. Their report shows that under French law it is a medicine, and its manufacture cannot be controlled by patents. Druggists have a right to fill prescriptions for antipyrin, no matter by whom manufactured, if it be a correct chemical compound.—*Le Progrès Médical*, March 3, 1888.

The Bacteriology of Beer.—Grönlund, of Copenhagen, has studied the fermentation which at times gives to beer a peculiarly bitter and disagreeable taste. He found that this process in the beer was caused by a germ known as *Saccharomycetes Pastorianus I.* He advises the greatest cleanliness in the vessels used in brewing, frequent bacteriological examination of beer, and the use of only the purest yeast for manufacturing beer.—*Centralblatt für Bakteriologie*, No. 10, 1888.

The Cause of Cleopatra's Death. — Grand-Marais, of Nantes, has recently written a pamphlet to prove that the death of Cleopatra was caused, not by the bite of the asp, but by asphyxia from carbonic acid gas. He is led to this conclusion by the fact that her attendant women were found dead beside the Queen's bed, while no marks of a serpent's sting were found upon her body.—*Annales d'Hygiene*, March, 1888.

The Implantation of Teeth.—*Science* of March 23, 1888, writes that Dr. Yonger, of San Francisco, was the first dentist in this country to perform successfully the experiment of implanting teeth. This process is not to be confounded with transplanting teeth, which has been practised by dentists for many years. In the latter operation, a tooth freshly extracted is inserted in a socket from which one has just been drawn, and the parts unite, circulation between the jaw and the tooth is established, and the latter actually takes the place of its predecessor.

In Dr. Yonger's experiment, the tooth to be replaced has long been extracted, and the socket filled up with bony substance. He drills into the jaw, gouges out a new socket, and then, taking a tooth that has long been extracted, cleans it thoroughly, soaks it in bichloride of mercury, and inserts it in the socket just formed. This new tooth in due time becomes firmly anchored, and as serviceable as the original one before it became decayed. Dr. Yonger holds that the tooth is held in its place by the soft tissues surrounding it, and that the artificial socket has nothing to do with anchoring it.

The experiment described above was performed by Dr. G. M. Curtis, of Syracuse, N. Y., who afterward extracted the implanted tooth, and sent it to Dr. W. M. Gray, the microscopist of the Surgeon-General's Office, who has made a very careful examination of it. His experiments prove beyond question that the tooth so implanted is revived, the circulation is established between the socket and the implanted tooth, and that the socket does take an active part in anchoring the tooth. A tooth so implanted is much more firmly anchored in the jaw

than one of the originals, and, in the case referred to, the tooth was held so firmly that Dr. Curtis broke it in extracting it. Dr. Gray does not doubt that the soft tissues do take an active part in the operation, but he has proved his propositions in regard to the bone and the tooth beyond all question.

The Sense of Taste. — Bailey and Nichols are quoted by *Science* of March 23, 1888, in their report of recent experiments upon the sense of taste, as follows:

1. The sense of taste is vastly more delicate for bitter substances than for any others. It is possible to detect quinine in a solution that is only $\frac{1}{20000}$th strength of a sugar solution, and we have previously shown that quinine is only $\frac{1}{10}$th as bitter as strychnine.

2. The order of delicacy is, bitter, acid, salt, sugar, and alkali.

3. The sense of taste appears to be more delicate in women than in men. This is true in the case of all the substances excepting salt. As we had found a similar difference in favor of female observers in an earlier and independent set of experiments, which agreed in every essential particular with the results of the present test, we do not regard it as an accidental difference, or as likely to disappear in more extended investigations.

Marked differences in the delicacy of the sense of taste of different individuals were met with in the course of these experiments. There were persons who could place in the proper class, solutions containing one part of quinine in 500,000, and other substances in correspondingly high dilution, while some failed to detect solutions of more than three times the above strength. In how far this was due to education, we are unable to say. Among the men examined were many who have been accustomed to handling and recognizing drugs and medicines, and yet even these were frequently surpassed by female observers who had no such training.

Suicide by Opium in China.—A Catholic paper published in China prints a statement of a startling description with respect to opium poisoning. Opium is the general medium for suicide in China, and the remedy which is recommended, namely, to make the would-be suicide swallow the blood of a live duck as an emetic, may be passed by with a smile—although, should it act as an emetic, it may, perhaps, be as useful as any other. The statement that follows, however, is more worthy of attention, for the native paper says that there is reason to doubt if the supposed successful suicides actually die at all, as the official exhumation of many bodies shows that after the fumes have evaporated the buried persons have struggled violently to free themselves. There are many well-attested instances of persons having been buried alive, and it is generally supposed that they have been the victims of a sort of trance closely simulating death.—*Indian Medical Gazette*, January, 1888.

Removal of a University Professor for Scandal.—A professor in the University of Padua has been recently suspended from office by the Government for furthering dissension among his colleagues and diffusing scandal.

A Novel by Dr. Richardson.—Dr. Benjamin Ward Richardson has written a novel, called "The Story of a Star; a Romance of the Second Century." Its plot is laid in the last struggle of the Jewish people for national independence. Messrs. Longman & Co., London, will shortly publish it in three volumes.

A Domestic Remedy for Ivy Poisoning.—Duffield writes to the *Scientific American* of March 24, 1888, as follows:

For many years I suffered terribly from this cause, but remembering that all poisons are acids, and that alkalies neutralize acids, I bathed the poisoned member in a strong lye made from wood ashes and obtained instant relief. Subsequently I found that the dry ashes alone, rubbed over the poisoned member, were equally effective. Since this discovery, I have had no further trouble, and having tried this simple remedy repeatedly on myself and on many others, with like good results, I am now thoroughly convinced that wood ashes will in every case prove a sure and sovereign specific for all cases of ivy poison.

Poisoning by Common Insect Powder. — A child, in Toronto, swallowed two drachms of common insect powder, and tetanic symptoms, with coma, followed. Death, however, was averted. Such symptoms as these are rare, and show that the various species of pyrethrum are not quite free from toxic properties.—*American Druggist.*

Professor Scanzoni.—The *Medical Press* writes that the celebrated professor of midwifery, of Würzburg, Scanzoni, bade last week an adieu to his professoriate. Although living for so many years in Germany, he was born in Prague in 1821, where he for some time performed the duties of clinical assistant in the Lying-in Hospital. In his valedictory lecture to the students he told them how in the fifties he had but little practice and plenty of time for literary activity. He was then summoned to Russia to attend the Empress, after which, at a bound, he became the most sought after obstetrician in Germany. Since that time his opportunities for literary work have been but few.

The Difficulties of Medical Journalism in Russia.—The *Medical Press* announces that in consequence of the confiscation of three articles by the official Censor, the appearance of the February number of the *Medizinskoïe Obosrenïe*, a leading Russian medical review has been delayed a month.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM MARCH 27 TO APRIL 2, 1888.

CROSBY, W. D., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for two weeks.—*S. O 29, Department of Arizona*, March 16, 1888.

AZPELL, THOMAS F., *Captain and Assistant Surgeon* (retired).—Died March 12, 1888, at Fort Lee, N. J.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

ORIGINAL LECTURES.

THE CARTWRIGHT LECTURES.
ON THE GENERAL PATHOLOGY OF FEVER.

Delivered before the Association of the Alumni of the College of Physicians and Surgeons, New York, March 29, 1888.

BY WILLIAM H. WELCH, M.D.,

PROFESSOR OF PATHOLOGY, JOHNS HOPKINS UNIVERSITY, BALTIMORE.

LECTURE I.

THE NATURE OF FEVER.

(Concluded from page 371.)

THAT the heat-regulating mechanism, although profoundly disturbed, is not entirely paralyzed in fever, is proven by the effect of heat and cold upon fevered individuals. Although Colasanti believed that his fevered guinea-pig had lost all power of heat regulation under varying external temperatures, a similar conclusion has not been reached by others who have investigated this question.

We can best describe the condition of heat regulation in fever as unstable or ataxic. External cold stimulates to some extent the heat production of an individual in fever, but by no means as much as it does in health. A person in fever is not able to maintain his bodily temperature under the influence of heat and cold to the same degree that he can under normal conditions. Liebermeister, as is well known, held that heat regulation in fever is simply adjusted for a higher point, although he admits not perfectly adjusted. Experience shows that this so-called adjustment is so unstable that it does not seem proper to compare it with that to normal temperatures in health, so that it is not clear what deep meaning lies in Liebermeister's idea.

We cannot imagine the heat-regulating mechanism to be other than a nervous one.

Some years ago this was about as far as the theory of the mechanism of fever could be carried. All paths led to this mysterious nervous apparatus, and beyond this nearly all was speculation. We stood, as has been said, before imposing processes veiled in the deepest obscurity. Since then the veil has been lifted here and there and we have caught glimpses of the nature of these processes. I refer particularly to the results of researches which have brought to light a more immediate and direct dependence upon nerve energy, than had been supposed, of chemical processes concerned in the disintegration and construction of tissue, and, therefore, in the production of heat.

With one side of the nervous mechanism concerned in temperature regulation, the classical investigations of Claude Bernard have made us tolerably familiar. This is the vaso-motor nervous apparatus presiding over the circulation of blood in the superficial parts of the body, and thereby controlling in great measure the discharge of heat. That the important part taken by the perspiration in the dissipation of heat is likewise under nervous influence, has been demonstrated by Luchsinger. The facts concerning this side of the regulation of heat are too well known to require elucidation on this occasion.

Heat regulation, however, is effected not only by variations in the elimination of heat, but also by changes in the production of heat. Familiar as the fact is, it can never cease to arouse our admiration that the temperature of the body remains the same in cold and in warm atmospheres. Man has become so dependent upon clothing that in the naked condition his capacity of preserving his normal temperature in a cold environment is much less than that of most animals. Pflüger has demonstrated that the heat regulation under varying external temperatures is accomplished by changes both in heat production and in heat loss, so that in a cold atmosphere more heat is produced and in a warm atmosphere less heat, provided the external temperature is not so high or so low as to make it physically impossible to preserve the body temperature. It is evident that this is the most rational and economical method of retaining the internal temperature of the body. To regulate the body temperature simply by variations in the discharge of heat, as was formerly supposed to be the method, would be, as has been said, like regulating the temperature of our rooms summer and winter by opening and shutting the windows without controlling the source of heat.

A heat-producing or thermogenic apparatus, therefore, is no less a part of the heat-regulating mechanism than is the heat-discharging or thermolytic apparatus, to use the terms employed by Foster. As the thermogenic apparatus is less generally understood it is not permissible to dismiss its physiology in this connection so briefly as I have the thermolytic, although our knowledge of the former is very imperfect.

I can assume that the convincing reasons are known to you which have led physiologists to conclude that most of the animal heat is produced in the muscles and the glands, and that the muscles have the larger share in this function. It is also well known that stimulation of secretory and motor nerves causes not only visible physical alterations in the glands and muscles, but also production of heat. This sort of dependence of heat production upon innervation has been long admitted. It may, however, not be so generally known that there are reasons to believe that nervous impulses control chemical changes which result in the production of heat independently of visible physical alterations of the tissues; in other words, that heat production or thermogenesis is at least in considerable part under the immediate and direct control of the nervous system. The idea is not a new one, and was advocated especially by Claude Bernard. Recent discoveries, however, have given it unexpected support.

This subject of the relation of innervation to thermo-

genesis is most pertinent to the pathology of fever, but it is essentially a physiological one, and as I wish to confine to a single lecture what I have to say concerning the theory of fever, it is impossible for me to do more than summarize the most essential points belonging here. This I can do the more readily as Dr. MacAlister,[1] in his admirable Goulstonian Lectures on the "Nature of Fever," which were delivered last year, has clearly and forcibly presented the main facts.

The larger part of these facts relate to the chemical changes and heat production of muscles under varying conditions.

That a large part of the chemical changes in a muscle in the condition which we call repose is under the influence of the nervous system, is made apparent by the great diminution in its consumption of oxygen and formation of carbonic acid, which follows the separation of the muscle from all connection with the central nervous system. This is conclusively shown by the experiments of Bernard, Pflüger, von Frey, and others. It is, of course, possible, and it has generally been supposed that under these circumstances it is simply the withdrawal of motor impulses which lowers the heat-producing energy of the muscle.

Far more suggestive as regards the point under consideration are the results of investigations which have been carried on in Ludwig's laboratory by Meade Smith, MacAlister, and Lukjanow. These experimenters have shown that heat production and contraction are in a measure independent properties of the muscle. By various influences the thermogenic property may be so impaired that a stimulus causes contraction with scarcely any development of heat. The laws governing the restoration and the fatigue of the thermogenic function differ from those controlling the mechanical function. These researches, upon which I here only touch, have made it extremely probable that there are in the muscle chemical processes resulting mainly in the production of heat and chemical processes causing mainly contraction, and that these processes, although coördinate, are not identical. A new light is shed upon the meaning of the term chemical tonus of muscle, which has for some time been used by some physiologists. Great caution is properly exercised by Ludwig and his pupils in the interpretation of these interesting results. They do not infer from them, necessarily, the existence of so-called thermic or calorific nerves. They suggest that it is possible to explain the phenomena upon the supposition that there are in the muscle two kinds of material, thermogenic and contractile, and the nervous impulses acting upon these may pass through the same set of nerves.

Proof of the existence in connection with muscles of thermic in distinction from motor nerves, would be afforded if we could succeed, after paralysis of the motor nerves, in exciting by nerve stimulation the thermogenic function of the muscle. We possess, in curare, a drug which paralyzes the terminations of the motor nerves. Meade Smith attempted by its aid to determine whether possible thermic nerves may be differentiated from motor, but he reached no positive conclusion on this point. There are, however, on record some observations which suggest the possibility that in moderate doses curare may leave intact thermic nerves after the suspension of the function of motor nerves. When an animal is profoundly under the influence of curare the internal temperature falls, and the processes of oxidation are greatly reduced. The animal is no longer able to resist the changes of external temperature, its own temperature rising and falling like that of a cold-blooded animal when exposed to heat or cold. This effect of curare poisoning is another proof of the dependence of heat production upon nervous influences. Claude Bernard in his early researches on the action of curare noted elevation of temperature soon after its administration. Voison and Lionville[1] observed after subcutaneous injections of curare in man rigors, perspiration, headache, and elevation of temperature to 104.7° F. They attribute to curare the power of producing all of the essential phenomena of fever. Fleischer[2] noticed in dogs and in rabbits rise of temperature after curare injections, and the same was observed in a rabbit in one case by Högyes.[3] Recently Mosso[4] claims that an animal may be placed so far under the influence of curare as to paralyze completely the voluntary muscles, and the internal temperature either remain normal or rise. He infers that these moderate doses of curare, although sufficient to paralyze the motor nerves, must have left intact the thermic nerves. That rise of internal temperature is not due to retention of heat, he thinks is evident from the normal or elevated temperature of the skin. Mosso is strengthened still further in his conclusion as to the existence of thermic nerves, by finding that after complete paralysis of the motor nerves by curare injections of strychnine cause an elevation of rectal temperature, which may amount to three degrees centigrade. Under these circumstances strychnine produces no spasms or other visible mechanical effect upon the muscles. Mosso brings forward a number of other experiments (decidedly open to criticism) intended to demonstrate the existence of nerves directly controlling heat production, but those which I have mentioned are by far the most striking. It seems to me that the natural interpretation of these experiments is in favor of the view that there are nerves controlling heat production in the muscle distinct from motor nerves. Far more conclusive as to this point than thermometric observations would be calorimetric experiments determining the heat production of animals under varying doses of curare.

This whole line of experimentation directed toward the differentiation of the mechanical and the chemical functions of muscle is certainly most suggestive, but so long as the interpretation of the results is not perfectly clear, we should be very guarded in drawing far-reaching conclusions. I cannot refrain, however, from pointing out that, as mentioned by MacAlister, all of these thermogenic phenomena may be found eventually to depend upon nerves whose chief function, on the one hand, is the disintegration, the metabolism of tissue, and, on the other hand, the restoration, the anabolism of tissue. From the study of the electrical changes which stimulation of the pneumogastric nerve produces in the heart muscle, Gaskell concludes that this nerve puts the heart in a condition of relative rest during which the energy of the muscle is increased. During this period there is reason to believe

that the material of the muscle, which, when disintegrated, gives rise to heat and mechanical work, is in the process of restoration. Hence Gaskell speaks of the pneumogastric or inhibitory nerve of the heart as anabolic—that is, it directs the restorative, formative, anabolic processes in the muscle. On the other hand, the accelerator nerve of the heart induces the opposite electrical changes in the heart muscle. Gaskell describes this nerve as katabolic—that is, its stimulation causes disintegration of the muscle materials, and liberates energy in the form of heat and of mechanical work. If it be found that similar inhibitory and accelerator nerves preside over the chemical changes in the voluntary muscles and other tissues of the body, then Gaskell's induction as to the existence of anabolic and katabolic nerves must be regarded as one of the most important and profound in modern physiology. Thermo-excitory nerves we should then rank as katabolic, thermo-inhibitory as anabolic.

These investigations tending to demonstrate the independent existence of thermogenic properties in the muscles and possibly of nerves directly controlling thermogenesis, have prepared us for the consideration of the relation of the central nervous system to the heat-producing properties of the body. Here you will willingly permit me to confine my remarks to the more essential and best established facts, without entering into a full discussion of one of the most perplexing subjects in the physiology of the nervous system.

The clinical basis of the doctrine that lesions of the central nervous system influence directly the temperature of the body was laid by Sir Benjamin Brodie, who reported the well-known case of fracture of the cervical vertebræ and injury of the spinal cord followed within a few hours by a rise of temperature to 111° F. measured between the scrotum and the thigh. Since then many similar instances have been reported. It is well to remember, in framing theories on the basis of these cases, that there are also on record not a few instances in which apparently similar injuries of the same parts of the spinal cord have been followed by equally striking fall of temperature.

The experimental basis for the acceptance of an influence of the nervous system on temperature was laid by Bernard, in his celebrated experiments on the effects of division of the sympathetic nerve in the neck. Bernard interpreted the increased temperature of the ear following this operation as referable not only to the larger amount of blood in the part, but also to increased tissue metamorphosis and consequent heightened heat production. The latter part of this interpretation is not generally accepted. It may be said here that the common idea that an organ or tissue simply because it receives a larger supply of blood indulges in more active metabolism is opposed by the investigations of Pflüger, who finds that the amount of oxygen taken up by the cells depends in a far higher degree upon the state of their innervation at the time than it does upon the supply of oxygen. The demand of the tissues for oxygen is not increased simply because the supply is greater. The arguments upon which Pflüger bases this line of reasoning, although not without opposition, would dispose of the idea that when any considerable increase of heat production in the muscles occurs this can be explained simply by vasomotor changes. I mention this here, because the opinion has been advanced that a large part of the increased production of heat in fever and after certain injuries to the nervous system is referable simply to vasomotor changes in the muscles.

In 1866 Tscheschichin[1] published experiments which he interpreted as indicating the existence in the brain of centres which, when irritated, moderate the production of heat, and which he called heat-moderating or heat-inhibitory centres, and in the spinal cord of centres which when stimulated excite the production of heat, heat-excitive centres. These conclusions were not justified by the experiments, but they have been widely accepted.

I may here say that, in this connection, I use the term heat centre as a convenient and generally adopted one. There is a proper reaction against the prevailing misuse of the word centre for all sorts of little understood localization of nervous functions. It would undoubtedly be more accurate to use some such expression as thermically active region instead of heat centre.

It is not easy to reconcile the clinical fact that in human beings lesions of the spinal cord may be followed at once, or in a very short time, by extraordinary elevations of temperature with the results of experiments on animals. That the rise of temperature in human beings is not due to inflammatory fever is apparent from the rapidity with which it follows the injury. It cannot be explained by vasomotor lesions, for the paralysis of the vasomotor nerves accelerates the discharge of heat from the surface of the body. The high temperature can be explained on Tscheschichin's assumption. The lesion either stimulates the spinal thermogenic centres or removes the influence of the thermo-inhibitory centres. These clinical observations are the strongest support which has been found for the belief in the existence of centres in the spinal cord which accelerate heat production. Complete section of the cervical part of the spinal cord in a dog or a rabbit is, under ordinary conditions, always followed by a rapid fall of the internal temperature and diminished oxidation. These varying results in man and in animals have been explained by supposing that after section of the cervical cord, on the one hand, the discharge of heat is increased by dilatation of the superficial bloodvessels, in consequence of vasomotor paralysis; and, on the other hand, the production of heat is increased by withdrawal of thermo-inhibitory cerebral impulses. If, as ordinarily happens in dogs and smaller animals, the first factor predominates, then, in consequence of sinking of the internal temperature, the heat-producing processes are so reduced that the influence of the second factor is not manifest. The attempt has been made to test this explanation by placing the animal in a warm atmosphere. If thereby the heat discharge be reduced to a minimum, it is found that the internal temperature of the animal often rises more rapidly than that of a normal one under the same external conditions. Here thermometric observations are not conclusive as to the point to be tested, for the more rapid rise can be explained simply by failure of the heat-regulating mechanism. Wood's calorimetric experiments seem to show that there is greater heat production, under these circumstances, in the animal with cut cord. These experiments admit of various interpretations, but if they be regarded as establishing the assumption from which we started, then it is

1 Tscheschichin: Reichert und Du Bois-Reymond's Archiv, 1866.

evident that in man and in large animals the increased heat production after injury of the cord would not be so readily overcome by the increased discharge of heat from the surface, for, in proportion to its volume, a large animal has less surface than a small one. The interplay, therefore, of these opposing tendencies might cause different results, according to the size of the animals.

Tscheschichin found that a transverse section made at the junction of the pons and medulla oblongata is followed, in a short time, by rise of internal temperature. As the superficial temperature is also elevated, he concludes that there is no retention of heat; moreover, the section is made above the dominant vasomotor centre. Wood has shown by means of the calorimeter that after this operation there is actual increase in the production of heat. He, as well as Tscheschichin, interprets the experiment as indicating thermo-inhibitory centres above the lower border of the pons. Bruck and Günter[1] repeated and modified these experiments under Heidenhain's directions. Out of seven cases in which they separated the pons from the medulla, they observed in only two rise of temperature; of eleven cases in which they punctured the pons with a needle, in five they noted increased temperature. Heidenhain thinks these experiments indicate heat-exciting rather than heat-moderating centres, and it must be admitted that the evidence is not conclusive in support of either view.

By far the most interesting and conclusive experiments, showing the influence of the central nervous system on thermogenesis are those of Isaac Ott, followed by Richet, Aronsohn and Sachs, Baginsky, and Girard.[2] The observations of Ott, Richet, and Aronsohn and Sachs were made independently and at about the same time, but Ott was the pioneer. The experiments of Aronsohn and Sachs are reported with especial fulness and detail. These investigators found that if the skull of a rabbit be trephined at the junction of the coronal and sagittal suture, and a needle be passed vertically down so as to puncture the anterior part of the caudate nucleus near its median convexity, there follows a rise of temperature, which may amount to three degrees or more, and which may persist for two or three days. The rapidity and the duration of this elevation of temperature vary somewhat with the depth of the puncture, parts immediately beneath the caudate nucleus being also thermically active. Puncture of the overlying cortex or medullary substance has no such effect upon temperature. With the exception of some increase in the frequency of the respiration and of the pulse, the animal after puncture of the anterior median part of the caudate nucleus presents no abnormal symptom other than the rise of temperature.

I have several times repeated this experiment and always with the result described. That the pyrexia induced by puncture of the caudate nucleus is not due to vasomotor changes causing retention of heat, is proven by Richet's and Ott's calorimetric experiments, and by the determination by Aronsohn and Sachs that the consumption of oxygen and the elimination of carbonic acid, and urinary nitrogen are increased. Aronsohn and Sachs and Girard find that electrical stimulation of the anterior median part of the caudate nucleus causes the same thermic phenomena as the puncture, and they, therefore, conclude that this region contains a thermo-excitor heat centre. This is the natural interpretation of their experiment, although Baginsky and Ott regard the centre as thermo-inhibitory on grounds which cannot be considered convincing.

Ott claims that there are four cerebral heat centres, one about the corpus striatum, the second in the caudate nucleus, the third in the anterior inner end of the optic thalamus, and the fourth near the median line between the optic thalamus and the corpus striatum. The greatest rise of temperature he found after injury of the thalamic centre.

No adequate demonstration has been afforded of any influence of the cerebral hemispheres upon thermogenesis. Corin and van Beneden[1] find that pigeons, after removal of their cerebral hemispheres, exhibit no change of temperature, no failure of the heat-regulating mechanism, and no alteration in the excretion of carbonic acid.

I have endeavored to present to you the main physiological facts bearing upon the relation of the nervous system to thermogenesis. It must be admitted that we are left to surmise as to the interpretations of many of the facts, and particularly as to their connection with each other. But certain important points come out clearly. We have found evidence of the existence in the body of chemical processes resulting chiefly in the production of heat energy. We have learned that these processes are under the direct control of the nervous system, and possibly of nerves distinct from those now recognized as motor or secretory. We have seen that there are regions in the central nervous system which are doubtless in some way connected with these nerves, and through them control the chemical processes resulting in the production of heat.

The bearing of these facts upon the theory of fever is evident. The study of heat production and of heat loss in fever has led us, by arguments which need not be repeated, to the conclusion that the pyrogenic agent must in some way act upon the heat-regulating mechanism. The study of this mechanism, more particularly of its thermogenic side, affords some insight into the manner in which the fever-producing agent may affect the regulation of heat. The main difficulty in the neurotic theory of fever has been to understand how by any action of the fever-producing agent directly upon the nervous system the chemical processes leading to heat production could be stimulated. I have dwelt thus at length upon the innervation of thermogenesis to show that this difficulty has been in great part overcome.

To some it seems more reasonable to suppose that the pyrogenic agent circulating in the blood acts directly upon the tissues, altering and stimulating their chemical changes. This is the hæmic theory, which, in some form, has always stood over against the neurotic theory of fever. Although it may at first glance appear simpler, the hæmic theory is really the more complicated, for it has already been set forth that we cannot explain fever simply by increased heat production, so that even if the primary effect of the fever agent were upon the heat-pro-

[1] Corin and van Beneden: Arch. de Biol., 1887.

ducing processes there must be a secondary influence upon the nervous system, for heat dissipation is no less disturbed than heat production.

If an animal be thoroughly curarized so that no impulses from the nervous centres can reach the muscles, the great heat producers, then it is found to be impossible to produce febrile elevation of temperature by the injection of pyrogenic agents. This fact, first demonstrated by Zuntz, is justly held to weigh heavily in favor of the neurotic theory of fever.

Contrary to the results of Murri,[1] I have not been able to induce rise of temperature or check its fall by the injection of pyrogenic agents into the jugular veins of dogs whose spinal cords have been cut in the lower cervical region. In these experiments I have employed various pyrogenic agents, and especially pepsin and papoid. One specimen of the latter which I used possessed very striking pyrogenic properties.

The pyrexia produced by puncture of the caudate nucleus in the manner already described, possesses all of the essential properties of fever, regarded as abnormal elevation of temperature. In this experimental condition there are increased production of heat, increased dissipation of heat, excessive elimination of urea and of carbonic acid, and excessive absorption of oxygen. The breathing and the pulse are increased in frequency. The elevation of temperature (usually after a brief fall) begins within half an hour after the puncture, attains a febrile height and persists sometimes for days. As no observations exist as to the heat regulation of these animals, I have made experiments on rabbits after puncture of the caudate nucleus, by placing them in a cold environment and in a box heated to various temperatures, and I find that their power of temperature regulation is less than that of normal animals.

These animals, in a word, present all of the essential symptoms of fever, and I do not know why we should not call the condition fever. If so, we must admit that injury to a circumscribed definite region of the brain is capable of causing fever. This experiment, therefore, is of the greatest importance in support of the neurotic doctrine of fever. It indicates, of course, that we may have fever of purely nervous orgin, without any pyrogenic agent in the blood. This experimental evidence is supported by the clinical cases collected by White in *Guy's Hospital Reports*, 1884. It is to be hoped that by careful thermometric study of focal brain and cord lesions a more accurate idea may be reached than is now possible of the topography of the thermically active regions in the central nervous system of man.

Admitting the dependence of fever upon the nervous system, I do not regard as particularly profitable with our present knowledge the discussion as to whether febrile thermogenesis is excited by the withdrawal of thermo-inhibitory impulses or by the stimulation of thermo-excitory nerves or nerve centres. If we regard, and there are forcible arguments for doing so, possible heat-inhibitory nerves as anabolic, and the heat-exciting nerves as katabolic, then inasmuch as the formative or anabolic processes are manifestly in abeyance in fever, we can reasonably infer that the function of the heat inhibitory nerves or centres is impaired. The phenomena of the febrile chill in which both the contractile and the thermogenic properties of muscle are stimulated, speak strongly in favor of direct irritation of the heat-exciting nerves in fever. We might infer, therefore, that both sets of nerves or nerve centres are affected.

But my aim in this lecture has been not so much to construct a theory of fever, a theory which, although it may be useful, must necessarily be largely speculative if it be coherent and rounded, but to bring before you the main facts concerning heat production, heat loss, and heat regulation in fever, and to point out the physiological basis on which their solution is to be expected.

LECTURE II.

Delivered April 5th.

THE EFFECTS OF INCREASED TEMPERATURE OF THE BODY.

In the last lecture I endeavored to bring before you the main facts which we possess bearing upon the explanation of febrile rise of temperature. After a review of our knowledge concerning heat production, heat dissipation, and heat regulation in fever, we were led to the conclusion that neither the changes hitherto observed in the production of heat nor those in the loss of heat suffice to explain febrile temperatures. Such an explanation seemed possible only upon the assumption that the fever-producing agents act either directly or indirectly upon the nervous mechanism controlling the relations to each other of the production and the discharge of heat. We then turned our attention to the relations of the nervous system to these processes, and found that the investigations of recent years have enabled us to obtain a much clearer conception than was formerly possible, of the manner in which the complicated heat relations in fever may be brought about by an action upon the nervous system. We found even substantial experimental basis in support of clinical facts which show that circumscribed lesions of certain parts of the central nervous system may induce directly febrile disturbances of animal heat.

To carry the subject further, to consider whether pyrogenic agents act primarily or only secondarily upon the processes concerned in heat production or upon those concerned in heat dissipation, or upon the apparatus regulating the relations to each other of these two sets of processes, to discuss whether these agents act directly upon the central nervous system, and if so upon what part; or upon the peripheral nerves or their terminations, or upon the tissues; to follow out more fully than we have done hitherto the themes here suggested would lead us with our present knowledge into a sea of speculation. We should find only here and there a faint light of fact to guide us. Even upon foundations as insecure as this speculations have their legitimate uses. A good hypothesis is a most valuable incentive to scientific work. It is not my purpose, however, to carry you with me further in this direction, although I realize that a single lecture has been far from sufficient for a thorough exposition of this subject.

After dismissing the considerations bearing upon the so-called theory of fever, there still remains a host of questions properly belonging to our subject. It is evidently impossible, even if it were desirable, that these lectures should include a discussion of all of these questions. I have, therefore, selected certain ones, partly be-

cause they seem to me of immediate interest and partly because I have given some attention to their study.

In the present lecture I wish to present to you some observations concerning the relation of elevation of temperature to other disorders of fever, and as to the question how far increased temperature is a source of danger in fever?

Here I may repeat that the word fever is used as a convenient name for a group of symptoms commonly associated together in febrile diseases. The association of these symptoms, however, is so loose that we regard only the dominant one—the increased temperature—as the essential criterion of the existence of fever. It saves circumlocution to adopt this somewhat vague and common signification of the term fever, although I think it would be an improvement to confine the term to abnormal elevation of temperature. The literature of fever is full of misapprehensions resulting from the various meanings attached to the word by different authors.

All of the bodily functions may be disordered in fevers. The various symptoms or classes of symptoms which are so commonly associated as to be regarded by many as belonging to the febrile process are, in addition to heightened temperature, increased frequency of the pulse and other circulatory disturbances, increased rapidity of respiration, muscular weakness, lessened secretions, disordered nutrition and digestion, and nervous symptoms.

What is the connection, if any, between these symptoms and the elevation of temperature? What degrees of elevated temperature are dangerous to life, and in what does the danger consist? This subject can, at least, claim the interest that attaches to the questions of the day. The various opinions which have been held by clinicians on these points are too well known to you to require an historical review. I need only remind you that until within a few years the views advocated with especial force for nearly thirty years by Liebermeister have prevailed, although not without considerable opposition. According to these views, the chief source of danger in uncomplicated essential fevers is the elevation of temperature, and the main indication for treatment is the reduction of temperature. Above all, it was urged with apparently convincing arguments that the weakness of the heart, which is undoubtedly one of the gravest dangers of fevers, is the direct effect of prolonged high temperature, and is manifested anatomically by parenchymatous or fatty degeneration of the cardiac muscle. Liebermeister sharply defined his position when he said, "A man whose temperature measures continuously 104° (40° C.) or more surely dies in consequence of the elevation of temperature, one in a few days, another after a somewhat longer time, according to the resistance of the individual." "If his temperature reaches 108.5° (42.5° C.) or more, then is he irrecoverably lost."[1]

At the present moment there is a decided reaction against these views, a reaction which in some quarters goes to the extent not only of denying that there is danger in febrile temperatures which do not exceed a very high point, but of asserting that the elevation of temperature is a beneficent provision, a most important *vis medicatrix naturæ*, which should not be checked by the interference of the physician. This reaction of opinion is plainly due, in great part, to the disappointment which has followed the high hopes raised by the discovery of a number of drugs which are admirable antithermic agents and, nevertheless, do not exert over febrile diseases that controlling influence which had been anticipated.

These questions, you may say, are clinical ones, and not much edification is to be expected from their discussion by a pathologist. So far as the propriety of the use of antipyretic agents or of any other mode of treatment in fever is concerned, it is true that the decision must be reached at the bedside and cannot and never should be controlled by the results of experimental pathology. But an appeal has properly been made to experimental pathology to shed light upon such questions as the effects of heat upon the functions of the whole body and of its various organs, and upon the causes of parenchymatous and fatty degenerations. The arguments advanced in support of the view that all of the characteristic symptoms of fever are directly dependent upon the increase of temperature and that high temperature is the chief source of danger, are derived no less from experimental pathology than from clinical observations.

Three methods have been employed to determine the effects of increased temperature in fever: one is to study the effects of external heat upon man and animals; the second is to examine in different fevers and in different cases of the same fever the relation of the temperature to the other symptoms, and to the general condition of the patient; and the third is to note the influence of reduction of temperature upon these symptoms. Each method has its limitations.

The condition produced by exposure to external heat, even if it be called thermic fever, is something quite different from ordinary fevers, and we cannot transfer the results obtained by this method directly to the explanation of febrile phenomena. On the other hand, in the clinical study of fevers it is very difficult and often an arbitrary matter to separate the effects of increased temperature from those of other factors nearly always present. Hence we find no agreement of opinion among physicians as to what symptoms or lesions in fever are referable to the heightened temperature, and what are due to infectious or other conditions often present. Even the frequent or constant association of certain symptoms with elevated temperatures and their subsidence or disappearance by reduction of temperature do not justify us in inferring that the high temperature is the cause of the symptoms, for both may be coördinate effects of the same cause, and the so-called antipyretic treatment may influence other conditions as well as the temperature. As has been frequently said of late, the high temperature may be rather an index of the severity of the disease than a source of danger in itself.

In hyperpyrexia and in many cases of insolation there can be no doubt that the high temperatures, as such, are the main elements of danger. But both of these conditions have important points of distinction from ordinary febrile processes. In hyperpyrexia there is probably almost complete paralysis of heat regulation, and we shall find that an analogous condition with similar dangers sometimes develops in animals artificially heated. The cases of insolation in which the high temperature is so dangerous are analogous to the condition which may be produced in animals by brusque elevation of the bodily temperature through exposure to heat, and which

[1] Liebermeister: Volkmann's Sammlung, No. 31, p. 240.

differs from that resulting from more gradual increase of temperature.

The most direct way of determining the influence of heat upon the body is to raise the internal temperature by the external application of heat. Here we are not disturbed by the presence of other factors, such as infection, which render doubtful so many of the conclusions derived from clinical observations as to the effects of high temperatures. For the solution of many problems it is evidently irrelevant whether the source of heat be within or without the body.

These experiments, if properly conducted, are calculated to shed much light upon many questions relating to the effects of febrile temperatures.

According to the testimony of all experimenters, a mammalian animal, artificially heated, dies when its internal temperature reaches 111.2° F. (44° C.) or 113° F. (45° C.). Death is preceded by convulsions and immediately or soon after death rigor mortis appears. At the moment of death the irritability of the heart and muscles ceases. Death seems to be due to heart paralysis, and the cause of this is usually set down as heat rigor, but this is not probable as death generally occurs at a temperature several degrees below that at which rigor of the heart muscle appears.

It is generally argued that temperatures several degrees below those which are fatal must exert toxic effects, and this conclusion seemed to be substantiated by the majority of experimenters, who found that animals whose temperatures were artificially raised to 105° F. (40.5° C.) or 107° F. (41.7° C.), or even to a lower point, manifested signs of illness. These latter results, however, are opposed to those obtained by Rosenthal, and especially Naunyn,[1] who points out that the conditions in most previous experiments were not favorable, as the animals were generally placed in small, dark, poorly ventilated metallic boxes. Naunyn succeeded in keeping a rabbit alive for thirteen days with an average temperature of 106.7° F. (41.5° C.).

Following Naunyn's example, I have had constructed a wooden box, three feet long, two feet high, and two feet broad, which fits closely within a double-walled galvanized iron box. The wooden box is provided with a perforated movable bottom, which allows the urine to escape. The space between the two walls of the iron box measures three inches across, and is filled with water, which, therefore, surrounds the inner box on all sides, except at the top, which is left open. The dimensions of this apparatus are somewhat larger than those of Naunyn's heating-box. A folded woollen blanket was drawn over each end of the box, so as to leave uncovered at least one-third, and generally more of the top. A rose burner placed underneath served to heat the box. At first a thermo-regulator was employed, but this was found unnecessary, as the temperature of the room varied but little, and there was no difficulty in keeping a sufficiently constant temperature in the box. The experiments were made upon rabbits, and only a single one was placed in the box at a time. Corrected thermometers were used. The temperature of the box was taken a short distance above the bottom, and that of the rabbit at a depth of three to four inches in the rectum. This occasion does not seem an appropriate one to describe these experiments in detail with their protocols. I shall take another opportunity for that, and at present give only a general account of those results which relate to the subject before us.

In the box described I have succeeded in keeping for three weeks two large black rabbits, the one with an average rectal temperature of 107.3° F. (41.8° C.), the other with an average temperature of 106.6° F. (41.4° C.). The rectal temperature fluctuated usually between 105.5° F. (40.8° C.) and 108° F. (42.2° C.), scarcely ever sinking below 105° F. (40.5° C.), but occasionally rising as high as 109.5° F. (43.1° C.). The temperature of the box varied between 96° F. (35.5° C.) and 106° F. (41.1° C.). The rabbits lay most of the time stretched out, breathing very rapidly. They took their food greedily, and did not appear ill. At the end of the experiment the first animal was removed from the box, and appearing perfectly well for ten days afterward it was used for another experiment; the second animal was killed at the end of the experiment, and presented marked fatty degeneration of the heart, liver, and kidneys. Both animals lost weight while in the box.

In these and similar experiments the rabbits were given only moist, green fodder, and were allowed to drink plenty of water, which they took eagerly. It is important for the success of the experiment that the temperature should be gradually, and not suddenly, raised.

Different rabbits offer varying degrees of resistance to the effects of high external temperature. It has seemed to me that black and gray rabbits surpass, in this respect, white rabbits. The same temperature of the box does not produce, in all cases, the same rectal temperature in different animals, or in the same animal at different times No factor is of more importance in determining the effects of external heat than the animal's power of temperature regulation. Failure of this power is manifested by a sudden rise of internal temperature, which may quickly attain a point incompatible with life. This event may take place without any alteration in the box temperature. The degree of internal temperature at which this paralysis of heat regulation occurs varies in different animals. One may be able to hold his temperature, for a short time, from further rise at as high a point as 109.5° F. (43.1° C.); in another, after the temperature has reached 107.6° F. (41.5° C.), there may occur, without any change in the box temperature, a sudden, and often fatal, elevation of temperature. In general, temperatures between 108° F. (42.2° C.) and 109° F. (42.8° C.) may be regarded as critical temperatures for these animals. One is forcibly reminded by these sudden and dangerous elevations of temperature of the occurrence of hyperpyrexia in certain fevers of human beings, and there is reason to believe that this, too, is caused by paralysis of heat regulation.

It seemed to me of some practical interest to determine what effect upon the rabbit's power of resisting high temperature is exerted by exhausting influences, particularly by anæmia. For this purpose rabbits which had been moderately bled, and others which had been used for some other experiments, were placed in the hot box. It was found that these animals are, although not without occasional exceptions, unmistakably less resistant to the effects of high temperatures than are robust animals. They succumb sooner, and at lower box temperatures.

We may now consider what inferences may be drawn

[1] Rosenthal: Zur Kenntniss der Wärmeregulirung u.s.w., Erlangen, 1872. Naunyn: Archiv f. exp. Path. u. Pharm., Bd. 18.

from these and similar experiments as to the effects of high bodily temperatures. It seems clear that a considerable part of the current arguments based upon experiments concerning the injurious effects of high temperatures must be revised in the light of Naunyn's experiments, and of those which I have briefly related. Because an animal may be killed by raising its temperature to 111° F. (43.9° C.), or 113° F. (45° C), it does not follow that an increase of temperature up to within 4° or 5° F. of this fatal point involves danger to life, or even any serious disturbance of the functions of the body. Although experiments in hot-air chambers show that in man brusque elevations of the temperature by only a few degrees give rise to serious symptoms, Krishaber[1] found that by habituation his temperature could be raised to 106.5° F. (41.4 C.), or 107.2° F. (41.8), without much discomfort. As small animals generally succumb more readily than large ones to artificial heating, it is not likely that the power of resistance in human beings is less than that found to exist in rabbits, and there is reason to believe that it is greater.

We cannot transfer directly to human beings the highest temperature at which we found rabbits can exist without serious discomfort save increased respiration. A rabbit's temperature is normally considerably higher than that of man, and apparently slight causes suffice to produce marked fluctuations. The normal rectal temperature of the rabbits used in my experiments was generally between 102° F. (38.9° C.) and 103° F. (39.4° C.). The highest average temperature at which a rabbit was kept for three weeks in the hot box exceeded, therefore, by 4° to 5° F. the average normal temperature. Such an increase would not correspond to a high febrile temperature in man. We can, however, with equal, and probably greater propriety, compare this temperature with that at which death surely occurs in a condition bordering on heat rigor. This temperature (111° to 113° F.) is probably about the same for man as for rabbits and other mammalians. From this point of view the inference may be drawn, although, of course, with much reserve, that human beings may tolerate temperatures of 107° F. (41.7° C.), or even higher, for a considerable time. This inference is supported by clinical observations, especially in cases of relapsing fever.

As already pointed out, the condition produced by artificial heating is not directly comparable with that in fever. In the former the loss of heat from the body is reduced to a minimum; the superficial temperature is three or more degrees higher than the internal, so that the average temperature of the whole body is higher than in fever with the same internal temperature. We cannot say, therefore, but that man may tolerate considerably higher internal temperatures when the elevation is brought about under conditions in which the discharge of heat is not checked than when the temperature is forced up by stopping heat dissipation. This would be proven if confidence could be placed in the enormous elevations of temperature reported by Teale and others. In these cases, however, even if authenticated, it is probable that heat is abnormally distributed in the body, and we cannot infer that the internal temperature is uniformly raised to such paradoxical heights.

It is of the utmost importance to bear in mind that, as my experiments have shown, not only do animals differ in their power of tolerating high temperatures of the body, but this resistance may be weakened by various depressing causes. Nothing would be more irrational than to conclude, because one individual in a certain condition can tolerate very high temperatures, another in a different condition possesses the same power. In fevers we have various factors, particularly infection, which we may well believe can lower the tolerance of high temperatures. That in some fevers, particularly relapsing fever, this does not appear, or only partially, does not disprove that in another fever, such as typhoid or pneumonia, the system may be placed by other factors of the disease in such a condition that even moderately high temperatures are injurious. It does not seem to me proper in these cases to lay, as some seem inclined to do, the sole stress upon the element of infection. This is in all likelihood the determining factor, but the practitioner cannot shut his eyes to the possibility that under its influence the high temperature, as such, is a source of danger to his patient.

With these restrictions I shall surely not be misunderstood when I assert that temperatures which are ranked as high febrile temperatures do not in themselves, independently of other factors, exert any such injurious influence as has been usually attributed to them.

Our attention up to this point has been directed to the effects of high temperatures upon the general condition of the body. It is of importance for the proper understanding of fever to determine the influence of heat upon the structure and functions of the various organs. To what extent can the febrile disorders of respiration, of circulation, of secretion, of nutrition, of innervation be attributed directly to the elevated temperature? These are questions which can be answered better by experimental methods than by clinical observation, for the latter has to deal with the effects of heat complicated by other circumstances whose influence cannot be accurately determined. The one method, however, should be made to control the other.

The most striking immediate effect of heat upon an animal is increased frequency of respiration. When a dog or a rabbit is placed in an atmosphere of 100° F. (37.8° C.), it at once begins to pant and the respiration may run up to 150° or more. The causation of this increased respiration, to which the name heat dyspnœa has been applied by Ackermann,[1] has been repeatedly investigated. Goldstein[2] in Fick's laboratory found that by applying to the carotid arteries tubes through which hot water is flowing the respirations may be greatly increased in frequency. Goldstein's experiment is usually cited as the crucial one, showing that the increased breathing is due to the effect of the heated blood upon the respiratory centres in the medulla oblongata. Sihler,[3] working in the Biological Laboratory of the Johns Hopkins University, however, has demonstrated that the increased respiration of an animal exposed to heat is due to two causes, warmed blood and stimulation of the skin by the heat, and that probaby skin stimulation is the more important factor. Some of Sihler's criticisms of Goldstein's experiments have been met by Gad and von Mertschin-

[2] Goldstein: Würzburger Verhandl., 1871.

[3] Sihler: Journal of Physiology, vol. ii., and Studies from the Biological Laboratory, Johns Hopkins University, Baltimore, vol. ii.

sky,[1] who have made it evident that increased temperature of the blood stimulates the respiratory centres, or increases their irritability. Section of the vagi does not check heat dyspnœa, so that this does not result primarily from the action of the increased temperature upon the terminal pulmonary expansion of these nerves. The removal of afferent impulses from the skin by section of the spinal cord does, however, exert so marked an influence that it cannot be doubted that heat stimulation of the skin is an important element in the causation. I have convinced myself of the correctness of Sihler's explanation by observing that in the hot box at temperatures of 90°–95° F. (32.2°–35° C.) rabbits often preserve their normal temperature, and still their breathing is markedly increased, and that, on the other hand, upon taking them out of the box the respirations may sink before the internal temperature begins to fall. In one striking experiment the respirations fell immediately to about normal upon removing from the hot box a rabbit whose skull had been trephined on each side of the median line, and the optic thalami punctured with a needle.

We cannot transfer directly to human beings the results of experiments on heat dyspnœa in animals, because in the latter respiration has a far more important function in temperature regulation than in the former. To keep cool a dog pants under circumstances when a man sweats. As heat regulation is largely influenced by the cutaneous temperature, it is not improbable that in man heat stimulation of the skin is less prominent than the warmed blood acting upon the respiratory centres in increasing the frequency of respiration in fever.

Inasmuch as disturbances of the heart and of the circulation in general are among the most important symptoms of fever it is natural that much attention should have been given to the study of the effects of heat upon the organs of circulation. The supposed injurious effects of prolonged high temperatures in fever have been usually attributed especially to some toxic action of heat upon the heart.

That the pulse-rate is quickened by artificially heating rabbits and dogs has long been known. The positive demonstration that this acceleration is due to the direct action of the heated blood upon the mammalian heart itself was first given by my colleague, Prof. Martin.[2] By conducting through the dog's heart, isolated physiologically by the ingenious method which he devised, Martin proved that the heart "beats quicker when supplied with warm blood and slower when cold blood is supplied to it; also, that the rate of beat depends much more upon the temperature of the blood in the coronary arteries than on its temperature in the right auricle or ventricle." These experiments make it unnecessary to recur to any action of the heated blood upon extrinsic cardiac nerves or nerve centres in order to explain the quickened pulse of fever. Moreover, Fick[3] found that the nervous centres of the heart and bloodvessels are unaffected by heating the blood flowing through the carotid arteries in the manner adopted by Goldstein in his experiments on heat dyspnœa.

[2] Martin: The Direct Influence of Gradual Variations of Temperature upon the Rate of Beat of the Dog's Heart, Philosophical Transactions of Royal Society, part ii. 1883.

[3] Fick: Pflüger's Archiv, Bd. v.

Prof. Martin has kindly permitted me in this connection to mention certain unpublished results of experiments which he is now conducting upon the effects of heat and cold on the isolated heart. As these results are pertinent to our subject I gladly avail myself of this privilege. The table of an experiment which I have examined shows that the isolated cat's heart beats regularly and more and more rapidly as the temperature of the blood is gradually raised to 111.2° F. (44° C.). At this point the beats become irregular, but are restored to their normal rhythm by feeding the heart with cooler blood. The temperature of about 111° F. (43.9° C.) appears to be a critical one for the isolated heart. Above 111.2° (44° C.) to 113° (45° C.) the pulsations become slower instead of quicker as the temperature is raised. At 122° F. (50° C.) the heart's action ceased, but the heart was made to beat again by supplying it with cooler blood, showing that the cessation was not due to heat rigor. This interesting experiment teaches among other things that very high temperatures may produce results differing not only in degree but also in kind from those of temperatures only a degree or two lower.

We may consider it then established that increased frequency of the pulse in fever is referable to the direct action of the warmer blood on the nervo-muscular substance of the heart itself. Clinical observation of cases of fever makes it evident that there may be and often are present other circumstances which influence the rapidity of the heart's pulsations, circumstances which in themselves may slow or may quicken the pulse. Large series of statistics, therefore, are required to bring out the ratio between the pulse-rate and the temperature in fever and even then for any given temperature the maximum and the minimum pulse-rates lie so far apart that the statement of the average increase in the frequency of the pulse for each degree of rise of temperature, such as has been computed by Liebermeister, has very little value.

Not only is the pulse-rate quickened in fever, but there are often other and more serious circulatory disturbances. In the fever produced in rabbits by injection of the swine plague bacillus I find a reduction of the blood-pressure measured in the carotid artery, and others have obtained similar results in the artificial fevers of animals. The determination of the blood-pressure in fevers of human beings by means of Basch's sphygmomanometer has given, in the hands of different experimenters[1] such contradictory results, that no conclusion can be drawn, unless it be the very probable one that the blood-pressure varies, being sometimes high, sometimes low, and sometimes normal in fever. That the arterial tension is often reduced is made evident by the marked dicrotism of the pulse wave. This dicrotism, however, characterizes particularly septic and typhoid types of fever and is absent during the chill of intermittent fever and often in exanthematous and some other fevers, so that we cannot consider the blood-pressure and arterial tension as having any such definite relation to fever as does the pulse-rate.

It has been observed by Paschutin, Senator, and Mendelson,[2] that the blood pressure rises with increasing

[1] Von Basch, Zadek, Arnheim, Wetzel.

[2] Paschutin, Ludwig's Arbeiten, 1873. Senator, DuBois-Reymond's Archiv, 1883, Supplement-Band. Mendelson, On the Renal Circulation during Fever, Amer. Journ. Medical Sciences, October, 1883.

bodily temperature, produced by exposure to heat. Mendelson found that the pressure begins to sink as the temperature approaches a point incompatible with life. In these experiments the animals were subjected to rapid elevations of temperature. I find that when a rabbit is gradually and cautiously heated in the hot box used in my experiments, the rise of temperature is less marked, and may not surpass even for temperatures of 107° F. (41.7° C.), the normal limits of variation which may be found in the blood-pressure of the same animal examined at different times. These measurements, however, are not very conclusive, for, as has been already remarked, rabbits which have been operated upon do not stand well artificial heating.

I have observed that the rhythmical contractions of the bloodvessels of the rabbit's ear are feeble or absent when the temperature is much elevated by artificial heating; whereas, it will be remembered that in experimental septic fever these contractions are irregular and exaggerated.

Upon the whole, I think that we are justified in concluding that the variations of arterial tension in fevers are much less dependent upon increased temperature than upon other factors, such as infection.

But the corner-stone of the doctrine which teaches that a chief source of danger in fevers is the elevation of temperature, is not the effect of increased temperature upon the pulse-rate or the arterial pressure, but it is the belief that prolonged high temperature exerts a directly paralyzing influence upon the heart. The main support of this belief is not the admitted fact that extremely high temperatures paralyze the heart, for these critical temperatures lie far above the ordinary high temperatures of fever, and in a region where all admit the dangers of the excessive internal heat. The stately superstructure has been built up chiefly on the basis of experiments showing that when the internal temperature of animals has been maintained for some time at a high point by exposure to external heat, parenchymatous or fatty degeneration of the heart muscle ensues. It is true that all experiments are not in accord upon this point, and that, as a rule, pathological anatomists have not given adherence to the doctrine that parenchymatous degenerations are chiefly dependent upon high temperature, still this doctrine has gained a wide acceptance among clinical men, and is advocated with especial force by Liebermeister. I have, therefore, thought it desirable in my experiments to give especial attention to this question.

Among previous experimenters on artificial heating of animals, Iwaschkewitsch, Wickham Legg, and Litten may be mentioned as finding parenchymatous or fatty degeneration of the heart, liver, and kidneys; and Walther, Obernier, and Naunyn as obtaining only negative results.

It is not necessary here to enter into a criticism of these different experiments, which are of very unequal value. Litten's[1] experiments on the one side, and Naunyn's[2] on the other, appear to be the most carefully conducted. Litten, whose experiments are those usually cited, kept guinea-pigs in a double-walled metallic box which was at a constant temperature of 98.8° F. (37° C.) with dry air, or of 96.6° F. (36° C.) with moist air. He never failed to find fatty degeneration at the end of thirty-six to forty-eight hours. The liver was first affected, and then the heart and kidneys, which become fatty by the second or third day. The animals did not survive longer than five or six days, and by that time the fatty degenerations had reached an extreme degree. Von Recklinghausen[1] urges with apparent justice against these experiments that the enforced inactivity of the muscles and the imperfect ventilation may have had as much to do in causing the degenerations as had the high temperature. These objections find support in the experiments of Naunyn, who, making use of a much larger and better ventilated heating box than Litten, failed to find any parenchymatous or fatty degeneration in his rabbits after they had been exposed for two weeks to higher temperatures than Litten employed.

As my experiments confirmed in other respects Naunyn's results, I was quite unprepared to find that my rabbits, after a variable period of artificial heating quite constantly presented fatty degeneration of the heart, liver, and kidneys, and sometimes of the diaphragmatic and intercostal muscles. I never found the degeneration at so early a period as did Litten. It was not until the rabbit had been kept for at least a week with an average rectal temperature of 106° F. (41.1° C.) that the degeneration was noticed, and then only in moderate degree. The higher and the less fluctuating the internal temperature, the more certain was the degeneration to appear. I could reckon upon obtaining rabbits with well-marked fatty degeneration of the heart, by keeping them for ten days with a rectal temperature between 107° F. (41.7° C.) and 108° F. (42.2° C.). I am not prepared to account for the discrepancy in this respect between Naunyn's and my experiments. The box used was larger than that employed by him, and every care was taken to keep it well ventilated by leaving at least one-third and often one-half of the top open.

I do not think that my experiments altogether do away with the force of von Recklinghausen's criticisms. The fact that in these experiments the degeneration made its appearance at the end of a week or ten days, and in Litten's in forty-eight hours, to say nothing of Wickham Legg finding it at the end of twelve hours, would suggest that if the rabbits were heated in a still larger and better ventilated apartment, the degeneration might not occur at all, or might be deferred to a much later period. In my opinion, however, even if full allowance be made for this line of argument, we must still admit that prolonged high temperature is a factor in the causation of fatty degeneration.

That it is not the sole factor no one can doubt. As is well known, fatty degeneration is produced by anæmia and by a variety of poisons, and even in fevers most pathologists are convinced that it bears a closer relation to the kind and the degree of infection than it does to the height of the temperature. It is more frequently absent than present in pneumonia, even where there have been symptoms of heart failure.

The kind of degeneration present in my rabbits was fatty and not parenchymatous. Probably all who make many post-mortem examinations will agree with von Recklinghausen, that altogether too liberal use has been made of the diagnosis of parenchymatous degeneration,

[1] Litten, Virchow's Archiv, Bd. 70. [2] Naunyn, op. cit.

[1] Von Recklinghausen: Handb. d. Allg. Pathologie d. Kreislause u. d. Ernährung, p. 512, Stuttgart, 1883.

and not sufficient account has been taken of the anatomical changes of the parenchyma produced by post-mortem chemical changes, such as acid formation, etc.

In order to determine what influence is exerted by infection combined with high temperature, I inoculated a rabbit, which had been in the hot box for four days, with the bacilli of swine plague. These bacilli, if not identical with, are closely allied to those of rabbit septicæmia, and are extremely virulent for rabbits. In thirty-six hours the animal, which had remained at a high temperature in the box, was dead, with characteristic lesions of the disease, and the most extreme fatty degeneration of the heart and other organs was found. As in other experiments the degeneration had not made its appearance at this early date, there can be no doubt that the infection was an important element in the causation. That it received powerful support in the high temperature, however, is proven by the fact that little or no degeneration of the heart is observed after infection with this organism when the animal is kept at ordinary temperatures.

Admitting, then, that high temperature aids in the causation of fatty degeneration of the heart in fever, the question arises, What do we know of the effects of this degeneration upon the functions of the heart? I will say nothing of the growing tendency to transfer a large part of the classical symptomatology of Quain's fatty heart to other conditions, particularly to disease of the coronary arteries and chronic myocarditis; we are concerned at present only with the occurrence of this degeneration in fever. Have we not been somewhat hasty in assigning to degenerations of the heart's muscle so large a share in the production of heart failure in fevers? One cannot look at a muscular fibre in which the striated substance is all replaced by fatty globules, and suppose that its functional activity was unimpaired; but into what serious errors should we fall if we attempted to deduce from the anatomical changes in the liver cells or the renal epithelium the corresponding functional disturbances? Certain it is that symptoms which are usually considered those of heart failure are often enough present in fevers without finding at the autopsy any degeneration of the heart; and, on the other hand, such degeneration may be discovered without any history of these symptoms, although, of course, the two are often associated.

In the face of these doubts it seemed desirable to determine, if possible, experimentally the damage inflicted upon the cardiac functions by the presence of fatty degeneration of the heart muscle. That this degeneration may exist without apparent injury is rendered probable by the fact that a rabbit which has been kept for three weeks in the hot box at a high temperature, and in which there is every reason to suppose that fatty degeneration has occurred, may present no symptoms of heart paralysis, and when removed from the box appear and remain perfectly normal. An instance has already been mentioned where one rabbit at the end of three weeks was killed and presented marked fatty degeneration of the heart; and another, which had possessed a higher average rectal temperature, was removed from the box at the end of the same period, and appeared for ten days perfectly normal, when it was used for another purpose. That this degeneration can be recovered from is, moreover, rendered probable by clinical experience, and is universally admitted.

Once in teasing out, in a warm room, a bit of fatty heart muscle from one of the rabbits, I made a curious observation. Near the edge of the cover glass, where there was a slight current in the physiological salt solution, rhythmical contraction was observed in a group of muscle-fibres. This interesting spectacle could be watched under the microscope for ten minutes. These contracting fibres were filled with fatty globules, and only here and there, and then indistinctly, could any trace of striation be detected. This observation teaches that a fatty degenerated muscular fibre is capable of contraction, but, of course, warrants no further conclusions.

Far more important than any inferences which can be drawn from such observations is the measurement of the actual blood-pressure in animals whose hearts have undergone fatty degeneration. This I have done in three instances. The rabbit was removed from the box at the end of ten days to two weeks, and the pressure in the carotid artery was measured by a mercury manometer attached to Ludwig's kymograph. In no instance was the blood-pressure found to be lower than that normally present in rabbits. In an experiment recently performed, the average pressure was 125 mm. of mercury; the pulsations were regular; the heart responded to stimulation of the vagi in an entirely normal manner. After such stimulation the pressure in one case rose to 176 mm. of mercury. Immediately after the measurement of the blood-pressure the rabbit, as in the previous instances, was killed, and marked fatty degeneration of the muscular fibres was found. In many of the fibres the striation could not be made out, and only fatty globules were visible; in others, which also contained fatty granules, the striation was distinct. The degeneration involved the whole muscular substance of the heart. A similar appearance in a human heart would be considered to indicate well-marked fatty degeneration.

These experiments show that a rabbit's heart which has undergone marked fatty degeneration from exposure to heat, may perform its functions, to all appearances, and for the time being, in a perfectly normal manner.

There is at least one consideration which should make us cautious in drawing far-reaching conclusions from these experiments. There are diseases of the heart—I need only refer to lesions of the coronary arteries—in which the functions of the organ are performed for a longer or shorter time, apparently in a perfectly normal way, and then heart failure suddenly appears. It is probable that here too the blood pressure would be found normal at a certain period of the disease, and still it would be an error to suppose that the lesion does not damage the heart.

Whatever force there may be in this analogy, I still think that these experiments, as well as careful pathological and clinical observations, necessitate some revision of the current opinions concerning the significance of fatty degeneration of the heart in fever.

So much time has been devoted to a consideration of the effects of heat upon the respiration and the heart that the limits of the present lecture will permit hardly more than a summary of the effects exerted by heat upon other functions and organs of the body. On account of the great clinical importance of the subject it seemed desirable to treat with especial fulness the influence of increased temperature on the heart.

What part has increased temperature in producing febrile consumption of tissue? In the first lecture men-

tion was made of Pflüger's experiments showing that animals with elevated temperature, produced by exposure to heat, absorb more oxygen and excrete more carbonic acid than at the normal temperature. This is in conformity with the general law that within certain limits cell activity is more energetic at high than at low temperatures. It was also shown in the first lecture that only a comparatively small part of the increased oxygen absorption and carbonic acid elimination in fever can be referred to the immediate effects of high temperature. It has not been demonstrated that the respiratory gases in human beings are increased by artificial elevation of temperature. Indeed, Voit[1] was unable to find any such effect of increased temperature in human beings on the respiratory gases as both he and Pflüger observed in animals.

Inasmuch as increased disintegration of nitrogenous material is such a prominent disorder in fever, much attention has naturally been given to determining how far this can be explained by elevated temperature. That it cannot all be so explained is proven by the interesting observation of Sydney Ringer, that excessive elimination of urea antedates the rise of temperature in intermittent fever, and Naunyn has found the same to be true of the septic fever of dogs. The experiments which have been made to determine the influence of artificial heating on the amount of urea excreted by man and by animals have yielded contradictory results. A number of these experiments are of little or no value, because no attention was given to establishing beforehand nitrogen equilibrium. Schleich's[2] experiments may be mentioned as, perhaps, the most accurate of those showing an increase in the urea excreted under the influence of exposure to heat. The more recent experiments of Simanowsky[3] were made in Voit's laboratory upon a dog with especial precautions as to the establishment of nitrogen equilibrium. He failed to find any increase in the excretion of urea as the result of exposure to external heat. While then this question must be left at present *sub judice*, there can be no doubt that only a part at least of the excessive disintegration of nitrogenous substance in fever can be assigned to the influence of the increased temperature.

The loss of weight exhibited by animals kept for a long time in a hot atmosphere is usually explained by the excessive evaporation of water from the body. In many of my experiments the rabbits were freely supplied with food and water, and still the loss of weight was very noticeable. I am inclined, therefore, to attribute to the increased temperature under these conditions a decided influence upon the consumption of tissue.

Senator[4] found the urine of rabbits artificially heated to contain more albumen than is ever found in the urine of healthy rabbits. This observation I have not been able to confirm on the rabbits in my experiments, and probably this difference is to be explained by the more rapid and intense heating employed in Senator's experiments. Senator explains the heat albuminuria by the rise of arterial pressure in the renal vessels, but this is not in conformity with the interesting experiments of Mendelson,[1] who found by means of Roy's oncometer that both in thermic and in septic fevers of dogs the kidney is anæmic, while the general blood-pressure is elevated.

No satisfactory explanation has yet been offered of the diminution of perspiration which distinguishes fever so strikingly from the condition produced by exposure to high external temperatures. Luchsinger's assertion that this is the result of lessened irritability of the sweat centres in the spinal cord remains to be proven, and at the best is not a satisfying explanation.

Bokai,[2] in a recent experimental research on intestinal peristalsis in thermic and in septic fevers, comes to the conclusion that the constipation of fever is to be explained by the heated blood stimulating the nerves inhibiting intestinal peristalsis. If this should be confirmed, then it would be proven that at least three symptoms of fever, the quickened respiration and pulse and the constipation, are direct effects of elevated temperature.

When we consider the important nutritive changes in the muscles accompanying increased thermogenesis, we shall be inclined to attribute in part, at least, to these alterations and the associated abnormal innervation, rather than to increased temperature, the muscular pains and weakness which form such an early and frequent complaint in many fevers.

The investigations hitherto published of changes in the blood produced by increased temperature within febrile limits are not of sufficiently definite and satisfactory nature to warrant any consideration on the present occasion.

Nor am I acquainted with any experimental evidence (save Bokai's work already mentioned) that increased temperature is concerned in the production of the digestive disorders of fever. It has already been said that the rabbits with high internal temperatures in the hot box ate greedily, but these voracious animals cannot be considered favorable subjects to test this question.

Especial emphasis has been laid by Liebermeister and those who accept his teachings upon the dependence of the nervous symptoms of fever, particularly the so-called typhoid symptoms, on the elevation of temperature. There is, however, abundant clinical evidence to disprove this doctrine. Reference need be made only to relapsing fever, and especially to the aseptic fever described by Genzmer and Volkmann, in which there is entire absence of the whole group of so-called nervous symptoms. Moreover, Liebermeister's opinion in this respect is not supported by adequate experimental evidence. Unless the temperature of the brain or of the entire animal be brusquely raised to a high point by coarse methods, no disturbance of the cerebral functions is noticed until the temperature reaches a critical point, beyond which further increase is likely to prove rapidly fatal. At this critical point the animal, which before has lain quietly, becomes very uneasy, and if the temperature rise higher it has convulsions and coma and dies.

I have endeavored to bring before you in this lecture the experimental evidence relating to the effects of increased temperature upon the general condition of the body and upon the functions of its various organs. I have given account, as briefly as possible, of some ex-

periments which perhaps shed additional light upon this important subject. In the course of this lecture emphasis has repeatedly been laid upon the necessity of controlling the results of the experimental method by clinical observation, and here and there I have endeavored to institute this control. Further than this I shall not attempt to set before you the clinical evidence regarding the effects of increased temperature in fever. There are those here more competent than I to deal with this side of the question. We may feel assured that when all the facts are before us and are properly interpreted, there can be no lack of harmony between the results of experimental and those of clinical investigations.

ORIGINAL ARTICLES.

A CASE OF CONSERVATIVE CÆSAREAN SECTION, TERMINATING IN RECOVERY.

By W. W. JAGGARD, M.D.,

PROFESSOR OF OBSTETRICS, CHICAGO MEDICAL COLLEGE; OBSTETRICIAN TO MERCY HOSPITAL.

I DESIRE to place on record the following case of conservative Cæsarean section performed under the relative indication, and terminating in recovery, and, in passing, beg to call attention to certain points of practical interest in connection with the indication for, and the technique of the operation.

Dr. P. Dougherty, of Chicago, a short time since invited me to see in consultation a case of alleged contracted pelvis. We examined the patient in the third week of February last, and elicited the following history:

CASE.—Mrs. E. S., thirty-six years old, born in Hillesheim in the region of the Eyfel Gebirge, Rhenish Prussia, married in the United States, October, 1880, shortly after immigration. She had been a sickly child, unable to walk until her seventh year on account of *Doppelglieder—i. e.*, rachitis. During infancy she suffered from tuberculosis of the cervical glands, two depressed cicatrices being visible on the left side of the neck at the time of examination. Since her seventh year she has enjoyed robust health.

Her mother gave birth to four children, of whom three were females. All of these labors were normal. Of the patient's two sisters, one has had normal confinements, while the other has been invariably delivered with the aid of instruments.

First pregnancy; patient's first child delivered May 13, 1882. Shoulder presentation, right-scapulo-anterior position. Difficult delivery after version and decapitation. Puerperium normal.

Second pregnancy; delivery June 20, 1883. Same presentation and position as in first pregnancy. Prolapsus of funis. Version, extraction, forceps to the after-coming head. Septicæmia, puerperium six weeks.

Third pregnancy; delivery October 4, 1884. Same presentation and position as in two former pregnancies. Version, extraction, craniotomy on after-coming head. Puerperium normal.

Fourth pregnancy; induction of premature labor at the end of the seventh lunar month. Same presentation and position as before. Version and difficult extraction. Child survived the operation a few hours. Puerperium normal.

Fifth pregnancy; beginning of last menstruation June 1, 1887. *Status præsens:* The patient, of strong frame and well-developed muscles, is four feet seven inches high, and weighs one hundred and thirty-five pounds. Pregnant, near term; distance from ensiform cartilage to pubes forty-five centimetres [17½ inches]; from ensiform cartilage to umbilicus, twenty-two centimetres [8¾ inches]; circumference around umbilicus, eighty-seven centimetres [34 inches]. Shoulder presentation, right-scapulo-anterior position. Pelvic measurements:

Distance between anterior superior spinous processes	27 cm. [10½ in.].
Distance between iliac crests	27 cm. [10½ in.].
External conjugate diameter (Baudelocque)	14 cm. [5½ in.].
Distance from sacro-coccygeal joint to subpubic ligament (A. G. E. Breisky)	9 cm. [3½ in.].
Distance between the great trochanters	30 cm. [11.7 in.].
Pelvic circumference (Kiwisch)	85 cm. [33¼ in.].
Diagonal conjugate diameter	7.5 cm. [2.9 in.].
True conjugate diameter (estimated)	5.5 cm. [2.14 in.].

Diagnosis: Simple, flat rachitic pelvis, with so-called absolute contraction of the true conjugate diameter. Apart from the pelvis, the osseous system showed no marked signs of rachitis. There was no abnormal spinal curvature, antero-posterior or lateral, and the long bones were perfectly straight.

Indication.—Notwithstanding the fact that the pelvis was a typical example of the so-called absolutely contracted, simple, flat, rachitic class, the history of former deliveries demonstrated plainly that the obstacle to the escape of the child through the natural passages was only relative, and not at all insurmountable. To explain the woman's survival of former labors it is not necessary to invoke extraordinary skill upon the part of the medical attendants—in all twelve in number—nor unusual physical endurance upon the part of the patient, although both conditions were doubtless supplied. Both parents were undersized, with relatively small heads, and the children were of a size less than is common. Moreover, the after-coming head invariably presented, and the accommodation of the passenger to the passages was thus greatly facilitated. The case was clearly one in which the woman could be delivered with safety in all probability by version, extraction, and craniotomy.

On the other hand, the child was living and Cæsarean section offered the possibility of saving both mother and child, although, of course, with enormously increased maternal risk.

The question of the induction of premature labor, so late in pregnancy, was not considered for obvious reasons. In a word, the relative indication for Cæsarean section was presented.

The most important condition upon which this indication rests at the present time, is the consent of the woman, obtained without direct or indirect

coercion. Accordingly a plain, unvarnished statement of all the facts in the case was made to the woman. She was clearly and distinctly informed that by destruction of the child her life would be almost certainly saved, and that the attempt to save both lives by Cæsarean section would be attended by great danger to herself. After a week's deliberation she elected the Cæsarean operation. In reaching this conclusion, she was assisted by the Roman Catholic priest of the parish. This gentleman remarked that the pregnant woman was the aggressor, that she had made the contract of maternity; the child was passive and had made no contract. In strict equity, entirely apart from ecclesiastical considerations, the child's claims to life should be considered at least equally with those of the mother.

Of course, as an operator, I was more pleased to perform Cæsarean section than craniotomy. However, I cannot forbear to reiterate here certain convictions which must always come up for discussion in similar cases. These propositions, I beg to submit if the expression be not too harsh, not so much as matters of opinion, as matters of fact.

1. The necessary maternal mortality of craniotomy, performed under the conditions demanded in Cæsarean section, with the best instruments and adequate skill, in cases of the contracted pelvis with a *conjugata vera* of six to eight centimetres, is zero. The maternal mortality of the conservative Cæsarean section is still considerable. The shock incident to the operation, entirely apart from sepsis and the loss of blood, is an element of danger that can never be completely eliminated. It is, perhaps, needless to remark that the necessary degree of operative skill, the necessary experience in Cæsarean section, and other conditions are much more difficult to supply.

2. The consent of the patient, obtained without direct or indirect coercion, is an essential condition to the relative indication. The time will probably come when the woman shall not be permitted to elect as freely as she must be allowed to do at present.

3. The life of the adult woman, who has already contracted relations with society, is of incomparably greater value, as judged by human standards, than the problematical existence of an unborn babe. Moreover, the expectancy of life in such children is decidedly less than in children of normal birth. If the operation is performed, as in the case under consideration, before the objective changes of labor are noticeable, there is the risk of the premature interruption of pregnancy, of obviously serious prognostic moment with reference to the child. The necessary, early ligature of the cord deprives the infant of an average amount of blood of ninety-two grammes (Budin, Ribemont). The mother is seldom able, even if she were to be permitted, to suckle her child. Finally, the offspring of women affected with rachitis or osteomalacia, are frequently feeble, sickly, unable to resist the unfavorable influences of the environment, entirely apart from the effect of hereditary disease.

Operation.—The patient at once entered Mercy Hospital. The urine was examined and found to be normal. The only preparatory treatment consisted in a daily bath, in tepid water, with the liberal use of soap, which the woman's mode of life before admission rendered necessary.

In the selection of the time for operation I had determined, acting upon Schroeder's advice, to choose the latest possible moment before labor actually began. The advantage of an aseptic genital canal, daylight, adequate assistance, and the like far outweigh the danger of insufficient uterine contraction and retraction after evacuation of the viscus. Of course, one runs the risk—of moment to the child—of interrupting pregnancy some time before term. From the usual data—date of last menstruation, size and position of the uterus, abdominal measurements, length of the child measured by callipers (Ahlfeld), estimate of the size and weight of the child by palpation (Carl Braun)—it was only possible in this case to make a probable diagnosis of the time of gestation. I concluded the woman was in the last fortnight of pregnancy.

Early Tuesday morning, March 6th, she informed me that she would certainly fall in labor within the next twenty-four hours. She based her prediction upon dull pain referable to the lumbar and sacral regions, and beginning painful uterine contractions. She had been enabled to foretell her other confinements by similar sensation, and I was inclined to attach considerable importance in this case to subjective signs. The only objective change, indicative of impending labor, was a slight increase in the force of the intermittent uterine contractions; accordingly, the hour for operation was fixed upon at one in the afternoon. All precautions were taken with respect to the most thorough cleanliness and disinfection of the operator, assistants, patient, instruments, and environment. Dr. W. E. Casselberry administered the anæsthetic, ether. Dr. E. C. Dudley, Dr. Bayard Holmes, Dr. G. W. Whitfield, Dr. B. L. Riese, Dr. M. Scheuer assisted me in the operation. Dr. P. Dougherty and Dr. Charles Caldwell assumed charge of the babe. I take this opportunity to make my grateful acknowledgements to these gentlemen for their efficient services.

The woman was in excellent condition, cheerful, pulse and temperature normal.

The steps in the operation were: after evacuation of the bladder, incision through the linea alba, from the navel to a short distance above the pubes, as low down as was safe on account of the bladder. The diastasis of the recti muscles was well marked, and the peritoneum was incised without dividing much muscular tissue. No omentum nor intestines pre-

sented between the uterus and anterior abdominal wall.

The median line of the uterus coincided with the incision, and the usual manipulation to correct lateral version and axial rotation was unnecessary. Before making the incision, Dr. Holmes placed one hand on either side of the cut, and rendered the abdominal parietes tense enough to prevent the access of fluid to the peritoneal cavity. I incised the anterior uterine wall in the median line at a point a short distance above the os internum with a scalpel, and rapidly enlarged the cut in the direction of the fundus to the extent of thirteen centimetres [5 inches], with a blunt-pointed bistoury. The thickness of the uterine wall was about one centimetre [⅓ of an inch]. The placenta was implanted over the line of incision, and the first gush of blood was frightful. The placenta was quickly separated by the hand, the amnion ruptured, the child caught by the feet, turned and delivered without any laceration of the uterine incision. The amnion was not previously ruptured *per vaginam*, because I had confidence in the ability of Dr. Holmes's hands to keep blood and liquor amnii out of the peritoneal cavity. The child uttered a lusty cry upon its liberation from the cavum uteri. I had requested an assistant to insert the index finger into the upper and lower angles of the uterine wound, and bring it up close to the abdominal incision as an additional precaution against the escape of fluid into the peritoneal cavity. In the hurry of the operation this request was forgotten. After, or rather during the evacuation of the uterine contents, Dr. Holmes, by his hands over the abdomen, pressed the uterus through the abdominal incision. When the organ was entirely without the peritoneal cavity it was enveloped in hot compresses of sterilized gauze, while Dr. Riese brought the edges of the abdominal incision together and effectually prevented any intestinal protrusion.

Hemorrhage was trifling after the contraction and retraction of the uterine musculature, following the escape of the fœtus and envelope, and was now fully controlled by Dr. Holmes, who firmly compressed the lower uterine segment with the thumbs and index fingers of both hands. I did not apply the elastic ligature around the lower uterine segment before or after the uterine incision on account of the danger of paralysis of the structures at and below the point of compression, a danger to which Sänger (*Transactions of Ninth International Medical Congress*), Doléris, and others have recently called attention. The amount of blood lost during the incision need not be much greater without than with the elastic ligature. It need not be much more than the amount of blood in the uterus at the time the incision is begun, provided subsequent procedures are executed quickly. After the uterus is empty, uterine contraction and retraction, aided by digital compression, render the further loss of blood insignificant.

Twenty-one deep sutures were inserted, including all the tissues down to the mucosa. For the introduction of these sutures, I used the long, slender laparotomy needle of Thomas Keith. This needle passes with astonishing ease through the thick uterine wall, making a very small puncture, which is completely filled up with the suture material—in this case silk. After passing a finger through the cervix from above downward, the uterine cavity was irrigated with a five per cent. solution of carbolic acid, a bacillus containing ninety grains of iodoform placed within, and the wound closed. Union of the peritoneum over the line of the incision was effected by a continuous silk suture. When the two rows of sutures had been drawn taut, the uterine wound was accurately closed and perfectly dry. The uterus, in a state of normal retraction, was returned to the cavity of the abdomen. The toilet of the peritoneum was brief, as no fluid had escaped into the abdominal cavity, and the intestines had not at any time protruded. The abdominal incision was closed with interrupted silk sutures.

The duration of the operation was about one and one-fourth hours. From the extraordinarily simple *technique*, it would seem that the operation had been needlessly prolonged. But the uterine sutures were inserted deliberately and with care; then, too, time was occupied in securing retraction by the application of hot compresses.

The total amount of blood lost was not great, scarcely more than the average loss in normal labors. The chief element of danger lay in the suddenness of the loss, but no indication arose for the employment of transfusion, the apparatus for which was in readiness.

The shock from the operation was profound, but brief. The patient fully reacted within three hours. Her convalescence was uninterrupted. The pulse at seven the same evening was rapid, 120 beats to the minute, tense, and small. It became gradually less frequent, less tense, until at the expiration of the first week, it was normal. The temperature remained nearly normal, showing slight variations in the second week. These variations were attributed to several severe burns, suffered as the result of the injudicious application of hot bottles immediately after the operation. On the third day the audible escape of flatus was noted, and about the same time the patient began to void urine spontaneously.

Tympanites was notable by its absence throughout the recovery. On the fifth day, the bowels were painlessly evacuated after the exhibition of citrate of magnesia, for which the patient expressed a preference.

The patient did not vomit at all, not even when she was recovering from the anæsthetic.

The lochial discharge was slight, odorless, and ceased at the expiration of two weeks. Lactation was not established. In all former confinements, the milk secretion was abundant. The uterus underwent rapid involution, and at the time of writing the vaginal portion and vagina show few traces of recent pregnancy. The patient returned to the ward at the end of the third week.

The child was a small, but perfectly formed, and apparently mature male; weight, 3000 grammes [8¾ lbs.]; length, 49 centimetres [19$\frac{1}{16}$ inches]. The infant thrived on artificial feeding until the sixteenth day, when, after exposure to cold, it died suddenly, in a convulsion. The autopsy disclosed intense pulmonary congestion. Although the child

was apparently well nourished, it is not improbable that inanition was a predisposing factor. The death of the child was a matter of regret, apart from other considerations, on account of the possible unfavorable influence on the mother. She, however, calmly bore the loss, feeling happy that she had given birth to a living child capable of baptism.

The diameters of the fœtal head were:

Occipito-frontal .	11 centimetres	[4.29 inches].
Occipito-mental .	12 "	[4.68 "].
Biparietal .	8¾ "	[3.4 "].

The following extract from a letter recently received from Dr. Robert P. Harris, is of general interest in this connection:

"Your case makes 16 Sänger-Cæsarean sections for the United States, with 7 recoveries; and 165 for the whole Cæsarean list, with 63 women saved.

"I have 12 cases on record for the last fifteen months, with 6 women and 9 children saved; yours makes the thirteenth. There were 8 operations in 1887, all Sänger's but one, with 4 women and 5 children saved. I have 3 cases in already for this year: one each, for January, February, and March; 1 woman and 3 children saved."

2330 Indiana Avenue, Chicago, Ill.
March 31, 1888.

AN AID TO THE DIAGNOSIS OF HEMORRHAGIC PLEURISY.

By FREDERICK P. HENRY, M.D.,
LECTURER ON BLOOD DISEASES AT THE JEFFERSON MEDICAL COLLEGE.

In a case of hemorrhagic pleurisy which I recently made the subject of a clinical lecture at the Philadelphia Hospital, I derived valuable diagnostic aid from Gower's hæmoglobinometer. Having excluded aneurism, tumor, and pericarditis with large effusion, I thrust into the pleural cavity a needle attached to a hypodermatic syringe, but much longer and stronger than the one employed for medicinal purposes. The fluid withdrawn appeared to be composed largely, if not solely, of blood, but on examining it carefully with the instrument referred to, I found that the amount of blood present in the exudation was really less than one per cent. In other words, if I removed fifty ounces of the fluid, the blood contained in it would not amount to half an ounce.

Of course, the blood withdrawn from the pleura was practically outside of the body before the aspiration, but the question to determine was whether, in case of rapid reaccumulation of the fluid, the amount of blood contained in it, supposing its proportion to remain the same, would be sufficient materially to lower the vitality of an already feeble individual. I was enabled to decide this question in the negative by means of Gower's instrument, and withdrew twenty-eight ounces of fluid with marked benefit to the patient. An enumeration of the blood corpuscles in the fluid was rendered impossible by the fact that these bodies were detected with great difficulty, being completely deprived of their coloring matter, and, therefore, identical in appearance with the phantom corpuscles (*Schatten*) described by Ponfick and others in cases of hæmoglobinæmia.

I am not aware that this test has ever before been applied in this manner, but there can be no doubt that it is a valuable aid to the diagnosis of hemorrhagic pleurisy.

ANGIOMA OF THE THYMUS GLAND.

By T. P. BERENS, M.D.,
RESIDENT PHYSICIAN OF THE PHILADELPHIA HOSPITAL.

J. C., aged sixty-three years, admitted to the surgical ward of the Philadelphia Hospital, November 29, 1887. His history was as follows: Mother and father died of senility, one brother killed accidentally, one brother and sister living and healthy.

The patient had always been a healthy man, moderate drinker of beer. Denied specific disease. For nineteen years had had leg ulcers, which he attributed to an attack of erysipelas. On admission he had two small, unhealthy ulcers, one upon each tibia. These, notwithstanding their treatment, grew worse, until the man developed marked constitutional depression, with many of the symptoms of pyæmia, dying ten days after admission.

The autopsy, performed under the supervision of Dr. Osler, revealed the following: The body is that of a good-sized, well-nourished man. Ulcers on each leg. Extensive hypertrophic nævus of lower lip; simple nævus of skin covering chin, right side of face, and right ear, extending also down the sternum, spreading and gradually fading into normal skin on either side of the chest. The tongue is much enlarged, and is noted to be in an angiomatous (cavernous) condition; immediately beneath it is a teat-like process, an inch in length and an inch at the base, where it seems to spring from the tongue above the frænum, and overlapping that structure. This also is a nævus. On removal of the sternum, in the anterior mediastinum the fatty tissues are permeated by a dense plexus of veins, which extends a short distance into the neck, forming a large nævoid tumor covering over the arch of the aorta, the roots of the great vessels of the neck, and the trachea up to the thyroid gland. On dissection this mass is seen to be composed of two distinct portions, and it represents a greatly enlarged thymus gland. The gland is enveloped in a capsule, under which some of the veins are large and prominent; on section the whole gland looks like a dense angioma; a plexus of veins closely surrounds the adventitia of the aorta. The thyroid is not enlarged; veins over it look full. Dr. Dock kindly cut sections which present those appearances commonly shown in cavernous angiomata, with but few if any traces of the normal glandular structure. In the heart the valves presented a condition of acute endocarditis, the rest of the organs being apparently normal.

A careful search was made through Virchow's *Archiv*, the Virchow-Hirsch *Jahresbericht*, *Transactions of the Pathological Society of London*, and many pathologies, without finding reference to such a condition of the thymus as is here described.

MEDICAL PROGRESS.

A Compound of Sulphuric and Carbolic Acids as a Disinfectant.—Laplace, who is studying the action of various antiseptics in Koch's laboratory at Berlin, reports in the *Deutsche medizinische Wochenschrift*, No. 7, 1888, his experiments with a mixture of crude sulphuric and carbolic acids, as follows:

His attention was drawn to the preparation of this compound by the insolubility of carbolic acid in water, and the need of overcoming this difficulty. To this end he combined crude carbolic acid with crude sulphuric acid; he found that equal parts of sulphuric with equal parts of carbolic acid (twenty-five per cent. in strength) produced a blackish, syrupy substance which remained soluble on cooling, and dissolved perfectly and rapidly in water. He further tested the potency of this compound as an antiseptic upon the bacilli of anthrax. His results showed that a four per cent. watery solution of this compound destroyed the virulence of anthrax in forty-eight hours.

Creolin, a recently tested antiseptic, is impotent in solutions of two per cent., to destroy anthrax; the acidified solutions of corrosive sublimate (1 to 1000) are potent against anthrax, but are not so available in practice. The cheapness of sulpho-carbolic acid, as Laplace styles this compound, and its availability for practical uses render these investigations of value.

Inflammation Masking Cancer.—Dr. Orecchia has recently called attention (*Gazzeta degli Ospitali*, March 4, 1888) to the frequent combination of inflammation with cancer in the same part, the graver disease being sometimes so obscured in this way as to be overlooked for a considerable time. He reports six cases in which this occurred. In one of these cancer of the larynx was supposed to be nothing more than perichondritis; in two, malignant disease of the jaw was mistaken for osteitis; in another periproctitis for some time masked a rectal cancer; parotitis concealed cancer or sarcoma of the parotid; and simple inflammation of the lip, an epithelioma. The possibility of malignant disease underlying what appears to be a simple inflammatory process should never be forgotten when the age and appearance of the patient, and the part affected, are such as to make the existence of carcinoma probable. Dr. Orecchia believes that in these cases the cancer is the primary disease, which, owing to the slightness of the symptoms, remains unnoticed till the supervention of inflammation calls attention to the part. In the stroma of all the tumors referred to, Dr. Orecchia found much extravasated blood, with abundance of leucocytes, of which there were also a great number in the neighboring tissues.—*British Medical Journal*, March 10, 1888.

Poisoning with Anilin Oil.—Dehio in the *Berliner klin. Wochenschrift*, No. 1, 1888, reports the case of a woman just recovered from childbirth, who took two and a half drachms of anilin oil with suicidal intent; the oil was used ordinarily to stain microscopic specimens. Coma, cyanosis, and profound depression followed. The skin was colored a grayish-blue, and intense hæmatogenic icterus followed, with extensive decomposition of the blood. Convalescence was tardy, recovery followed in about a month.

The Treatment of Convulsions in Children.—Simon has found the following, by rectal injection, most useful:

Chloral hydrat.	gr. 15.
Tinct. mosch.	gtt. 20.
Aquæ	ʒ 12½ to 15.

This may be given in two rectal injections, care being exercised to avoid violence, which may irritate or injure the bowel.—*Gazette Médicale*, March 3, 1888.

Multiple Salivary Calculi.—Dr. Nikolai J. Moiseëff, of Shtchizry, reports (*Proceedings of the Shtchizry Medical Society*, 1887, vol. i. p. 68) the case of a retired major-general, aged seventy, who sought his advice on account of incessant profuse salivation, pain on deglutition, and sublingual swelling of several years' standing. An oblong, hard elevation was found along the course of Bartholin's duct, which, even on slight pressure, gave the finger a distinct grating sensation. The duct was considerably distended along its whole course, and contained three salivary calculi lying in close contact. The nearest and smallest concretion, of the size of a big pea, was easily removed with forceps, but the other two could be extracted only after slitting up the duct, since they were considerably larger, especially the deepest one, which measured ¾ of an inch in length and ⅜ in breadth, and in addition was intimately adherent to the gland substance; it resembled a bird's bill in shape. When dry it weighed 33 grains, and consisted of a comparatively hard and compact nucleus, with a spongy, friable outer capsule. The smallest calculus was of a pyramidal form, of spongy consistence, and a grayish-yellow color; while the middle one was quadrangular, with rounded angles, and of a distinctly laminated structure. The total weight of the dried calculi was 38 grains. The wound healed well in a week. Dr. Moïsëëff has been unable to find another recorded instance of multiple calculi simultaneously present in the same salivary duct.—*British Medical Journal*, March 10, 1888.

The Reduction of Ferric Chloride by Pepsin and Allied Substances.—Duncan writes as follows on this subject to the *Chemist and Druggist*:

To the fact that the old tinct. ferri muriatis of the Edinburgh *Pharmacopœia* always contains ferrous chloride, is ascribed its alleged superior efficacy to the tincture of the present pharmacopœia. The following experiments which I have made seem to favor this view, and bear out a theory that ferric salts are reduced in the alimentary canal before absorption, and that their therapeutic value is in direct proportion to the amount of this reduction. Two grains of pepsin, B. P., were shaken up with 100 minims of water, and 10 minims of liq. ferri perchloridi, B. P. (free from ferrous salt), added, the whole being well shaken together. After standing for five minutes, 10 minims of two per cent. potassium ferridcyanide solution were added, when a blue color was

at once developed, showing that reduction of the ferric chloride had taken place. The same experiment was repeated with eight different samples of pepsin, all of which gave a similar result. With some, however, the reduction seemed greater than in other cases. It was also noticed that it increases with the length of time the pepsin and iron are left in contact. A control experiment was made in each case with pepsin and ferridcyanide, but in only one case was any blue color developed, and this most probably was due to an impure hydrochloric acid having been used in making the pepsin preparation. The ferridcyanide apparently does not undergo reduction, as the mixture does not become blue on the addition of a drop of pure ferric acetate solution. Possibly an albuminoid compound may be formed with the iron and pepsin, the iron being reduced during the combination; but I could find no evidence of such reduction with white of egg and ferric chloride. Similar results to these obtained with pepsin were given with ox-gall, pancreatin, papain, and saliva. The same experiments were made with liq. ferri acetatis and liq. ferri dialysatus. The former showed a slight reduction, the latter none at all, even after standing in contact with the pepsin for twenty-four hours. It is generally recognized that ferric acetate is less active therapeutically than ferric chloride, and dialyzed iron is least active of all, some therapeutists even denying that it has any efficacy, and this is apparently quite in accordance with the foregoing results. I do not regard these experiments as conclusive or complete, but the results are suggestive, and, as such, I record them, hoping that the investigation will be carried further.

The Treatment of Phlyctenular Keratitis in Children.—TROUSSEAU, in the *Revue Gén. de Clin. et de Thér.* of March 8, 1888, reports that he obtains good results from the following:

Vaselin	gr. 75.
Hydrarg. ox. flav.	gr. 3¾.

Once daily a bit of this ointment as large as a grain of wheat should be introduced into the eye. Three times daily compresses wet in a warm solution of boric acid should be placed upon the eyes for a quarter of an hour:

Acid. boric.	ʒ 3.
Aquæ	ʒ 11.

Trousseau classifies keratitis and its treatment as follows: Keratitis phlyctenular, superficial and vascular, and corneal opacities may be treated with the yellow oxide of mercury. Certain superficial keratites, corneal ulcers, and abscesses, call for eserine. In cases of parenchymatous keratitis atropia should be employed.

Ligature of the Superficial Femoral Artery, without Rupture of its Coats.—LUNN, at a recent meeting of the Clinical Society of London, reported the following interesting case:

C. W., æt. forty-five, widow, occupation a needle woman, was admitted May, 1887, into St. Marylebone Infirmary, Notting Hill, with pulsating tumor in the right popliteal space. No history could be obtained of a blow, strain, or syphilis, etc. The urine contained no albumen. She noticed a pulsating swelling about the size of an egg behind the right leg in the popliteal space, which gradually enlarged, and she was obliged to give up her work. The circumference of the pulsating tumor measured sixteen and a half inches. After giving a fair trial to different methods of treatment, and having failed to make any impression upon the aneurism, it remained only for me to advise the patient to submit to the usual operation of ligature of the superficial femoral artery, which she consented to do. The usual antiseptic precautions were taken; when the sheath of the artery was opened, the vessel wall was noticed to be a tallowy color, and not the usual pinkish tinge of health. Wishing to try Mr. John Smith's suggestion, and ligate the vessel with a clove-hitch, and as Mr. Ballance had had some experience of the clove-hitch in his as yet unpublished experiments on the carotids of horses and asses, I asked him to pass the kangaroo tendon, and occlude the vessel by means of a clove-hitch without rupturing the coats. This he did. The pulsation of the tumor was arrested immediately, and the woman made an uninterrupted and perfect recovery. The patient was kept in bed for seventy-two days after the operation. "The case is offered to this society as a contribution in aid of the advance of our knowledge of the surgery of our arteries."—*Medical Press*, February 29, 1888.

The Bacillus of Indigo.—The indigo of commerce is produced by the precipitation of a colorless glucoside contained in certain leguminous plants. This precipitation and the formation of the blue color of the indigo are effected, ALVAREZ believes, by a bacillus which causes a fermentation in the plant. This germ resembles that of pneumonia and of rhino-scleroma; and when injected into living organisms produces inflammation, especially of the genito-urinary tract.—*Revue de Clin. et de Thér.*, March 8, 1888.

A Physician's Experience in Self-treatment of Phthisis with Creasote.—The *British Medical Journal* of March 10, 1888, quotes the experience of a Russian physician as follows: The writer, who has been suffering from pulmonary and laryngeal tuberculosis for about two years, had tried the drug on himself in small doses (half a grain four or five times a day) some time ago, but without appreciable benefit. After perusal of the observations of Professors Sommerbrodt (*Berlin. klin. Wochenschrift*, No. 15, 1887) and Guttmann (*Deutsche med. Zeit.*, No. 42, 1887), however, he again began to take creasote in gradually increasing large doses, beginning with four grains a day, and reaching, in about two months, a daily dose of forty-four grains. There took place, fairly rapidly, an unmistakable and permanent improvement in his symptoms. Fever disappeared in a week; expectoration, cough, and dyspnœa steadily decreased to a considerable degree; laryngeal spasm, which had formerly occurred once or twice every month, ceased altogether. As regards the objective signs, however, there was only some diminution of dulness over a certain area, with complete disappearance of fine crepitant *râles*. As to tubercle bacilli in the sputum, they remained just as numerous as before the creasote treatment. The latter has lasted in all four months, during which period not less than four ounces and two drachms of pure creasote have been ingested. The drug must be taken in doses of about five grains four times daily, in the form of capsules (filled up *ex tempore*), after meals. With regard to

disagreeable after-effects Dr. Bogdanovitch observed in himself, when, by way of experiment, he took as much as twelve grains at a time, or twenty grains in the course of an hour, only giddiness, cardiac palpitation, small and accelerated pulse, general weakness, pallor, and anxiety; but all these toxic phenomena disappeared spontaneously and completely in about half an hour or an hour. On an empty stomach, however, he experienced epigastric uneasiness and pain even from small doses. Dr. Bogdanovitch resumed of late the use of creasote in order to study the effect of a six months' course.

Formulæ for Caustic Crayons.—De Sinéty gives the following formulæ, in *L'Union Médicale* of March 17, 1888:

Acid. carbolic. cryst.	gr. ¾.
Tannin.	gr. 60.
Glycerin.	gtt. 5.
Gum. tragacanth.	q. s.

These crayons should be about one inch long, and one-eighth of an inch in diameter.

The Contamination of Vaccine Matter by Micro-parasites.—Pourquier, in a recent communication to the Paris Academy of Sciences, reports his conclusions from several years' study of vaccine virus, which have led him to believe that ill results from such virus depend largely upon its contamination by a micro-parasite. He concludes that whenever the field of vaccination in a heifer presents an unduly inflamed and unhealthy appearance, the animal should no longer be used for that purpose. It may happen that but a portion of the surface used in an animal is affected; only the healthy pustules should then be chosen. Rigid antisepsis is imperative in instruments, the care of the animal and all concerned in its abode and treatment. If the micro-parasite enters a stable infecting a herd, the stable should be most carefully disinfected to limit and abolish the mischief.—*Gazette Hebdomadaire*, March 9, 1888.

Cocaine in Tooth Extraction.—The employment of certain salts of cocaine, and even the alkaloid itself, in dental surgery, has now received a fairly wide trial. It must be confessed that authorities here and abroad have arrived at very various results, some averring that cocaine is in all cases successful, while others have relinquished its use. To reconcile these discordant statements is at present quite impossible; we can only indicate the best means of applying this anæsthetic, and warn against its indiscriminate use. As a rule, from half a grain to a grain of the hydrochlorate dissolved in ten minims of water, and injected into the tissue of the gum by two punctures, one on the lingual and one on the buccal aspect of the tooth, insures a painless extraction. It is best to inject very slowly, and to wait from five to ten minutes after the completion of the last injection before extracting. However, in some persons cocaine fails entirely; nor is it possible to anticipate in whom it will succeed or in whom it will prove abortive. Simply painting the gum is valueless in tooth-extraction, except as a preliminary to the punctures of the hypodermatic syringe, for some persons are as much afraid of the pain incident to the pricking the hyperæmic gum as they are of the more severe operation. Although many persons experience no unpleasant effects from the injection of one grain, yet a certain proportion are painfully and alarmingly upset by its action. Syncope, extreme respiratory distress, feelings of complete prostration lasting for hours, vomiting, great nausea, facial paralysis, muscular paresis, and swelling of the tongue may ensue; thick utterance has been present in many cases; while vertigo, headache, and hallucinations are not uncommon sequelæ of cocaine given hypodermically. As a rule, these symptoms, although very alarming at the time, pass off in a few hours, but may persist for days. Cocaine sometimes loses its anæsthetic powers after the first injection. Many do not recommend cocaine for prolonged dental operations, preferring nitrous oxide gas, which is sure and safe, for short procedures, while others lean to a combination of the two agents.—*Lancet*, March 17, 1888.

A Good Domestic Disinfectant.—The *American Druggist* recommends the following solution:

Sulphate of zinc, commercial .	16 tr. oz.
Sulphate of iron, crystallized .	16 tr. oz.
Hypophosphorous acid (10 per ct.)	120 minims.
Oil of thyme	60 minims.
Naphthol	15 grains.
Water . . enough to make	5 pints.

Dissolve the two salts in four pints of boiling water, add the naphthol, and the oil of thyme, and shake or stir the mixture frequently while it cools. Then add the hypophosphorous acid, and make up the volume, with water, to five pints. Shake or stir the mixture frequently during a few days, then filter it through a wetted filter.

This solution will have a very handsome green color, and resist oxidation for a long time.

For use, it may be directed to be diluted with from five to ten parts of water, the strength depending upon the work it is expected to do.

Tannin Wool.—Benjamin Ward Richardson writes in the *Asclepiad*, No. 17, 1888, that in treating ozæna and other diseases attended with fetid odors, tannin wool turns out to be of great practical service. I had thought that the manufacture of this preparation had become a general fact; but as many medical friends have at various times written for the method, it may be of service to give the details here.

To make tannin wool, add to distilled water heated to 140° F. pure tannin up to saturation, stirring carefully all the time. When the water is saturated, add to it pure cotton wool, bit by bit, until all the solution is taken up by the wool. Lastly, put the saturated wool in an evaporating dish, and dry it slowly until it is quite dry. It is then ready for use, but must always be kept in a closed bottle. It must be neatly teased out before being used; but it is well to keep it in the rough state.

A good stock of tannin wool is at all times a useful thing to keep at hand. It is a ready styptic and possesses good antiseptic properties. It can easily be iodized by making an ethereal solution of iodine, saturating a portion of the cotton with the solution, and allowing the ether to evaporate. One grain of iodine to an ounce of the cotton is sufficient to make a very good specimen; and an iodized cotton made in this proportion is one of the best applications for bedsores that can be adopted. It rarely irritates, it removes odor, and often favors the healing of the sore.

Anthrarobin in the Treatment of Skin Diseases.—At a recent meeting of the Berlin Medical Society, BEHREND reported that he had used anthrarobin in cases where chrysarobin and pyrogallic acid were commonly used, with good results. Anthrarobin is a whitish-yellow powder, sparingly soluble in water, soluble in ten parts of glycerine at 212° F., in ten parts of cold, absolute alcohol and five parts of warm alcohol. It makes a good ointment with oil, and was used in ointments of ten and twenty per cent., in a tincture of ten per cent., and a glycerine solution of ten per cent. Anthrarobin is less irritating than chrysarobin, and can be used upon the face and eyelids. It colors the skin yellow, and a burning sensation follows its first application, which does not generally persist. It is well to precede the use of anthrarobin by the use of green soap, which will remove any obstacles to the action of the medicament. The effect of anthrarobin lasts longer than that of chrysarobin, and it is considerably cheaper. It is more potent than pyrogallic acid.—*Deutsche med. Wochenschrift*, March 8, 1888.

An Application for Sore Nipples.—SCARFF, in the *Maryland Medical Journal*, prescribes the following:

Balsam of Peru,		
Tr. arnica	āā	℥ss.
Expressed oil of almond,		
Lime water	āā	ℨss.

Mix. Shake well, and apply to inflamed nipples with a camel's-hair brush, after cleansing them with borax and water.

An Urea Centre.—The *Lancet* writes that in the animal economy centralization is carried to its most extreme degree. It is certain, from Brown-Séquard's experiments, that there exists a centre irritation of which can suspend the chemistry of the body, making the blood in the veins flow red and reducing the temperature of the body. MM. Sée and Gley, experimenting on dogs with a view to producing glycosuria, caused azoturia by irritating the central end of the divided right vagus with a mixture of glycerine, water, and lycopodium injected into that part of the nerve after section.

Glycerite of Bichloride of Mercury for Antiseptic Use.—The *American Druggist* writes that there has been for a long time prepared for use in the public hospitals in New York, a glycerite of bichloride of mercury, containing one grain of the salt in every two minims. In addition, there is about a quarter of a grain of chloride of sodium in this quantity. When this solution is made, there is always a more or less decided formation of calomel (which is, however, greatly diminished by the use of the chloride of sodium). In order to make the final product as accurate in proportions as possible, the original solution is made somewhat stronger, and then allowed to become perfectly clear by standing, the clear liquid is poured off and, having added alcohol to the residuary portion, this is passed through a filter. The calomel retained by this is washed and dried. Making allowance for the amount of bichloride hereby lost from the original amount, the product is adjusted so that it will represent one grain of the mercurial salt in two minims. It is advisable to take about one-sixteenth part more of bichloride, at the start, than is theoretically required, so as to leave a sufficient margin for dilution. Such a solution, *slightly tinted with fuchsine*, would be very handy for carrying about with the field hospitals and medicine chests.

Purpura Hæmorrhagica Caused by Mental Shock.—DR. ED. DE SMET of Brussels, has recently had a case of a young woman of a highly nervous temperament who, in consequence of severe fright, experienced an eruption of purpura hæmorrhagica, though she had never had any eruption of the kind before. Some four months subsequently, however, in consequence of a fall, a similar eruption made its appearance. The treatment was directed mainly to the nervous system, which was evidently very much affected. Dr. de Smet refers to M. Lenoir of Lille, who has published cases of various skin diseases—eczema, psoriasis, herpes, pemphigus, and vitiligo—which have followed a mental shock.—*Lancet*, March 17, 1888.

The Treatment of Epithelioma by Chlorate of Potassium.—The Paris correspondent of the *British Medical Journal* of March 17, 1888, writes that DR. HYVERNAUD has treated sixty-three cases of epithelioma by local applications of chlorate of potash; of these, thirty-two were cured, fifteen were benefited, and sixteen cases were unrelieved. In the successful cases, the disease was situated on the skin of the face, nose, eyelids, cheeks, neck, in the lumbar region, on the back of the hand, and on the inner surface of the leg. Chlorate of potash fails as a rule when the mucous membrane is the seat of disease, although two cases of epithelioma of the lips and nostril were cured by it. It is especially useful when the affection is slow in its progress. A six per cent. solution slightly heated, or a fine powder of chlorate of potash, is applied to the wound, after it has been freed from scabs. The dressing is renewed once a day, or oftener. The effect of the solution is chiefly to heal the wound, while the powder slightly cauterizes it. The surface of the tumor or ulcer is thus destroyed, small eschars come away, and cicatrization ensues. In most cases, several weeks, or even months, are required to obtain complete cicatrization.

A Convenient Solution of Saccharin.—CHAMBERLIN, in the *Australian Journal of Pharmacy*, No. 26, 1888, reports the following convenient preparation of saccharin:

I have, as a sample, produced the following, and found it makes a pleasing reliable solution: Saccharin, gr. 80; potass. bicarb., gr. 40. Mix intimately in glass mortar. Add glycerine, ℥iss; aq. destil., ℥iss. Allow escape of carbonic acid, transfer to flask, and melt gently in water bath. This contains about gr. 1 in min. 20, sufficient for a cupful of milk.

Geranium Maculatum in Chronic Bronchitis.—The *Journal de Médecine* of March 11, 1888, gives the following as a useful prescription in chronic bronchitis and bronchorrhœa:

R.—Tinct. nucis vom.	℥ i.
Tinct. sanguinariæ	℥ i.
Ext. fluid. geranii	℥ i½.
Syrup. simpl.	℥ ii¼.

Of this a drachm should be taken every four hours.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, APRIL 14, 1888.

ENGLISH AND AMERICAN CÆSAREAN RECORDS COMPARED.

The late Dr. Thomas Radford, of Manchester, with very commendable zeal, prepared upon three several occasions—the last when he was eighty-seven years old—tabular records of the Cæsarean operations performed in the British Isles, from January 9, 1738, to May 20, 1879, aggregating 132 cases, with 109 deaths. We now add to this list 19, 7 of which he overlooked, making 151, with 122 deaths. So far, then, as known, there have been 29 women and 83 children saved by gastro-hysterotomy in England, Ireland, and Scotland, in a period of one hundred and forty-nine years. That our late friend and correspondent failed to note a number of cases is not to be wondered at, and these were not always fatal, although never published. The same process of personal solicitation will be found requisite in England for the obtaining of unreported cases as has been so effectual here in filling out our record. Such a work is very discouraging, because it brings to light such a picture of fatality; but it is only in this way that the misfortunes of the past can be studied, comprehended, and avoided. We know that Dr. Radford must have failed to secure records of many cases, which ought to be and might be still secured by a young and energetic worker. Mr. Henry Jackson, of Sheffield, and his son Arthur, both operated on the same woman at an interval of seven years, the second operation proving fatal; the case was never published. Mr. Lawson Tait operated twice (cases fatal) during Dr. Radford's day, but he failed to answer the published letters of the latter, asking for reports to be sent him. The late Mr. Samuel Smith operated at the Infirmary of Leeds, in 1863, and the late Mr. Samuel Hay, in 1865. Mr. Scattergood operated in Otley, in 1869; the women were all malacosteon subjects, and all died; but the children were saved. A search through the traditions of Glasgow, we are informed, will show a repetition of the work of Leeds; and a general investigation in many localities in England will accomplish what has been done in some of our individual States—as in Louisiana and Georgia; in the former, 10 out of 19 cases were never published, and in the latter, 7 out of 11.

We have now a record in the United States of 164 Cæsarean operations, of which 16 were Sänger cases. Of this list, 56 were never published, and would have been entirely lost to science but for the search made; many other cases were *communicated*, but were subsequently reported through the journals, or will yet be. 62 women and 63 children were saved; those born moribund, or that very soon died, are not counted in this record.

The Cæsarean operation is much more frequently performed in the United States now than in former years, the average per annum having increased from 3 to 6, there having been 24 in the last four years, which is not likely to be reduced, under the prospect of a diminishing fatality, by the adoption of the Sänger method. Great Britain does not yet appear to realize the capabilities of this valuable death-reducing improvement; possibly the three successes in order of Prof. W. T. Lusk, of New York, during the past year, who is one of the vice-presidents of the British Gynecological Society, may induce some of her members to make trial of it. Since May 20, 1879, when Dr. Radford's record closed, there have been published only 12 British Cæsarean operations, saving 4 women. We know that the number of cases has fallen off in latter years, but do not believe that this is even nearly all of them. From the date given to the present time, our own country numbers 40 cases. In the three years 1865, '66, '67, there were 20 British cases; in 1875, '76, '77, ten years later, there were, as far as known, 10; and in 1885, '86, '87, only 6.

ERYTHROPHLŒIN.

In The Medical News of March 10, 1888, we called attention to the experiments of Liebreich and

Egasse, Nevinny, and several other investigators on the action of haya or erythrophlœin, the new local anæsthetic, derived from an African plant. In the *Berliner klin. Wochenschrift* of February 27, 1888, is an additional communication by Liebreich, made to the Berliner med. Gesselschaft, and a discussion of his paper by Lewin. Again, in the *Therapeutische Monatshefte* for March, 1888, is a very full paper by Liebreich, while in the *Deutsche med. Wochenschrift* of March 8th is a discussion on a paper by Karewski, concerning the same drug.

Medical literature has been so burdened by reports of the action of the poison that it is at first difficult to reach a conclusion as to its true anæsthetic value. At present, however, its most enthusiastic upholders confess to its inferiority to cocaine, and there can be no doubt that it is possessed of far greater toxic powers than its sister anæsthetic. Enough clinical work has not been reported to enable us to point out any conditions in which it can succeed where cocaine has failed, and we doubt if any such properties will be discovered. The enthusiasm over its introduction is but another evidence of the yearning of humanity after anæsthetics which do not produce unconsciousness.

THE AGNEW JUBILEE.

ON Friday, April 6th, Professor D. Hayes Agnew passed the fiftieth anniversary of his entrance into the medical profession. This anniversary excited such widespread and kindly interest, that the word "jubilee" expresses most fitly the sentiment of his professional brethren on that occasion. This sentiment has found expression in the call for a jubilee meeting, to be held by his students, on April 24th, at the University of Pennsylvania, and reached its most felicitous demonstration April 6th, when the guest of the day was banqueted by a large assembly. Here, some of those who witnessed the work of his earlier years bore eloquent testimony, in prose and verse, to the value of his career, while the consensus of feeling and opinion exceeded the compliments usual on social occasions, and became heartily and affectionately congratulatory. And well they might be; for to have participated in the development of surgical science for fifty years with that intelligence which only anatomical study can bestow; to have seen the greatest enemy of the surgeon, septicæmia, in a large measure vanquished; to have shared actively by precept and example in this the greatest advance in the medicine of the century; and to have won the affectionate regard and high esteem of his guild, and of his fellow citizens is a career preëminently successful.

Such a career has influence, constant and potent; whether spoken or written, the utterances of such a mind, exemplified in personal sincerity and devotion to science, are the noblest plea that scientific medicine can make for the respect, the admiration, and affection of mankind. We join most heartily in the jubilee of this distinguished professor and surgeon, and wish him many years of enjoyment of the honors and usefulness so widely extended to him. We wish him, then, long life, for

> "He most lives
> Who thinks most, feels the noblest, acts the best."

THE army of medical doctors has been augmented by recent graduations, as follows:

Jefferson Medical College, Philadelphia	188
Louisville Medical College	95
College of Physicians and Surgeons, St. Louis	44
Western Pennsylvania Medical College. Pittsburg	34
Medico-Chirurgical College, Philadelphia	20

AT the meeting of the Paris Academy of Medicine on March 13, 1888, Professor William T. Lusk, of New York, was elected a corresponding member, receiving forty votes against ten for Sir William MacCormack and two for Victor Horsley, of London.

THE importation of smallpox from Italy has probably ceased for the time, at the port of New York. The Health Officer of that station has adopted more stringent measures and more thorough vaccination of immigrants coming from infected ports. The correspondence of that officer and the Health Boards of New York City and Brooklyn, bearing upon the alleged defective inspection of immigrant vessels, has been very pointed, and at times almost acrimonious. As a result, the less frequent introduction of smallpox may be expected.

DR. NETTER, of Paris, has found, in the saliva of three healthy persons, a pathogenic microbe capable of causing death in animals. It appears to be identical with the bacillus discovered by Friedländer in the lungs of patients having pneumonia, and known as the diplobacillus pneumoniæ of Weichselbaum. It is sometimes associated with the pneumococcus of Fränkel. Netter found this microbe rarely; he met with it only three times in 180 specimens taken from

105 persons. It was rapidly fatal when injected into the blood of guinea-pigs and mice, but had no effect upon rabbits. Man may share this immunity, or it may be transient, as proved by Thost, that Friedländer's microbe may exist innocuously in the nasal mucus of healthy persons. The author believes that pneumonia is always connected with the pneumococcus of Fränkel, and that the action of Friedländer's microbe has not yet been proved to be constant and pathogenic. In his opinion, it will be found to be rather an accidental concomitant, due to its presence in favorable regions of the air-passages, rather than a necessary agent in the production of pneumonia. Further research must be had in order to determine the action of this organism as a disease-germ.

The total reported mortality in 1887 in the State of New York was 96,453, of which 36.3 per cent. were under five years of age. The average death-rate stood at 17.5 per thousand. The population is here taken to be five and a half millions—a figure wanting in certitude, in view of the fact that there has been no census for seven years. The average rate of death in certain regularly reporting districts—almost wholly urban in character—was 23; while in other districts, chiefly rural, the rate ran at 18.4 per thousand. If, by reason of known defects of registration of deaths in some incompletely organized sections, the entire State be given this last-mentioned rate, the total deaths would have reached 101,200. Zymotic fatality was higher than during the three years past. Diarrhœal deaths were unusually numerous during the midsummer months, with a correspondingly great loss under five years. The percentage of mortality in that age in the month of July was as high as 52.7; in June and August it was 40 and 45.3, respectively.

Judge Ewell writes to the *Journal of the American Medical Association* that "there is absolutely no doubt whatever, that in publishing clinical lectures without the lecturer's consent, a legal wrong is committed, for which the courts give an adequate remedy," and he offers to furnish authorities for this statement.

The establishment of a "Stomatological Society," whose object is the scientific study of diseases of the mouth, the teeth, and adjacent parts, is announced at Paris. In view of the development which laryngology has attained, a pure "stomatologist" will be a curiosity, especially interesting to laryngologists and dental surgeons, who will be concerned in allotting territory to the new specialty.

English-speaking residents in Switzerland are exercised over the Swiss law, whose enforcement is threatened, which withholds license to practise from any but graduates of the Swiss medical colleges.

The tendency of those who minister to the soul to include the body in their sphere of action, has been repeatedly exemplified, notably in the "faith cure" superstition, at present prevalent in America. The physicians of Belgium have resented the usurpation of their functions by the clergy, and are endeavoring to repress what they consider unjustifiable interference in their field of work.

The Royal College of Physicians held its annual election for President on March 31st. Sir William Jenner declined to be again a candidate, having held the position for seven years. In the balloting, which followed the presidential address, the race was very close between Sir Andrew Clark and Dr. Quain, but the former was elected. On the first ballot Dr. Quain had the highest number of votes, but he fell short of a two-thirds majority, whereupon in the second ballot Sir Andrew ran ahead of him, having seventy-nine votes to Dr. Quain's seventy-one votes.

Under the title *Nouvelle iconographie de la Salpétrière*, MM. Nicher, Tourette, and Londe announce the publication of a journal under Professor Charcot's direction, which will be a bimonthly review of the diseases of the nervous system.

The publication of an Italian edition of the *American System of Medicine* is announced, by Dr. Francesco Vaalardi, at Milan.

Albert G. Browning, M.D., of Providence, R. I., died April 6th, at the age of forty-nine years. The cause of his death was apoplexy, by which he was first prostrated March 8th.

Dr. Browning was born in Woodstock, Conn. After graduating from the Academy in that town, and teaching for a while in the schools thereabouts, he began the study of medicine under Dr. George H. Church, of Wickford, R. I., and subsequently graduated from the Yale Medical School. He practised medicine successfully in Providence and

vicinity about twenty-five years, and during the last half of that period gave much attention to the special uses and applications of electricity as a means of treating disease.

He was a cheerful, genial man, a ready speaker, and possessed a vast fund of witty anecdotes and stories. Politically he was a staunch Democrat. He had been a Fellow of the Rhode Island Medical Society since 1863. His wife and his aged mother are the only near relatives who survive him.

REVIEWS.

The Prescription. By Otto A. Wall, M.D. St. Louis: Aug. Gast Bank Note and Lithograph Co.

This little book, while it contains quite a large amount of information as to the derivation of signs and symbols will, we believe, only prove useful to the student of pharmacy, or to the physician who has sufficient time to devote himself rather to the non-practical details of medicine than to those of daily life.

While many of the definitions are interesting because of their derivation, the book is marred by tautology to a very large extent, and lacks smoothness. The advice given is unsuited to the well-educated physician, and the book contains too much matter for the busy medical student, as is evident when the number of pages is considered, one hundred and seventy-seven. No book can ever avoid treading upon some one's toes, which tries to give advice to both the physician and druggist at one and the same time, yet this is the avowed object in his preface of the author of *The Prescription*. The book savors of placing the druggist on the same plane as the physician, which is a mistake, since, while the professions are to a certain extent linked together, they never can be identical.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 5, 1888.

The President, A. Jacobi, M.D., in the Chair.

Drs. E. C. Seguin and Robert F. Weir read a double paper entitled

A CONTRIBUTION TO THE DIAGNOSIS AND SURGERY OF CEREBRAL TUMORS,

which will appear in full in an early number of *The American Journal of the Medical Sciences*.

Dr. W. W. Keen, of Philadelphia, gave some details of the case briefly referred to in The Medical News of December 24, 1887. The full report of the paper had not been published yet, he said, as he preferred to present it at the Washington Congress next September. At the age of three years the patient fell from a window, his head striking on a brick. A superficial wound was made, but no trouble was experienced from the injury until twenty years had elapsed, when epilepsy developed. This was associated with aphasia and paresis and paralysis of the right arm and leg. No history could be obtained of any "signal symptoms," on which Dr. Seguin had laid stress in the paper. Later there was complete recovery from the paresis, paralysis, and aphasia.

The operation was performed December 15, 1887. Instead of marking upon the skull with a colored pencil, the spot where the opening was to be made, as had been done by Dr. Weir in his case, a little piece of bone was gouged out at a point corresponding with a slight scar which was presumably left by the injury to the head received when the patient was three years old. The tumor removed measured nearly three inches in its long axis, and about two inches in its short axis. During the operation great trouble was experienced from hemorrhage, due in great part to the extreme friability of the vessels. The hemorrhage was controlled partly by hot water, partly by ligation, and partly by pressure. In tying a vessel it was found that if one end of the catgut was pulled at all more strongly than the other, the ligature would invariably cut through; so that absolute equality of traction was required in order to accomplish this successfully. The hot water employed was at a temperature of from 120° to 130° F.

The patient did perfectly well for two days after the operation. On the third day marked symptoms of pressure showed themselves, and this was ascertained to be due to the presence of a large clot, of greater size than the tumor itself. This was removed by careful washing, and all went well for ten days, when pressure symptoms were again observed. There was also severe diarrhœa and a temperature of 104½°. Under the circumstances, the presence of pus was suspected, and the wound was accordingly reopened. Afterward Dr. Keen regretted having done this, as it resulted in *hernia cerebri*, and he become convinced that the unfavorable symptoms noted were largely due to the diarrhœa. Later the patient had two or three other attacks of diarrhœa (less severe than the first), which were also accompanied by more or less rise of temperature. The hernia remained for a considerable time, and in order to facilitate the process of healing skin-grafts were transferred from the arm. The wound was dressed with bichloride gauze for eight weeks, but there was no evidence of its producing any toxic effect upon the system; the diarrhœa not being attributable to this cause. While the healing was going on the surface remained considerably elevated, but when the cicatrizing process had been completed it suddenly became concave, instead of convex, and has so continued ever since. Photographs were exhibited of the *hernia cerebri* and of the wound when healed.

Recurring to the operation, Dr. Keen said that he did not employ the spray, but made use of all the other ordinary antiseptic precautions. In speaking again of hemorrhage, he said that he regretted that previous to the operation he had not administered a dose of morphia, as recommended by Horsley, for the purpose of diminishing the blood-supply to the parts. In another case he should also be inclined to give ergot, and perhaps antipyrin, and he preferred to use cocaine locally if occasion required. Such agents, he thought, afforded a much better chance of controlling hemorrhage in this class of cases than the mechanical means commonly resorted to. He then spoke of the importance of completely shaving the head, for purposes of examination, of every patient in whose case there was any brain trouble

likely to call for operation, and said that in a case of epilepsy that had recently been referred to him, two scars were discovered when the scalp had been shaved. In regard to the question of drainage, in his case he had been compelled to keep this up for a much longer time than he desired. Such a course was rendered necessary, however, on account of the large clot and the discharge which followed it. According to Horsley, drainage should not be maintained for more than twenty-four hours, and he believed that this might suffice, except under special conditions, such as existed in the present instance.

NEWS ITEMS.

The Agnew Jubilee.—Over two hundred members of the medical profession of Philadelphia sat down to a banquet in the Foyer of the Academy of Music last Friday evening in honor of the fiftieth anniversary of the graduation in medicine of Dr. D. Hayes Agnew. Dr. Da Costa presided, and on his right sat Dr. Agnew the guest of the evening. There were also present a number of Dr. Agnew's professional friends from other cities, including Drs. Sayre, Weir, and Agnew, of New York, Tiffany, of Baltimore, Billings, Ford Thompson, and Yarrow, of Washington, Hunter McGuire, of Richmond, Weist, of Indiana, and Parkes, of Chicago.

Dr. J. M. Da Costa, after the cloth was removed, spoke as follows:

Fifty years ago, on this very day, there stood, with the honors of a University just received, a young man on the threshold of his life. His thoughts were the pleasant ones of the occasion; his aspirations had hardly taken shape; he was the popular comrade of the hundred and fifty-five whose real life, like his own, was to begin. Fifty years have passed, and their Agnew has become our Agnew of the many thousands of the American profession.

Honored Guest: In addressing you to-night I feel that I speak not simply for those who are gathered around you; nor for those in this Commonwealth whose interest will centre here; but for the whole profession who hold you in such esteem, and whose sympathetic thoughts, could they reach you, would come to you in messages of such good-will and affection as to overwhelm you with their warmth.

Your career has been, indeed, a remarkable one; and you must pardon me, and let the occasion be my excuse, if, in your presence, I allude to its success, and to the main causes of that success. Nor is it wholly unfitting in one to do so who has known you, and watched your progress with friendly interest, almost since you came to this city, to try your powers in a wider field. The training you brought with you as a rural practitioner of note was indeed valuable. Self-reliance, cool judgment under difficult circumstances, are not the least reward of a country physician's hard life. You enrolled yourself as a teacher of medicine in its most laborious branch, and fittingly took charge of a school which has been the nursery of famous anatomists and surgeons—where Godman's practical skill was displayed, and Joseph Pancoast laid the foundation of that intimate knowledge of the human frame which made him afterward so great a surgeon.

This Philadelphia School of Anatomy, in College Avenue, has, indeed, left its mark in the history of medicine. It has been to us what the Windmill Street School was to the London of William and of John Hunter, of Hewson, of Cruikshank, of Baillie, of Benjamin Brodie, of Charles Bell. Its rickety structure harbored not only anatomists—some of them your own pupils, who were to succeed you as celebrated teachers—but its dingy walls heard eloquent discourses on diverse branches from more than one of your future colleagues; in its garret, independent and fruitful researches on the textures of the body were pursued; in its cramped lower room, physiological experiments were carried on, which have made their deep impress on the science of our day.

For ten years working in this school of anatomy you lived laborious days and nights, and in its stern training your classes grew, until the narrow quarters would hold them no more, and you became the popular, admirable teacher you have proved yourself since, on a larger scale and on a different branch, as Professor of the Principles and Practice of Surgery in the famed University with which your reputation is forever identified. You learned to present facts plainly and impressively, to teach Nature's truths with Nature's simplicity, and without a deadly paralysis of words.

But in these ten years of unremitting work you did something more than teaching. You laid, by exact knowledge, by steadiness of purpose, and affability, the foundations of that large practice which you have since enjoyed, developing every day, more and more, into the trusted surgeon whose deft hand and cool judgment caused his advice to be generally sought. Every country shows in its professions the national traits. You certainly represent, as a surgeon, besides much skill, the American characteristic of resolute common-sense.

You have been tried in many a hard case. In none harder, than when your reputation caused you to be selected among the counsellors at the wounded couch of one for whose relief millions were anxiously watching. That in these trying times you bore yourself with the same calmness and dignity we know in you, every one in these millions recognized.

Your success as a surgeon of great repute must, indeed, have been gratifying to you. Not only for the opportunities it afforded you of doing so much active work in your profession; not only because it gave a personal value to your writings, especially to your opinions expressed in your elaborate work on *Surgery;* but because it enabled you to carry out a plan of action, of which I may not speak,—one which showed you to be possessed of the same high sense of honor for which Sir Walter Scott has received the unbounded admiration of mankind.

May you, dear sir, who have these many claims to distinction and esteem; may you on this, the fiftieth anniversary of entrance into a profession which you have graced by your industry, your sagacity, your skill, your character; may you accept the homage of those who are engaged with you in the same pursuit as a sign of widely felt regard and appreciation. May your vigorous frame preserve your power of doing good, of teaching truths, for many a long year. May there always remain with you the assurance that, as age gently lays its hand on you, the chilling finger of time will not lessen the respect, nor benumb the tenderness of feeling, with which old and young alike regard you.

Dr. Agnew, upon rising, was greated with enthusiastic cheers. He said

Mr. Chairman: When I glance over this table and see so many distinguished and representative men of my profession who have come to do honor to one of the humblest of their guild, I confess it is with a deep sense of embarrassment that I wish to respond to the complimentary sentiments embodied in your toast and in your address. I can say without affectation that had it been the pleasure of my friends, a less conspicuous demonstration of their goodwill than the present would have been more in consonance with my feelings and taste.

It is a great distinction for any man in whatsoever sphere of life he may move to win the confidence and esteem of his fellows, and it is scarcely necessary for me to say how profoundly I realize this mark of your respect. Any man who has lived long in this world, and has taken a thoughtful retrospect of his past life, must be forced to confess that the influences and forces which have conspired to mould his character, and to shape his destiny are most mysterious indeed. Plans constructed with infinite care have miscarried; fondly cherished hopes have been suddenly crushed with a shock, as when a precious vase is broken to fragments on the pavement; glowing anticipations just about to be realizations dissipated in a moment into thin viewless air like earth mists before the morning sun. One of Scotland's gifted but unfortunate sons has condensed these thoughts into the expressive couplet,

> "The best laid schemes, o' mice and man
> Gang oft aglee."

And the great bard of England, rather the bard of all peoples and all times, has crystallized the same sentiment in those expressive lines,

> "There is a divinity which shapes our end
> Rough hew them how we will."

And a greater than either has said it is not in man to direct his steps.

About thirty-five years ago I came to this city, a stranger. Though previously enjoying a large practice, in a wealthy and populous district, yet the field was never a satisfactory one. The horizon seemed too contracted, the prospects uninviting. Possessing naturally strong anatomical tastes, I was able to gratify these to only a moderate degree by dissections of the human body and the bodies of animals; yet the prejudice against studies of this nature was calculated to render their prosecution unpopular, not to say very embarrassing. The desire, therefore, to obtain a larger field for the gratification of the idol of my thought, induced me to make Philadelphia my home.

The scene of my early labors, as most of you know, was in College Avenue, in the Philadelphia School of Anatomy. This institution—not a chartered, but a private one—had both an ancient and honorable history. It was here that Godman and Webster and the elder Pancoast and Allen laid the foundation of their reputations. It was indeed a school of the prophets; a gymnasium in which were trained the great majority of the men who, as teachers and writers, have filled so large a place in the medical world. Among these names may be mentioned that of Gerhard, the pioneer of physical diagnosis in America; of Wallace, who became Professor of Obstetrics in the Jefferson Medical College; of Bridges, Professor of Chemistry in the Philadelphia School of Pharmacy; of Keating, elected Professor of Obstetrics in Jefferson College, but compelled to resign on account of ill health; of Henry H. Smith, Professor of Surgery in the University of Pennsylvania; of Frances Gurney Smith, Professor of Physiology in the same institution; of your honored Chairman, Professor of the Principles and Practice of Medicine in the Jefferson Medical College; of Penrose, Professor of Obstetrics in the University of Pennsylvania; of Brinton, one of the Professors of Surgery in the Jefferson Medical College; of Garretson, the author of a popular work on oral surgery; and of Keen, Professor of Surgery in the Women's Medical College of Philadelphia. It was here that Brown-Séquard delivered his lectures on operative physiology, and it was here that Mitchell conducted his classic experiments on snake poison, and on many physiological problems, which have placed his name alongside that of Ferrier, and given him a high place among the scientists of the present day. It was in this institution that for several years, summer and winter, night and day, rarely taking a vacation, I studied the mysteries of this wondrous frame, with a love and a zeal which never flagged, and drew around me—notwithstanding the hostility of the two great medical schools—from the small beginning of twelve medical students, the largest private classes, only limited by the capacity of the building, that had ever followed a private teacher in this country.

Those were happy days; Yes, I think the happiest days of my life. I was then master of my kingdom. Those old dingy rooms had more attractions for me than the frescoed and fretted walls of a palace, and those anatomical odors were as sweet as those of Araby, the blest. The curriculum of instruction consisted of lectures on descriptive anatomy, surgical anatomy, operative surgery, and dissections, and when I was induced to accept the demonstratorship of anatomy in the University of Pennsylvania it was with reluctance and regret that I left the Philadelphia School of Anatomy.

It is entirely natural that my thoughts should linger about College Avenue—for it was there that I formed those friendships which, like hooks of steel, have bound me to the men of every part of this country and not a few across the sea.

In 1854, a united effort was made to reopen the Philadelphia Hospital for medical teaching, the doors of which had been closed for several years. History furnishes innumerable instances in which the most momentous events have been determined by the most trivial incident. All these fade into insignificance when contrasted with that which closed the doors of this great clinic against the profession. The cackle of a few geese saved Rome, a presumptuous cock-roach barred the gates of the Blockley Hospital—and let me say here in parenthesis, that to Dr. Henry H. Smith and Dr. J. L. Ludlow more than all others combined, the profession and the country at large are indebted for the restoration of this important hospital to clinical instruction. By their unwearied and indefatigable perseverance, by their unceasing importunity, like the widow with the unjust judge, these men succeeded in revolutionizing the antagonistic and settled sentiment of the Board of Guardians, and gained this great conquest, and on the same day that the hospital committee made their favorable report, Dr. Smith and myself were

elected surgeons to the institution; and for twelve years, save for a short interregnum, when self-respect demanded the resignation of the Medical Board, I continued to discharge the duties of a clinical teacher of surgery in the hospital. In 1864, I was elected one of the surgeons to the Wills Hospital for Diseases of the Eye, fulfilling the duties of the place for a period of about six years. In 1865, I was honored by an appointment on the surgical staff of the Pennsylvania Hospital, and for about eleven years continued my service in that venerable institution until the inauguration of a policy which compelled me to resign. Let me say here that I have made it a rule of life never knowingly to violate my sense of duty—and with the help of God's grace, it has never cost me one moment's hesitation to turn my back on any proposition or place however tempting, the acceptance of which would compel me to surrender my conscientious conviction of right. In 1877, the Board of Managers, of its own motion and unsolicited, with a cordiality and unanimity which I can never forget, reëlected me to my former place on the surgical staff. In 1867, I was elected one of the surgeons to the Orthopædic Hospital, then situated on Ninth Street, and which has now grown to be one of the important institutions for the treatment of deformities in this country.

In 1870, the Trustees of the University elected me to the Chair of Clinical Surgery in that institution, and a year later to the Chair of Principles and Practice of Surgery, and on the completion of the University Hospital building I was appointed one of the clinical professors of surgery—why I should have been honored with so many appointments to places of dignity and influence, I know not. Other and abler men could have filled them. But this much I can say, I never schemed or planned for one of them. Any place in the republic of medicine was honorable enough to me. I knew there were golden apples in the garden of Hesperus, but I was too much in love with my own particular study to attempt the play of Hercules and the dragon.

My love for the profession was inborn, wrought into the very fibre of my mental organization, and inspired not by the honors at her command, but from the unspeakable satisfaction and pleasure of being able to use her resources for the benefit of our common humanity. How long I may be able to continue in this good service I know not. This I leave to the wisdom of Him who numbers the hairs of the head and notes the flight or the fall of a sparrow. When that supreme moment comes I shall be satisfied. I have had all that I could wish, more than I deserve, and now, gentlemen, this is a great honor which you have done me: to be the guest of such a company should satisfy the most exacting ambition, and let me say to each and all of my professional brethren here to-night, that I have no words which can fittingly express the profound obligations under which I am placed, to your generosity and kindness.

Dr. S. Weir Mitchell then read the following poem, which he had written for the occasion:

MINERVA MEDICA.

A golden wedding; fifty earnest years
This spring-tide day from that do sadly part,
When, 'mid a learned throng, one shy grave lad,
Half-conscious, won the Mistress of our Art.

Still at his side the tranquil goddess stood,
Unseen of men, and claimed the student boy,
Touched with her cool sweet lips his ruddy cheek,
And bade him follow her through grief and joy.

"Be mine," she whispered in his startled ear,
"Be mine to-day, as Paré once was mine;
Like Hunter mine, and all who nobly won
The fadeless honors of that shining line.

"Be mine," she said, "the calm of honest eyes,
The steadfast forehead, and the constant soul,
Mine the firm heart on simple duty bent,
And mine the manly gift of self-control.

"Not in my service is the harvest won
That gilds the child of barter and of trade;
That steady hand, that ever-pitying touch,
Not in my helping shall be thus repaid.

"But I will take you where the great have gone,
And I will set your feet in honor's ways;
Friends I will give, and length of crowded years,
And crown your manhood with a nation's praise.

"These will I give, and more; the poor man's home,
The anguished sufferer in the clutch of pain,
The camp, the field, the long, sad, waiting ward,
Watch for your kindly face, nor watch in vain;

"For, as the sculptor years shall chisel deep
The lines of pity 'neath the brow of thought,
Below your whitening hair the hurt shall read
How well you learned what I my best have taught."

The busy footsteps of your toiling stand
Upon the noisy century's sharp divide,
And at your side, to-night, I see her still,
The gracious woman, strong and tender-eyed.

O stately Mistress of our sacred Art,
Changeless and beautiful and wise and brave,
Full fifty years have gone since first your lips
To noblest uses pledged that forehead grave.

As round the board our merry glasses rang,
His golden-wedding chimes I heard to-night;
We know its offspring; in a hundred towns
His pupil children bless his living light.

What be the marriage-gifts that we can give?
What lacks he that on well-used years attends?
All that we have to give are his to-day—
Love, honor, and obedience, troops of friends.

Dr. Thomas Wistar also read an ode to Dr. Agnew.

A Protest against the Introduction of Water Gas into Philadelphia.—The College of Physicians of Philadelphia last week adopted a protest against the introduction of water gas into Philadelphia, based upon a report prepared by a special committee consisting of Drs. H. C. Wood, T. G. Wormley, J. W. Holland, H. Leffmann, I. Norris, Jr., and Homer Jayne.

The committee reported that the various analyses of water gas, as published, show that it contains from thirty to forty-five per cent., or even more, of carbonic oxide, while ordinary coal gas has in it from three to seven per cent. of the same compound. A comparison of the deleterious or poisonous substances yielded to the surrounding atmosphere during the combustion of an equal volume of each of the gases showed that the combustion of 100 cubic feet of coal gas would give rise to 55.84 cubic feet of carbonic oxide gas; whilst the combustion of an equal volume of water gas would generate 73.32 cubic feet of carbonic oxide. That is, the combustion of

a given volume of water gas would produce over thirty per cent. more carbonic oxide than the combustion of an equal volume of coal gas, and would, therefore, contaminate about one-third more of the air of a room.

In regard to the relative poisonous properties of the two gases before they are burnt, the report says, it depends upon the quantity of carbonic oxide in them, the other ingredients being comparatively harmless. When quantities of either gas get into a room a certain proportion escapes through the windows, doors, and other apertures, so that it does not follow that a gas containing twice as much poison as another will be doubly as fatal. According to most authorities, one-half of one per cent. of carbonic oxide in the atmosphere of a room is sufficient to cause death. The presence of one per cent. of coal gas would necessitate the presence of six-hundredths of one per cent. of carbonic oxide, which would not be sufficient to produce immediate bad results. On the other hand, one per cent. of water gas would be equivalent to from thirty to forty-hundredths of one per cent. of carbonic oxide. It is plain that three per cent. of coal gas in the atmosphere would do no serious injury, whilst but little over one per cent. of the water gas would be required to take life.

The introduction of water gas into cities has, so far as the committee has been able to get at the facts, always been accompanied by an extraordinary increase in the number of deaths from gas poisoning. In New York City in the seven years terminating January 1, 1888, there were 177 deaths from water gas and nine deaths from coal gas, whilst the number of deaths in January of this year in New York City from water gas is said to have equalled all the deaths from coal gas in Boston in the last fifty-five years. In the five years ending January 1, 1885, there were in the city of Baltimore forty-five deaths from water gas. In the year 1887, following the introduction of water gas into San Francisco, the number of deaths was twelve. Eleven deaths were reported in the New York newspapers as having occurred in Chicago in 1886 and 1887. Of the exact number that really did occur in Chicago the committee has no accurate information.

The committee has been very much struck by the fact that whenever they have met with the report of deaths occurring in a small city from the inhalation of gas, upon looking into the list of cities, supplied with water gas, they have invariably found that the city in which the death took place was upon the list. Within the week an occurrence in Reading, Pa., points out a very important danger. It is generally thought that these deaths are the result of carelessness in leaving the gas turned on, although extinguished. It would appear, however, that owing to the variations in pressure, and probably also to the variation in the mixture of the constituents of the water gas or to other cause, when the gas is left burning low at night it is entirely possible for the light to go out, and afterward sufficient gas to escape into the room to cause death. Thus on March 30th, in the Keystone House, in Reading, two gentlemen were found dead in their beds from water-gas poisoning, and, according to the testimony at the Coroner's inquest, the gas had been left by them lighted.

According to Mayor Fitler's annual report, over 12 per cent. of the yearly product of the Philadelphia Gas Works is lost in leakage, equal to 440,340,319 cubic feet annually. While it is not possible to form a definite opinion of the extent of ill-health caused by breathing noxious gases that escape in this manner, the committee believe it a subject for urgent consideration in selecting a gas for use in a large city like this.

Dangers that already exist from this source would be alarmingly multiplied by the substitution of water gas for coal gas. In Troy, N. Y., during the winter of 1886–87 fifteen persons were overcome by the escape of water gas from a leak in the soil, and required medical attendance to revive them. The inhabitants of an entire row of houses in the same city were similarly overcome, and in the cases which terminated fatally death was attributed to carbonic oxide poisoning.

It has been ascertained from Mayor Fitler that sufficient water gas would be introduced into the gasometers in this city to constitute one-third of the entire bulk used, and that the manufacturers who will bid for the contract to supply the water product admit that it will contain 30 per cent. of carbonic oxide. After it is mixed with the coal gas, the substance which is supplied for illuminating purposes will contain 13½ per cent. of carbonic oxide. There is no limit of safety in the percentage of carbonic oxide, the report says, and the line must be drawn arbitrarily. The committee believe that 10 per cent. ought to be the maximum in any gas intended for use by the public as an illuminant. In Massachusetts a protest against the use of water gas containing more than 10 per cent. of the deadly vapor was sent to the Legislature with the signatures of all the leading physicians in the State, including the professors of Harvard College, and the medical examiners and health officers of the various counties and towns.

In conclusion, the committee recommended the adoption of the following, which was endorsed by the College of Physicians:

Whereas, the College of Physicians of Philadelphia has learned that it is proposed to furnish the citizens of Philadelphia with illuminating gas consisting of two parts of coal gas and one part of water gas, a mixture which would probably contain at least about 15 per cent. of carbonic oxide; and

Whereas, in the opinion of this College, the use of any illuminating gas which contains more than 10 per cent. of carbonic oxide would be attended with very grave risks to the health and lives of the citizens of Philadelphia; therefore, be it

Resolved, That the Mayor of Philadelphia is hereby petitioned that if, in his opinion, it be necessary to use water gas in connection with illuminating gas, that great care be taken to render it certain that the mixture shall at no time contain more than 10 per cent. of carbonic oxide.

New York Neurological Society.—At the meeting held April 3d, the following officers were elected:

President.—George W. Jacoby, M.D.

Vice-Presidents.—C. L. Dana, M.D., and M. A. Starr, M.D.

Recording Secretary.—B. Sachs, M.D.

Corresponding Secretary,—E. D. Fisher, M.D.

Treasurer.—G. M. Hammond, M.D.

Councillors.—I. Weber, M.D.; E. C. Seguin, M.D.; J. C. Shaw, M.D.; W. R. Birdsall, M.D.; E. C. Harwood, M.D.

THE DIFFERENTIAL DIAGNOSIS OF PERIPHERIC AND CENTRAL DISEASES OF THE EAR.[1]

BY D. B. ST. JOHN ROOSA, M.D., LL.D.,

PROFESSOR OF DISEASES OF THE EYE AND EAR IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL, SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL.

I BELIEVE that it is not generally understood among neurologists that otologists are possessors of, and are in the constant use of pretty reliable methods for making a differential diagnosis of peripheric and central diseases of the ear. By *peripheric* affection of the ear, one external to the labyrinth is meant. A central affection may be situated either in the labyrinth itself, in the trunk of the nerve, or the brain. In the large majority of cases it has become practicable to decide whether a given lesion is situated chiefly in the tympanum, or in the labyrinth, or trunk of the nerve. The power to determine whether the seat of the affection be in the nerve trunk, its expansion in the cochlea or at its origin, is very often, as yet, quite beyond us. Still we are able sometimes to discriminate between a pure affection of the semicircular canals and of the percipient apparatus. The methods for such a differential diagnosis ought by this time to be the common property of all scientific members of the profession. To contribute to this end is the object of this paper.

What I have to say is chiefly founded upon clinical observations made by my associate, Dr. J. B. Emerson, and myself at the Manhattan Eye and Ear Hospital, and also upon studies in private practice.

It has been supposed for many years, if not ever since the study of diseases of the ear had any scientific history, that a diagnosis had been made when a plug of black wax was found in the auditory canal of a person with impaired hearing. But we have learned that inspissated cerumen is usually only a symptom of an incipient or advanced lesion of a more serious nature. He who removes the wax and congratulates his patient on the usually much improved condition of his hearing, without a thorough investigation of the lesion which has induced this abnormal condition of hardening and collection of the wax, has omitted an inquiry that may be very important to his patient.

Yet it is true that there is quite a large class of cases of aural disease where an adequate diagnosis is readily made of a peripheric disease. Such are cases of acute catarrh and acute suppurations of the tympanum.

There is, however, a large class in which it is impossible without a painstaking examination, with a careful weighing of the subjective and objective symptoms to determine whether the causative lesion is in the peripheric or central parts of the organ of hearing. These cases are not attended by suppuration. A large proportion of them present no marked symptoms, except loss of hearing and *tinnitus aurium*. A closer examination will, of course, find many more evidences of disease of the ear than these, but they may suffice for a crude classification.

In a given case of aural disease, in which we wish to differentiate between disease of the outer or inner parts of the ear, it is wise to begin by an examination of the effect of noise upon the hearing power, and upon the sensory part of the ear. It is now definitely settled that there is a class of patients who hear better in a noise than in a quiet place, and that they themselves, not only hear better than they do under what are properly considered favorable conditions for hearing, but that they hear better than do those whose ears are in a normal condition. It is thus shown that this improved condition does not depend upon the fact that people speak louder in a noise, but that the noise makes a change in the working of the apparatus by which hearing is accomplished.

Observations, repeated over and over again for a number of years, have convinced me that this symptom of hearing better in a noise, belongs only to the peripheric affections, and never to those of the nerve. It cannot be readily observed unless both ears are affected, although it may even then be detected in very intelligent patients. I recall two such. They have found out that with one ear they hear exceedingly well in a noise, and with the other badly. They utilize this knowledge in travelling in the railway cars.

The determination of the existence of this symptom is then a very good guide in the diagnosis of aural disease. How has the fact been ascertained that it is found only in affections of the auditory canal, tympanum, Eustachian tube—in short, in lesions situated peripherically to the perceptive apparatus? I answer, by a long series of observations upon cases which are similar in all other respects to affections of the outer or middle ear. In one instance, I was for a

[1] Read before the Section in Neurology, New York Academy of Medicine, April 13, 1888.

long time—that is, for two or more years—very much puzzled by the persistent declaration of an intelligent patient that he always heard better in the railway cars, although I felt sure, from the history, and from the other symptoms, that he was suffering from a central affection.

This patient is a man of fifty-nine years of age, who has been, but who is not now a practitioner of medicine. He suffers intolerably from the unpleasant effect which noise has upon his ears and head. To mitigate this, he had caused to be made, plugs of vulcanite very ingeniously and neatly constructed, which he wears constantly in the street and other noisy places. One day when, upon one of his visits occurring at long intervals, he was reiterating to me the fact that he heard better in the cars than where it was quiet, I asked him if he wore the obturators in the cars. He answered affirmatively, and he also stated that his hearing became worse the instant he took them out.

I learned on examination, to anticipate what I shall have to say of the use of the tuning fork, that with the obturators in his auditory canals, bone conduction was better, while when the ears were free from these, aërial conduction was better.

The explanation of the apparent exception to what I had supposed to be a rule was evident at once. I found that unlike persons with disease of the middle ear alone, he did not hear with ease, or better than those whose ears are sound in the noisy cars, but that he heard better than he could in quiet places, and also that the obturators made his hearing worse when he was trying to listen to one person in a quiet room. The plugs added a peripheric lesion to the central one. They diminished the intensity of the sound of the tuning fork by aërial conduction, just as as a plug of wax will in the ear of a boiler-maker who suffers from disease of the acoustic nerve as a result of his occupation, or as in the same class of cases a catarrh of the tympanum will mask the central lesion.

As I have shown in a paper upon "The Effects of Noise upon Diseased and Healthy Ears,"[1] boilermakers' deafness depends upon a central affection, one of the labyrinth or acoustic nerve. Like people who have no such disease, they may have a peripheric affection of the ear added to this. They will then present what may, perhaps, be called a mixed case, and often the symptoms of the disease of the canal (wax) or of the tympanum (acute catarrh) will predominate, as far as the tuning-fork is concerned, until the peripheral disease disappears. My patient had artificially packed his auditory canal. Hence the relatively better hearing in a noise and the diminished intensity and duration of the aërial conduction.

It not unfrequently happens that the peripheric disease advances to be also one of the vestibule and labyrinth, or it may simultaneously affect both parts, as in suppurative inflammation of the tympanum in scarlet fever. We may have, and often do have, at the same time intense congestion or even suppuration of the labyrinth also. In chronic non-suppurative affections of the middle ear the labyrinth may also become diseased. It is only in well-demarcated cases, or those in which the symptoms of peripheric or central disease, as the case may be, predominate excessively over the others that this symptom of hearing better or worse in a noise can be readily made out. Although I am no friend to the system of the too rigorous bounding of the situation of a disease, such, for example, as the classification of an affection of the iris as entirely distinct from one of the ciliary muscle and choroid, I believe that we are very often able to demarcate a disease of the tympanum from one of the labyrinth. The parts are anatomically quite distinct.

It is not always easy to decide definitely that a given patient does, or does not, hear better in a noise. It is astonishing that even moderately intelligent persons, who hear very badly in the ordinary semi-quiet of their homes when engaged in conversation, and who hear better than their neighbors with good ears in the elevated railway, or surface, or steam cars, or in the din of a machine shop, will sometimes persistently declare that they hear worse in a noise. Their preconception of what they believe to be the case, causes them to ignore the facts, when they often might have much more comfort of their lives if they appreciated that they always hear better under certain conditions. "None so deaf as those who won't hear," is particularly applicable to these cases. I wish to deduce from this fact of the common failure of correct observation, that patients should be subjected to a careful cross-examination before their statement that they hear worse in a noise, is accepted.

I think we may set it down as a fact that persons with impaired hearing, who actually hear worse in a noise than in a quiet place, are suffering from some central disease of the ear. But we may easily accumulate the evidence on this point. We are by no means confined to this one symptom in making a differential diagnosis in aural disease. It should be added, while upon this subject, that noise not only decreases the hearing capacity in those affected with central disease of the ear, as it does in those with good ears, but it is unusually distressing and disturbing to them. Those who are affected with purely tympanic disease experience none of this distress or discomfort. If there be any apparent exceptions to this latter statement, a little close examination will show that they are only apparent.

In many cases of acute catarrh of the tympanum, noise is distressing, but other symptoms soon indi-

[1] Archives of Otology, vol. xii. p. 103.

cate that we have to do with a case of *panotitis*, or of simultaneous affection of the labyrinth and tympanum. A well-defined chronic or acute inflammation of the tympanum will show no discomfort in noise, but will be very favorably affected by it, while it is a part of the necessary treatment of an inflamed acoustic nerve to exclude the sound from it by plugging the auditory canal, and other devices.

I should have observed before, that many people who speak very feelingly of the variability in their hearing power, are really mistaken when they suppose that their hearing varies under the same conditions. It is the variability of these conditions, and chiefly as to noise and quietude, and not of their hearing power, especially in chronic cases, that is really the explanation of the variable capacity to hear.

The disproportion between the capacity for hearing the watch or acoumeter and conversation, which usually exists in central diseases of the ear, may sometimes add another link to the chain of evidence. In these cases the human voice is heard in a quiet place relatively much better than the watch. In peripheric disease there is no such disproportion. Persons with disease of the tympanum hear all sounds badly in a quiet place.

Important as is the consideration of the effect of noise upon the ear in differential diagnosis, it must yield the place in significance to the evidence given by the tuning-fork.

The literature of otology from the time of E. H. Weber, 1858, to our own is rich in suggestions as to the use of the tuning-fork in the diagnosis of aural disease. But it is not, in my opinion, until Rinne's experiments were modified and amplified by American observers, that we had what I think we now possess, a simple means, in the vast majority of cases, of making a differential diagnosis as to peripheric and central aural diseases.

It does not fall within the scope of this paper to recount the steps that have been taken to bring us where we are now, nor will it be supposed that I am entirely ignorant of them because I simply allude to them. I am anxious simply to show neurologists and practitioners in general that we have finally acquired a simple and tolerably exact system of diagnosis in these important cases.

If the tuning-fork known as C^1 or $C,^2$ be listened to by a person under fifty years of age, with normal hearing power, it will be found that it is always heard louder through the air, when placed in vibration and held in front of the *meatus auditorius externus*, than when its handle is placed firmly on the mastoid process. It will also be heard for a longer time. According to Emerson's experiments,[1] C^1 and C^2 are heard about twice as long (thirty-eight seconds) through the air as through bone; hence, as Rinne's famous experiment shows, if the person upon whom the observation is made indicates the instant that he ceases to hear the fork through the bones and it is held in front of the meatus, it will still be heard the number of seconds necessary to the proportion. If now we use the tuning-fork on the assumption that these observations of Emerson's have shown the truth as to ears with normal hearing, we have a most reliable test by an observation of the departure from a normal standard in a given case.

It has been observed, although Emerson's paper, written in 1882, makes no mention of this, that after middle life bone conduction is much reduced. This is due, I think, to senile changes, and I have named the condition *presbykousis*. This must be taken into account in all investigations, but it may be allowed for, and will not interfere with the diagnosis. If an auditory canal of a normal hearer be artificially plugged in any secure manner, or by disease, the bone conduction becomes at once intensified and it is longer. Observations upon many thousands have shown this.

This is equally true, with a few exceptions, when pus is seen to block the tympanum. In these exceptional cases the tuning-fork is heard better through the air than through bone. But when the pus is removed and the tympanum somewhat, although perhaps not entirely freed from inflammatory products, the bone conduction will again predominate. In these cases pressure has been placed upon the vestibule and cochlea, and a case of tympanic disease converted into one of the labyrinth also.

I have already alluded to the change of a case of acoustic neuritis, such as occurs in boiler-makers, by a plug of wax or tympanitic catarrh, to one of peripheric disease.[1] In this case the tuning-fork will be temporarily heard better through the bone. From these two series of facts, it is not far to the deduction that we are dealing with a disease of the peripheric part of the organ of hearing, where the bone conduction is louder and of longer duration, and that we have a central trouble when the reverse is true, and the tuning-fork is heard better and longer through the air. Taken in connection with the effects of noise upon the ears, we have a tolerably accurate means of diagnosis.

Why it is, that the sound of the tuning-fork is intensified when conducted through bone in disease of the middle ear and auditory canal may perhaps be easily explained. But why in disease of the central apparatus is the tuning-fork heard best through the air? I suppose it is simply because in any failure of the perceptive apparatus, the sound is best heard through the most favorable channel for the conduction of sound. Just as the pupil is the best

[1] Archives of Otology, vol. xii. p. 63.

[1] Transactions American Otological Society, 1886.

gateway for the entrance of light to the retina, so is the auditory canal the best entrance for sound to the membrana tympani. On the other hand, when the peripheric parts of the ear are converted by plugs of wax, or by collections of mucus or pus, or by thickening of the ligaments of the ossicula, or of the mucous membrane of the tympanum into solid conductors and resonators, sound passing through them is intensified. To such a degree may this go on, that, as we have seen, a person suffering from disease of the acoustic nerve may, by plugging his ears like his companion, who has only chronic inflammation of the tympanum, increase his hearing in a noisy place.

In 1874[1] I made some investigations upon the effects of quinine upon the ears, and I came to the conclusion that the impairment of hearing caused by the drug was due to its effect upon the cochlea. I was not then fully aware of the value of the tuning-fork in the differential diagnosis of peripheric and central aural disease, but since then I have made several observations upon patients clearly affected with cinchonism, having, among other symptoms, great impairment of hearing, and in all the cases the bone conduction was greatly diminished, and only the aërial remained present to any extent.

I have offered no apology for the assumption, easily deduced from what I have said, that the neurologist is bound to attempt to differentiate between a central and a peripheric aural lesion. Many of the cases that present themselves to you have aural symptoms. None but the most narrow specialism can afford to pass over the investigation of these symptoms or to relegate them to the otologist. The capability to examine the membrana tympani, and the use of the tuning-fork, in the manner that has been indicated, will furnish the means, in the vast majority of cases, for an accurate differential diagnosis.

I may then recapitulate as follows the steps of the method which I have endeavored to demonstrate.

1. Determine the effects of noise upon the hearing power and sensibility of the patient. If noise increases, or does not diminish the hearing power, the case is probably a peripheric trouble. It is central if noise diminishes the hearing. If noise is painfully disagreeable it also points strongly to central disease of the ear.

2. Observe whether the patients hear the watch relatively as well as the voice. Those suffering from lesions beyond the tympanum usually hear the human voice out of all proportion to their ability to hear the tick of a watch.

3. Test the aërial and bone conduction by means of the tuning-fork C^2. If the vibrations be heard better and longer through the bone, it is only exceptionally that the disease is not peripheric. If, on the contrary, they be heard better through the air, the disease is one of the labyrinth or of the trunk of the nerve, or of the nerve centres.

A YEAR'S WORK IN LAPAROTOMY.[1]

BY WILLIAM GOODELL, M.D.,
PROFESSOR OF GYNECOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

DURING the year 1887 I had fifty-three laparotomies, as follows:

	Cases.	Deaths.
Ovariotomy	27	5
Oöphorectomy	19	1
Hysterectomy	1	
Malignant tumor of omentum	1	1
Pelvic abscess	2	
Exploratory incision	3	
	53	7

With regard to the fatal cases I shall begin with those among my *ovariotomies*.

Case 194 was one of a small but malignant papillary cyst of each ovary. The papillary growths had penetrated into and through the wall of each cyst, and appeared in large masses on the surface, causing ascites, and infecting every abdominal organ. Intestinal adhesions needed three ligatures, and the application of Monsel's solution of iron. On the third day, obstruction of the bowels set in, followed by obstinate vomiting and great tympanites. The temperature kept natural, and the pulse under 100; yet, in spite of large doses of calomel and of belladonna, and of many turpentine enemata, the bowels were not moved, and the woman died on the seventh day.

Case 195 was that of a short but extremely fat woman. Two months before the operation she weighed 272 pounds, but had failed so much in health and strength that, at the time of the operation she weighed 254 pounds, and she could not walk without assistance. Owing to excessive deposit of fat in the abdominal wall, which was also œdematous, the incision had to be a long one, as well as a deep one, and the area of raw surface made by the wound was the most extensive I have ever made, or have ever seen. Both ovaries, being diseased, were removed. The left one was a large, multilocular, papillary cyst, weighing about twenty pounds. Its whole anterior surface had contracted very firm adhesions to the abdominal wall. A considerable amount of ascitic fluid was present. As she was operated upon at her home in the interior of Pennsylvania, I did not see her again. She died, from peritonitis, on the fourth day.

Case 204 was in a very low condition at the time of the operation, which was undertaken in every sense as a forlorn hope. To allay her sufferings, she

[1] Read before the Philadelphia Obstetrical Society, April 5, 1888.

had been tapped by her physician sixteen days before. At the time of the operation she was delirious, had a high septic fever, and suffered extreme abdominal pain. Her shrieks so disturbed the inmates of the University Hospital that she was removed to a room at a distance from the wards. The cyst was intraligamentary, weighing probably about twenty pounds, and it was adherent to the abdominal wall, the intestines, the stomach, the aorta, the womb, and to the whole pelvic basin. Which ovary was implicated I cannot say, for I was unable to find a pedicle, or to discover the second ovary. All the adhesions were severed, save those to the womb and to the pelvis, and these were not touched, as the woman seemed to be dying. During the whole operation, indeed, hypodermatics of alcohol and of ether had to be given frequently, to prevent fatal collapse. All the free portion of the cyst was cut off, the rest stitched to the wound, and a drainage tube put in. The patient never rallied, and died seven hours later.

Case 205 was one of colloid cyst, weighing thirty-three pounds. The woman had been tapped one month previoüsly. At the time of the operation she was bedridden, greatly emaciated, and much prostrated by pain and sleeplessness. The cyst had burst some weeks before, and every internal organ was infected. The adhesions were universal. The peritoneal cavity was thoroughly cleansed, and a drainage-tube put in. She died on the eighth day, from sheer exhaustion.

Case 211 was one of suppurating, dermoid cyst, and had been bedridden for several weeks by an attack of peritonitis, followed by septic fever with night sweats. The cyst, weighing ten pounds, was full of hair, and a putrid matter which gave off an offensive odor. The walls were so rotten that they tore in several places, while very firm adhesions in the right loin were being severed. Hence, some of the contents of the cyst escaped into the abdominal cavity, which, however, was carefully washed out, and a drainage-tube put in. She died on the fifth day, from septicæmia.

Of my nineteen *oöphorectomies* I lost one case, and that one on the fourth day, from suppression of the urine. It was one of papilloma of each ovary, and of the broad ligament. The operation was not a very difficult one, yet it was followed by suppression of urine and uræmic coma. Previously to the operation there had not been any symptoms pointing to renal disease, and the urine had not been examined, but kidney-mischief must have existed. Toward the close the patient's breath became excessively offensive, and she died at the end of three days.

Among my oöphorectomies I had several difficult operations, both from adhesions, and from the presence of large uterine fibroids, for which the operation was performed. But I shall not enlarge upon these cases, as I wish to defer their consideration for another paper.

Of the seven remaining laparotomies one resulted in death on the forty-eighth day. It was a case of malignant colloid tumor of the omentum, in a patient of Dr. I. W. Hughes, of West Philadelphia. Ascitic fluid was present in abundance, and the patient had been confined to her bed for many weeks, from attacks of great abdominal pain. From the hypertrophy of the omentum, from the excessive vascularity of the parts, and from intimate intestinal adhesions, the operation was one of difficulty. At the end of a week I left the city for my holiday. During that time, and for the following week, the lady did well; then fever set in, and, after a few days, a large, deep-seated abscess broke through at one end of the abdominal wound. Later on, another abscess burst into the large intestine, and she died from exhaustion, on August 16th, the operation having been performed on June 29th.

The other successful laparotomies consisted of two cases of chronic, pelvic abscess, in which the incision into the sac was sewed to the abdominal wound, and a drainage tube put in. In one of these a ventral hernia resulted. There were three cases of exploratory incisions. In one, a patient of Dr. George D. Nutt, of Williamsport, Pa., there was a painful fibroid or a sarcoma of the womb. On February 17th I attempted to remove her ovaries, but I could not reach them, on account of firm and deeply seated pelvic adhesions. In the second, a patient of Dr. J. S. Hunt, of Easton, Pa., the abdominal section was made to determine the character of a tumor, which was a carcinoma, probably of the kidney and of the adjacent intestine. The incision, being just large enough to admit two fingers, did not enable me to make out a precise diagnosis as to the organs involved. But, as the growth was unquestionably malignant, I did not feel justified in enlarging the wound. The patient, although seventy years old, recovered promptly from the operation, but she died a few months later. The third exploratory incision was in a patient from whom I removed, on February 14, 1885, a subperitoneal, fibroid tumor of the womb, weighing eight pounds. She remained well for some months, and then began to lose flesh and to suffer from severe abdominal pains. Several tumors could now be felt filling up the abdominal cavity, and she was urgent for an operation. So, although my diagnosis leaned to malignant disease, I opened the abdomen on March 8, 1887, before a ward class at the University. The growths proved to be a sarcoma of the womb and of the ovaries, these organs being so fused together that their removal was impossible.

The case of hysterectomy consisted of the removal of a subperitoneal fibroid of the womb, with a very short pedicle. While ligating the pedicle, I tore it partly off from the womb, and the bleeding that fol-

lowed could be checked only by the thermo-cautery. The tumor weighed about two pounds, and it was removed on account of the pain it gave, and the vesical irritation which it produced.

Among the twenty-seven ovariotomies there was a larger proportion of difficult cases than usual, nor did I decline a single case. In sixteen both ovaries were removed. Twenty-three had adhesions, and drainage was resorted to twelve times. In three of these the adhesions were universal; in six very firm intestinal adhesions existed; while in three the cysts were intraligamentary, presenting very embarrassing obstacles to their removal. In one of these cases of intraligamentary cyst the operation was not completed on account of the collapse of the patient, who died seven hours later. The other two recovered, but in one of these the wound had to be reopened four hours after the completion of the operation, in order to arrest a secondary hemorrhage from deeply seated pelvic vessels. The drainage tube told the tale of internal hemorrhage, otherwise the collapse would have been attributed to shock. In this case, also from injury to the rectum, a fecal fistula was established a few days later. Here again the drainage tube did good service to the woman, saving her life for the second time.

This formidable class of cysts needs a special treatment, which I described in a paper read before this Society a few months ago. It consists, firstly, in beginning the enucleation at the vascular portions of the cyst so as to cut off the blood supply early in the operation; secondly, in preserving the capsule of broad ligament as whole as possible; and, thirdly, in isolating the capsular cavity from the peritoneal cavity, by the sewing of the edges of the former to the abdominal wound and by the introduction of a drainage tube.

Special points of interest in my ovariotomy cases are as follows: Monsel's solution of iron was applied to oozing surfaces in Cases 194, 197, 198, and 209. In the first one it was applied to a bleeding intestine, from which the peritoneal coat had been stripped off. This patient died from obstruction of the bowels, due, as I believe, to a kink formed by the adhesion of the raw surface to some other viscus. I do not think that the iron salt had anything to do with the fatal adhesive inflammation. In the three other cases the iron was applied to oozing surfaces on the abdominal wall, and they all recovered promptly. Oozing raw surfaces on the bowels are often troublesome, and I have had to check the hemorrhage by fine ligatures, by Monsel's solution of iron, and by the thermo-cautery at a dull heat. Of all these modes I prefer the last when practicable. But when the oozing surface is a large one, or the bowel is not readily accessible, I prefer the iron solution as the safer remedy. Nor have I ever had any reason to believe that its action has been otherwise than beneficial. Usually, in these cases, a drainage tube has been inserted, not because of the use of the iron styptic, but because of the extent of the adhesions demanding its use. In Case 198 a drainage tube was not employed.

There were three cases of colloid cyst which had burst into the cavity of the abdomen some weeks before the time of the operation. In Case 201 the left ovary had burst, and much colloid and ascitic fluid had escaped from the abdominal incision. Every abdominal organ had apparently become infected, as all peritoneal surfaces with which the colloid fluid came in contact were roughened with miliary prominences. The abdominal cavity was flushed with plain warm water and a drainage tube put in. The woman got well without a bad symptom, and, as far as I know, is now enjoying good health. In Case 205 the cyst had burst evidently from a fall, and the health of the woman began at once to fail. She rapidly grew weak and very thin, as if slowly poisoned. When she was brought to me she was wretchedly weak and emaciated, and apparently near her end. The operation revealed a colloid cyst which had burst and partly emptied itself. The cyst had universal adhesions, and every abdominal organ presented an appearance of infection analogous to that of the preceding case. The abdominal cavity was also flushed and drained. Fever did not follow the operation, but the patient grew daily weaker, and died on the seventh day from sheer exhaustion. Case 207 was also very weak and greatly emaciated. The feet were also swollen, and she was virtually bedridden. In the operation I mistook the thickened peritoneum for the wall of the cyst, especially as a large quantity of ovarian fluid and large masses of lymph had escaped from the incision into the supposed cyst, which was in reality the abdominal cavity. The peritoneum was, therefore, stripped up for some distance before the mistake was discovered. The wall of the cyst was thick, but it had wholly collapsed by an opening made into it by the outward growth of one of the papillomatous masses which it contained. Chronic peritonitis had been the result, and the intestines, covered with false membrane, were agglutinated into one small bunch lying near the stomach. Every organ in the belly was either affected or infected. Enormous quantities of dirty, ragged and broken-down false membrane filled up every nook and cranny of the abdominal cavity. Two handfuls were removed from under the liver, and many handfuls from Douglas's pouch. The contents of the abdominal cavity weighed fifty-four pounds. The stripped up portion of the parietal peritoneum was cut away, the belly flushed and drainage employed. The tube was removed on the third day, which was remarkably early, considering the gross lesions of the peritoneal cavity. The woman slowly recovered, and in the fifth week returned to her home in West Virginia.

Table of Twenty-seven Cases of Ovariotomy.

Total number.	Name and Residence of Previous Medical Attendant.	Age.	Condition	No. of children.	Place of Operation	Date of Operation.	Adhesions.	Ovary Diseased	Weight of Tumor.	Length of Incision.	Drainage.	Result.	Remarks.
190	Dr. E. Hopkins, Marshalton, Pa.	35	M.	9	Private Hosp.	Feb. 5	Pelvic.	R. L	15 lbs.	Short	None.	Recovery.

216	Dr. W. F. Shine, St. Augustine, Fla.	49	M.	...	Home.	Dec 24	Omental, parietal, intestinal.	L.	20 "	"	"	"	Had septicæmia at time of operation; had three tappings.

In Cases 196, 211, and 213 the cyst burst during the process of breaking up adhesions, and some of the fluid escaped into the belly. In all such cases, although the danger is, in my opinion, overrated, I carefully cleanse the peritoneal cavity by pouring into it several jugfuls of warm water; but I do not always use a drainage tube. In Case 211 the cyst—a broken-down dermoid—contained putrid fluid, and the woman died, although drainage was resorted to. This case was, however, a bad one; the woman labored under septicæmia at the time of the operation, being, in fact, confined to her bed, and her death is attributable more to that cause.

The after-treatment of my cases of laparotomy is a simple one. For thirty hours nothing is given by mouth save teaspoonful doses of whiskey in a tablespoonful of water, and then only when needed by delayed reaction. Milk, beef-tea, and whiskey are, however, given freely by rectal enemata when indicated by extreme thirst or by feebleness. After thirty hours have elapsed, milk or beef-tea is given by the mouth in gradually increasing amounts.

I try as much as possible to avoid the use of opiates, and usually can get along without them. But I have to leave the decision of their administration to the skilled nurses who attend my patients; for in some cases it would be cruel and even dangerous to withhold opiates when the sufferings are acute. This anodyne is given either in a rectal suppository or in the nutrient enemata when they are needed.

LOCOMOTOR ATAXIA CONFINED TO THE ARMS: REVERSAL OF ORDINARY PROGRESS.[1]

By S. WEIR MITCHELL, M.D.,
of Philadelphia.

E. C. B., M.D., of California, aged fifty-five, was in active practice until two years ago. He has no constitutional disease of any description. By his own description he was a well man up to July, 1887, possessing nearly perfect health. Near to that time he observed that, in writing with a steel pen, his hand began to change—becoming unsteady. There was no tremor, certainly none manifested in his handwriting. He only discovered that there was slightly increasing numbness in the cushions of the finger-ends of both hands, extending through the hand, up into the arm, through the chest and down over the belly and back. About September 20th, this was slightly present in the toes, but more distinctly afterward. There seem to have been no preceding eye or bladder symptoms, nor, indeed, any warning such as usually attends an outbreak of locomotor ataxia. The character of the case has not greatly changed since the first attack; it has only shown more decisively its nature. Perhaps the best description I could give of it would be that which I take from my note-book of January 15, 1888. To make clear what follows, I will state that the case is in my experience exceptional. I have seen none which I could place alongside of it. It consists of an attack of locomotor ataxia affecting practically the upper extremities. In other words, the legs now show the same condition which one is apt to see in ordinary cases of this disease in the arms after the legs are pretty well on their course of degenerative change.

Nutrition.—This gentleman weighs one hundred and thirty-eight pounds; has lost twenty pounds; his height is five feet nine inches; his limbs are thin; throughout the body the muscles are more or less flabby, notably in the upper extremities, but nothing to be called atrophy; the legs are liable to swell slightly during the day; the arms are more liable to be swollen after sleep. The patient, an accomplished physician, declares the swelling not to be at any time œdematous. It offers slight resistance to pressure, and but a part of the swelling is due to serum. There is an appearance of yellow pallor about him which caused me to request Dr. John K. Mitchell to make an examination of the blood. The result surprised me. The corpuscles amount to 3,980,000 per c.cm.; the coloring matter is seventy-five per cent. of the normal, by Fleischl's test. Certainly the appearance of the skin would seem to indicate a want of blood not shown to exist by accurate test, repeated again and again. This condition of things I have several times seen in posterior sclerosis, a not excessive want of color or corpuscles, and a whiteness of skin and mucous surfaces which once we would have accepted as sure evidence of anæmia.

Sensation.—There is no pain of the character of neuralgia. He says that since his boyhood he has been liable to aches in the great trochanter and between the shoulders.

Touch.—At a half inch the compass points begin to be felt as two in the finger of either hand. There is no remarkable difference between the two hands. The sensation of numbness with which the disease began is, perhaps, more pronounced in the legs now than at first; but about the clavicles the sensation in all kinds appears to be normal; also it is fair for heat and cold, but decisions as to these are less rapid in the arms than in the legs. The pain sense is everywhere preserved. I ought to add that when the left hand is chilled it is apt to cause pain to run up the arm on that side. The special senses appear to be normal.

Dr. G. E. de Schweinitz gives the following statement of the eye conditions: "Vision in each eye with correcting glasses, normal; no disturbances of accommodation and his reading glasses allow comfortable range; three degrees of insufficiency of the interni; no other muscular anomalies, except slight drooping of the right upper eyelid. Pupils present normal reactions for light and accommodation; ophthalmoscope shows fine floating vitreous opacities; distinctly gray optic disks with hazy edges and general epithelial choroiditis. Form fields are normal; there is concentric contraction of the color fields. From these facts I conclude that there is beginning gray degeneration of the optic nerves, as well as disturbances of the choroid and vitreous humor."

[1] Read before the Philadelphia Neurological Society, March 26, 1888.

Motion.—Motion is generally weak; when he walks any distance he moves slowly, and in action the arms tire more easily than the legs. He stands well with his eyes open; but with his eyes shut he sways one inch to the right and an inch and a half forward, so that his station may be stated to be good for a man in his condition. It certainly shows how little ataxic trouble there is in the lower limbs. He moves the legs well, and the common actions of the feet exhibit little incoördination in these parts. On the other hand, the upper limbs are awkward in their movements. There is a great lack of coördination in every effort to make delicate adjustments, as when he attempts to touch his nose or ear with the eyes shut or to bring the forefinger of his right hand in contact with the tip of the little finger of the left hand. He fails also in the test of weights; he is unable to tell the difference between an ounce placed in his palm and a half ounce, or an ounce and a half. I took tracings of his efforts to hold a pencil steady. They showed no tremor—less than is common, and this negative symptom is a remarkable one in ataxics. The effort to draw *a* from right to left resulted in a singular illustration of defective co-ordination.

Electrical reactions.—There are no unusual peculiarities.

Muscular reaction.—All the muscles of the arms react to a direct blow, but are incapable of being reinforced by motion. The leg muscles have, as I judge, about the normal amount of response to the hammer blow, but are readily reinforced by hand motions. It is interesting to contrast these conditions of the leg and arm muscles. Elbow-jerk is lost on both sides, and non-reinforcible by motion or sensation. Knee-jerk is *excessive* on both sides and is easily reinforced. Ankle-jerk is also extreme, and when powerfully reinforced a slight clonus exists. Thus, if the tip of the foot be pushed upward so as to stretch the tendo Achillis, the blow on it results in two or three forward movements of the foot; at the same time, the patient makes a powerful motor reinforcement. I remark in this case, as I have done in others, that a blow on the left patellar tendon gives rise to motion in the left leg, also to what seems to be a reflex jerk of the left arm. I suspect that this phenomenon is due to the strong reinforcements produced by emotion; for, while it is frequently seen in the first interview with the patient, it may be impossible to evolve it at another sitting.

Secretions.—Generally normal; occasional diarrhœa; no painful gastric crises. There is no trouble with the bladder or rectum. Sexual power is lost.

Reflexes.—Skin irritations of the soles of the feet appear to cause no motion. Testicle reflexes absent, as also abdominal reflexes.

Remarks.—This case stands alone in my experience. It is a locomotor ataxia beginning in the arms. These lose their tendon reactions, but show excess of direct mechanical excitability. In the legs we find excessive knee-jerk and normal mechanical responses. The conditions seen in common cases of ataxia are here reversed. I have little doubt that in the earliest stages of this disease the tendon reactions are excessive.

SIX CASES OF EPIDEMIC CEREBRO-SPINAL MENINGITIS.[1]

By CHARLES K. MILLS, M.D.,
and
W. C. CAHALL, M.D.,
of Philadelphia.

Of the six cases briefly detailed in this communication, five were observed at the Falls of Schuylkill, Philadelphia, and one in the southwestern portion of Philadelphia. At the Falls of Schuylkill several other cases have recently been observed, and it is interesting to recall that it was in this neighborhood, during 1864 and 1865, that the disease was widely prevalent and very virulent. In the first case an elaborate autopsy was made, which gives the case a distinct scientific value; in the other cases, certain special points of interest make them worthy of being recorded. They are reported briefly so as not to load the paper with unnecessary details. The first four cases occurred in the practice of Dr. Cahall, and two of them were seen by Dr. Mills in consultation; the fifth was a patient of Dr. J. V. Kelley, of Manayunk, Philadelphia; the sixth was a patient of Dr. J. W. Dick, and was seen several times by Dr. Mills in consultation.

Case I.—Mrs. W., aged thirty, the mother of three children, had had bad health since the birth of her last child, now two years old. She was greatly depressed in spirits and imagined she had all sorts of diseases, but for a few months she had regained, to a considerable degree, her former health and spirits.

February 21, 1888, she was taken with chills and headache, and on the morning of the 22d, when first seen by Dr. Cahall, she complained of acute pains down both legs, but more intense in the posterior aspect of the knee-joints, any movements of the limbs causing her to scream with pain. She already had headaches, contraction of the muscles of the neck; and ten to fifteen irregularly shaped spots of a color from pink to purple, and from the size of a pea to a silver dime, were scattered over the legs and abdomen. Diarrhœa, abdominal distention, and tenderness were present from the first. Delirium came on by the morning of the 23d, with lucid intervals, when she said she saw everything double. All the other symptoms were intensified.

On the 24th she was totally blind and partially deaf, but when aroused could give sensible answers to questions. She still complained of the headache, but not of the legs unless pressure was made along the course of the nerves, when she would cry out as though suffering great pain. The pulse was rapid, but the temperature was never over 103°. There was general hyperæsthesia.

[1] Read before the Philadelphia Neurological Society, March 26, 1888.

On the 25th she sank into a stupor, from which it was gradually more and more difficult to arouse her. She died upon the morning of the 29th, on the eight day of her sickness.

Dr. Mills saw her in consultation the day before her death.

Autopsy.—Drs. A. H. P. Leuf and Judson Daland performed the autopsy, at which the writers were present, and examined the specimens. The following are the results of the megascopic examination.

Brain: The pericranium was very vascular. The veins of the dura mater were gorged with dark venous blood on the outside, and the inner side of the membrane showed marked arterial injection. It was adherent to the convexity of the right hemisphere at the upper border of the quadrate lobule. In front of this on both sides, were Pacchionian adhesions of the dura to the brain. The anterior lobes of the brain, especially on their convexity near the great median fissure, were œdematous, with a few slight opacities of the pia. At the base was seen liquid and semi-liquid pus about the optic chiasm, interpeduncular space, pons, and oblongata. The auditory and facial nerves were bathed in pus, as were, in fact, all the nerves at the base of the brain except the olfactories. All the cranial nerves were soft, especially the olfactory and optic. Softening of the crura cerebri, pons, crura cerebelli, and oblongata was also decided. The pia covering the isthmus was intensely injected, but this could only be seen by the removal of the pus that covered it. The arachnoid between the medulla and cerebellum was also covered by a thick layer of pus.

The puncta cruenta were well marked, numerous, and dark. The basal ganglia were normal, except some venous puncta. The fornix was softened. The fissure of Sylvius presented nothing abnormal on either side when opened for inspection; and all the cerebral vessels appeared normal.

Spinal cord: On opening the spinal canal, the cord lay flat and spread out in its membranes, instead of being narrow for the canal, and bulging with well-marked convexity. The dural vessels were well injected externally and internally. On section of the dura pus exuded freely. The membranous coverings of the spinal nerves within the canals were almost ecchymotic. This was most noticeable in those given off opposite the lumbar enlargement, and especially on the left side. The whole cord was surrounded with yellow creamy pus. The lower half of the back of the cord was covered with a yellow gelatiniform pus layer, while the same covering was found on only the lower two inches in front. All the pus was situated between the dura and pia. The anterior and posterior spinal vessels were gorged with blood, and there was a fine injection of the arterioles of pia and dura. A few adhesions between the pia and dura were noticed behind, but many throughout the whole length of the cord in front.

Peripheral nerves: The lower end of the left sciatic in its two divisions (the internal and external popliteal) were removed; they were marked externally by several distended bloodvessels. On the right side this was not so noticeable as on the left. The second, third, and fourth digital nerves of the dorsum of the right foot presented nothing abnormal, but slight pressure at the end with forceps caused some blood to appear. The same was true of the second and third digitals of the dorsum of the left foot.

Muscles: A piece of muscle was excised from the lower end of each semimembranosus. To the naked eye it presented nothing abnormal.

Thoracic and abdominal viscera: Careful examination showed the lungs to be crepitant throughout and apparently entirely normal. The pleural cavities were free from effusion. A few adhesions were present on the right side, and numerous adhesions on the left, many of which were evidently quite old.

So far as could be determined by careful naked-eye examination, the heart and aorta, intestines, liver, and kidneys were normal.

The stomach was normal in size, but here and there, under the mucous membrane, were seen small extravasations of blood. The spleen was twice its normal size, but of firm consistence, and its capsule normal. The uterus and its appendages were normal in size, shape, and position. The endometrium was somewhat thickened, and of a dark red color; there were considerable submucous extravasations of blood.

Marked evidences of recent moderate, adherent peritonitis were found. This was particularly noticeable on the surface and between the coils of the small intestine. At no place did the layer of lymph exceed the thickness of a sheet of paper, and the peritoneal cavity contained no liquid effusion.

A small drop of purulent-looking substance from the thick exudation covering the spinal cord was examined microscopically by Dr. Daland, and showed numerous leucocytes imbedded in a gelatinous-like substance, probably lymph; apparently there was not as much pus as would be expected from the marked yellow color.

CASE II.—N. W., aged eleven, daughter of Mrs. W. (Case I.), was of a nervous disposition inherited from her mother.

Three days before her mother's death the child was taken suddenly ill with pain in her left leg below the knee, particularly severe around the ankle-joint. Slight redness and swelling were perceived about this joint.

Tincture of opium and sodium salicylate were prescribed, and on the following morning the leg was much better, but her neck was painful and drawn to the left side, from contraction of the sterno-cleido-mastoid muscle. There was tenderness along the spine from between the shoulders to the occiput. She did not suffer with headache and had no delirium. The special senses remained normal. The bowels were constipated. In the evening a slight rise of temperature was noticed, but her pulse was slower than normal.

Under ordinary circumstances the case would probably have been dismissed as an ordinary one of rheumatic or neuralgic torticollis, but the patient's mother was lying up stairs with an undoubted attack of cerebro-spinal meningitis, which had commenced in a similar though more violent manner. This aroused

suspicion as to a similar cause for the two attacks. An eruption was looked for, but did not appear until the fourth day, when five spots, two pink and three purple, made their appearance on the legs and lower part of the abdomen.

The tincture of opium and sodium salicylate were continued in moderately large doses. Friction and counter-irritation were used upon the neck, but the contraction and tenderness on pressure remained in a marked degree for several days, and did not finally disappear for several days longer.

Case III.—M. M., aged twenty-four, a mill-girl, had a history both in herself and in the female portion of her family, of a highly nervous temperament. On the 16th of January, while enjoying her usual health, she had gone to her work. During a passionate debate among the employés as to the advisability of a strike, which she opposed, she proceeded, with the others, to the sidewalk, laboring under great mental excitement. The day was very cold, and shortly after reaching the windy street, she fell to the pavement screaming with a pain in her neck. She was taken to the house of a neighboring physician, who gave her two hypodermatic injections of morphia, after which she was brought home. At first she complained of nothing except the intense pain in the neck. The head was drawn backward. She had no fever; pulse 60. The day following her neck was about the same, while an intense headache of a constricting character was added. The mental faculties were clear and all the functions of the body were well performed. Fever was still absent, and pulse 60.

After the use for two or three days of morphia, bromide, and chloral, without the slightest improvement, hysteria was suspected, but later a genuine organic disease seemed manifest. At about the end of a week she complained of great pain in both legs, and especially upon pressure over the nerves. Dr. Mills saw her at this time in consultation. While the pain in the legs continued the headache and neckache were greatly lessened. Morphia, sodium salicylate, and oil of gaultheria were given, under which the pain in the legs disappeared. The headache never returned with its first intensity, but an active delirium took its place. Illusions and delusions kept her in a state of excitement for days with scarcely any sleep, in spite of large doses of anodynes. The drawn state of the neck was persistent. Fever came on, although never high. The pulse continued slow.

The patient drifted from bad to worse. The active delirium gave place to a heavy stupor, when it was difficult to administer either medicine or nourishment; but as nourishment was considered the most pressing need, it was regularly and persistently forced upon the patient. A flea-bite eruption appeared on the arms, face, and neck, but not until after the second week. The eruption would disappear and reappear, but never so distinctly as at first.

For three weeks longer, or to the fifth week of the sickness, the patient's mental condition remained practically unchanged. Iodide of potassium, 5 grains and bichloride of mercury $\frac{1}{48}$th grain were given three times a day. In three days the girl's mind was perfectly clear, and she remembered her sickness only as a disagreeable dream.

Case IV.—R. L., aged nineteen, a mill girl, was taken suddenly ill while at her work upon the 1st of March. An intense headache followed by chills ushered in a high fever. Her temperature was 103.5° the first evening. She complained of pain in the limbs and neck, but there was no contraction of the muscles of the neck until March 3d. Nausea and vomiting were present during the first three days, and during the nights of the same days the patient was delirious.

Pills of opium and quinine, with an effervescing fever mixture, reduced the temperature by March 4th to 100° F., above which it never again rose. From the 4th to the 9th the case remained at a standstill. The headache was greatly better, but the contraction of the muscles of the neck was increased, fixing the head immovably backward. Hyperæsthesia and deep-seated pain upon slight pressure were present over the whole posterior region of the neck. The patient complained of feebleness and exhaustion. On the 9th, the opium and quinine were given at longer intervals, and iodide of potassium 5 grains, and bichloride of mercury $\frac{1}{48}$th grain, four times a day.

In two days the patient was sitting up with fever gone, neck greatly relieved, and appetite and sleep returned. Her convalescence was from this date forward rapid and complete. No spots were found in this case.

Case V.—Notes of the following case were furnished by Dr. J. V. Kelley, of Manayunk, Philadelphia:

The patient, a young man, was first seen February 18, 1888. He was in good health until the preceding day, when in the evening he was taken with a chill, vomited twice, and had two stools. He worked during the forenoon of the day he was taken sick, although feeling very badly. At 2 P.M., when first seen by Dr. Kelley, he was in bed and complained of great soreness. He complained of tenderness, confined to the abdomen, so much so that the case was at first thought to be one of enteritis. He was very cold; pulse 134, and he seemed much prostrated. He was placed on brandy and tonics, and the next day in a manner revived.

February 20th, he was seen by Dr. Bruen, who thought the case to be one of cerebro-spinal fever. Herpes labialis was beginning to show. The next day he had some delirium; his pulse was still 134.

On the 22d, he was seen by Dr. Pepper, who agreed that the case was one of cerebro-spinal fever. Herpes labialis was now profuse, some delirium was present, and hearing and sight both defective. He had two offensive stools, and complained of great general soreness, but had no characteristic spots, although there was a vesicular eruption on the chest. He had no retraction of the head, although his neck was somewhat stiff. His abdomen was tympanitic, and this persisted until death occurred, February 28th.

About the fifth day of his seizure the patient complained of blindness. On one occasion he bled from the nose and spat some blood. No lung or heart symptoms could be demonstrated by examination,

and the man died from prostration on the eleventh day of the disorder. He showed typhoid signs, but the case was certainly not typhoid fever. The treatment was by stimulation and tonics, with full feeding. Brandy, quinine, digitalis, opium, and turpentine were given.

Case VI.—The following interesting case occurred in the practice of Dr. J. W. Dick, and was seen by Dr. Mills several times in consultation. The patient, R. A., a boy eight years old, in the latter part of October, 1887, had an attack of mild scarlet fever, followed by slight nephritis, which kept him in the house until the last of December. After this time he began running out of doors in all sorts of weather, in his play sometimes lying down in the snow. He seemed to be in the best of health until February 2d, when he was suddenly taken sick at school. He came home complaining of violent headache, and was taken down also with vomiting and high fever, with marked delirium. The delirium soon subsided, and he sank into a semi-conscious condition. He would not answer, as a rule, any question or demand, but sometimes ask for a drink, and he would give notice when he wished to evacuate the bowels or bladder. On the fourth day an eruption appeared over the entire body, more especially marked on the face, neck, and upper extremities. The eruption consisted of small pin-point, fleabite-like spots, which did not disappear on pressure. It faded in about four days after its first appearance.

His temperature varied at first from 103° to 105° F., sometimes higher in the morning than in the evening, and sometimes the reverse. The following is the temperature record from February 17th to 26th:

February.	Morning.	Evening.
17th	104.4°	104° F.
18th	104.4	103.8
19th	103.6	103.6
20th	102.6	103.2
21st	102.4	102.6
22d	102.4	101.6
23d	102	102
24th	101	101
25th	101	101
26th	101	101

After this his temperature showed a tendency to fall, and came down to 99.5°.

His pulse was weak, but regular, varying usually from 112 to 120. His respirations ranged from about 30 to 40. The vomiting lasted only during the first day, after which he took and retained both food and medicine. His bowels were usually slightly constipated, but responded freely to enemata. After February 22d he did not attempt to speak, but lay in a comatose condition, with frequent sudden out cries, as if in pain. His abdomen became decidedly scaphoid. He was troubled with a cough throughout his entire sickness. There were abundant mucous râles, with a little dulness on percussion on the right side.

In the beginning of his sickness the slightest movement gave rise to intense pain. This gradually subsided, but he continued throughout to have great tenderness on pressure in the region of the neck and in the legs. The pain in his lower extremities was a very marked symptom; handling them, and pressure along the nerves or squeezing of the muscles, caused great suffering. No swelling of the joints was present. He exhibited some pain and tenderness in the upper extremities, but not nearly as marked as in the lower; the knee-jerks were retained. He could move the legs up and down freely, but the feet had a tendency to assume the equino-varus position; this foot-drop was more marked on the right side. No paralysis of the cranial nerves was present. For three weeks before his death he was apparently both blind and deaf; for a short time he had a slight discharge from the left ear. He died on the thirty-sixth day.

Remarks.—These cases are of considerable interest from various points of view, but we shall only be able to call attention to a few of the most important features. At a former meeting of the Society it had been suggested by Dr. Mills that neuritis was probably present as a complication or coincidence in some of the cases, and in others the infectious agent caused a multiple neuritis rather than a cerebro-spinal disease. As no microscopical examination has yet been made from the specimens of Case I, we are not able to say positively that neuritis was present, but the gross examination of the sciatic and other nerves led to the suggestion that either congestion of the nerves or neuritis was present.

A few words might be said with reference to treatment. Bromide of potassium, in half-drachm doses, failed to relieve the headache or produce sleep in the severe cases (the same result followed chloral). Nothing definite can be said as to the effect of quinine. Sodium salicylate and oil of gaultheria gave relief to the neuritic pains in the legs, but produced no appreciable benefit to the head and neck. Opium and morphia did positive good in every case, but after the more acute symptoms had passed the good effect seemed to be lost. In the two cases where iodide of potassium and the bichloride of mercury were used by Dr. Cahall, the effect was surprising to patient and physician alike. The improvement was too rapid to be the result of the alterative properties of the drugs, but more like the action of specific remedies.

MEDICAL PROGRESS.

When to give Digitalis.—The *Medical Press* writes that it has been observed that he who discovered and laid down rules for the administration of digitalis would be doing infinitely greater service to the profession than they who encumber therapeutics with new and untried though much belauded "cardiac tonics." There are difficulties in the way of any comprehensive directions for the employment of this drug, because it is sometimes observed clinically to produce distinctly beneficial results in cases where theoretically its effects are contraindicated. Dr. James Stewart has recently suggested a sign of value which we commend to practitioners. He points out that

in cases of heart failure too pronounced to allow of resort to alternate methods of treatment involving exercise the best results are obtained by rest in bed with full doses of digitalis, the supply of liquids being curtailed to the minimum. The first marked effect of cardiac failure is a fall in the aortic blood-pressure leading to diminished excretion of urine and a lowering in the vital processes generally. The diuretic power of digitalis is directly dependent on its influence in restoring the diminished pressure, and to effect this the drug must be given in full doses. The important fact to bear in mind is that when the amount of urine falls, after increasing, under digitalis, the administration of the drug should at once be suspended. The failure in the renal excretion may be taken to indicate that the heart is incapable of reacting further to the stimulus, and serious risk attends non-attention to this rule. The amount of the drug and the time required to bring about this secondary fall varies greatly according to the susceptibility of the individual to its effects. Forty minims of the tincture four times daily for three days are generally sufficient, but as much as half an ounce daily in divided doses is sometimes required. Scilliain and mercury are both direct diuretics, and are very useful in conjunction with digitalis. Caffeine is another useful diuretic, and a combination of caffeine with digitalis is very highly spoken of. In these observations we have several points of practical importance in the treatment of a very difficult class of cases.

Extirpation of the Kidney for Sarcoma; Recovery.—At a recent meeting of the Society of Physicians of Vienna von Frisch exhibited a patient from whom, four weeks previously, he had extirpated the left kidney for sarcoma. The patient had first observed a tumor beneath the margin of the ribs on the left side four months before the operation, which grew rapidly. When brought under observation a hard, non-sensitive and immovable tumor was found, which extended from the border of the ribs to the anterior superior spine of the left ilium; it gave the patient no inconvenience, and when punctured by an aspirating needle gave clear blood. An incision was made from the xiphoid process to the umbilicus, and a second incision at right angles to the first exposed the tumor; many adhesions required separation; bleeding points and the pedicle of the tumor were ligated. The tumor weighed six pounds, and proved on microscopic examination to be a round-celled sarcoma containing giant cells. Prompt recovery followed. the wound healing by first intention. — *Wiener medizinische Presse*, March 25, 1888.

Formulæ for Prescribing Iodoform.—The *Centralblatt für die gesammte Therapie* for April, 1888, gives the following formulæ:

In pill form,

Iodoform,	
Cort. cinnam.	āā gr. 30.
Extr. cascarill.	ʒ 1.

Ft. pil. 60 in num.
Sig.—Three pills daily.

Iodoform and potassium iodide may be thus given:

Iodoform.	part 1.
Potass. iodid.	parts 70.

Triturate carefully and add

Glycerin.	parts 70.
Spts. vini. rectif.	parts 200.

Dose, fifteen drops on sugar, three times daily.

Successful Reimplantation of a Trephined Button of Bone.—Burrell describes a recent trephining, in which the button of bone was successfully replaced, as follows, in the *Boston Medical and Surgical Journal* of March 29, 1888: The trephining was an exploratory one done on a boy, aged thirteen, to determine the presence or the absence of a depressed inner tablet of the skull that might have accounted for a group of existing cerebral symptoms. Operation: the child was etherized and the localization lines were drawn by Dr. W. N. Bullard; a large semilunar incision was made with the base downward, including the cicatrix; a second incision was made through the periosteum, and this was completely and freely elevated from the bone, which was then removed with a large trephine: no fracture was detected, and no abnormal appearance of the dura mater was found; an exploratory puncture with a trocar was made into the cerebral substance in the direction of the median portion of the ascending frontal convolution, entering, perhaps, four inches—no result. The bone, which had been carefully preserved in an antiseptic solution, was then carefully replaced in the skull, the periosteal flap was secured in position by a fine continuous catgut suture, and the overlying structures were similarly dealt with. Drainage being secured in the scalp by a dozen or more strands of catgut, an antiseptic dressing was applied, and the recovery from a surgical standpoint was uneventful. When the dressing was first removed at the end of two weeks, the wound was found completely united; for a short time after this a dressing was kept on the boy's head as a protection against any injury to the recently repaired structures. The child's cerebral symptoms gradually grew worse, and he finally died in the Boston Lunatic Hospital, in December, at the expiration of nearly eight months after the trephining.

Congenital Facial Paralysis.—Dr. B. H. Stephan, of Zaandam, publishes in the *Weekblad* of the Dutch *Tijdschrift voor Geneeskunde* an account of a rare case of congenital facial paralysis, the explanation of which is very obscure. The subject was a woman to whom her mother had given birth before the arrival of the medical man, the labor having, of course, been a simple, and not a prolonged one. It was very soon noticed that the two sides of the face were different in appearance, the left being "like a mask," in striking contrast to the right, which was "full of expression." The condition remained unchanged as she grew up. When seen by Dr. Stephan, the pupils were equal, and reacted equally to light. There was but little difficulty in eating or drinking, owing to practice. Sensation was equal on the two sides. The hearing was, however, somewhat dull on the left side. No difference could be detected in the tympanic membrane. Dr. Stephan, on looking up the subject in medical literature, was unable to find any description of a precisely similar case. Professor Hensch, who mentions the existence of congenital facial paralysis in his lectures on the diseases of children, on being communicated with, replied that he had scarcely ever seen a case

reported, and that he did not know of any description which had been published. Dr. Stephan believes that there are three forms of congenital facial paralysis, two of which are transient, and depend on the application of forceps or the pressure of a tumor, etc., during a prolonged labor, and a third, of which his own case is, perhaps, the only described instance, where the paralysis is permanent, and where it may, as he suggests, depend upon necrosis, the main difference between this and the other two forms being the affection of the hearing, which may, he believes, be an indication of the permanent character of the paralysis, its existence in any case being sufficient to cause the practitioner to give a guarded prognosis.—*British Medical Journal*, March 24, 1888.

Quinine, Hypodermatically.—Beurmann and Villejean, in the *Bulletin de Thérapeutique* of March 30, 1888, conclude that when *neutral* hydrochlorate of quinine cannot be readily procured the *basic* hydrochlorate, commonly found, may be used in the following prescription:

Acid. hydrochloric. pur. . . .	♏ 75.
Aquæ destill.	ʒ 3¾.
Quinine hydrochlor. (*basic*) . .	ʒ 5.

Dissolve at gentle heat and filter.

Fifteen minims of this solution contain seven and one-half grains of *neutral* hydrochlorate of quinine.

The Effect of Tight Lacing on the Secretion of Bile.—Collins writes in the *Lancet* of March 17, 1888, as follows:

In the course of a series of observations upon the secretion of bile, which I have undertaken at the instigation of Dr. Lauder Brunton, I had occasion to make biliary fistulæ upon several anæsthetized guinea-pigs. I was very soon struck by the considerable effect which respiratory movements had upon the passage of bile along the canulæ. With each descent of the diaphragm there was advance of the column of bile, and with each expiration a slight retrogression or arrest of advance. Moreover, a powerful respiratory exertion considerably augmented the outflow, and even the slightly accelerated respiration which accompanied the administration of ether was not without its distinct effect. It occurred to me to see what would be the result of placing a constricting band around the lower part of the thorax. I accordingly selected a guinea-pig in which the biliary discharge from the canula was free and in full quantity, and I collected the amount of bile secreted at regular intervals until a fair average could be obtained. I then tied a tape band about one inch wide round the guinea-pig's waist (if such, by courtesy, can be allowed to exist), reducing the circumference thereof from five inches and a quarter to four inches, but not so as to cause any formidable risk of dyspnœa. After collecting the bile secreted at stated intervals, I removed the "stays" and again collected as before. I found that before the tight lacing began bile was being secreted at the rate of 8.4 cubic centimetres per hour; during the tight lacing this fell to the rate of 4.5 cubic centimetres per hour, and after the removal of the constriction again rose to 7.8 cubic centimetres per hour. I repeated the experiment in other animals with the same result; so that it would appear that by reducing the circumference of the lower part of the thorax by about one-fourth, the bile secretion is reduced about one-half. It is useless to assert that it is bile expulsion, not bile secretion that we are dealing with here, for the bile being secreted at a pressure very slightly above that of blood pressure, the mere presence of bile in the canaliculi is to some extent detrimental to secretion behind it; whereas, the rapid evacuation of the bile channels, which free diaphragmatic movement insures, is salutary to increased elimination of bile.

Urethral Medicinal Bougies.—Von Düring, in *Monatshefte für Praktische Dermatologie*, No. 5, 1888, gives the following formula for medicinal bougies, for the local treatment of urethral affections:

Ol. cacao	6 parts.
Cer. albæ	5 "
Acid. boric. or iodoform . . .	2 "
Zinc. oxydat.	1 part.
Tragacanth.	4 parts.

These bougies may be made of any length or size desired.

A New Method for Supplying the Galvanic Current for Medical Use.—Carpenter, of Cleveland, describes his method of procuring the galvanic current for office use, as follows:

The device to which we have the pleasure of calling the attention of the profession consists simply in that of using the current of the incandescent lighting system direct from the street-wire passing the door—Thompson-Houston or Edison. We have the wires of the former system placed in our office, and by means of a rheostat resistance sufficient to reduce the current to a minimum is interposed, then by the use of an ordinary switch-board, the current is increased or diminished according as resistance is cut in or out. A millliampère-meter is made use of whereby the current is accurately measured while the patient is in the circuit.

The device is absolutely safe, as the entire voltage of the wire can be handled without the rheostat being used. My wire furnishes a very smooth continuous or galvanic current, with an electromotive force of one hundred and ten volts with a maximum strength of $\frac{11}{20}$ of an ampère, equal to about eighty Leclanché cells. This current is constant, does not vary in voltage, and is always ready, night or day, as the main line from which my connections are made is used for commercial purposes, and furnishes lighting for basements, dark shops, and rooms. This, I am informed, is the case in all large and in many small cities, so that little trouble will be met with in securing a wire with a day current. When a wire is once placed in our office, the task of caring for a battery of cells is at an end, and we have an apparatus that is at an once always ready, reliable, economical, cleanly, and durable. The rapid introduction of the incandescent lighting system, together with the great increase in the use of this form of light, will place within the reach of very many physicians this current for electrolytic work.

The charge for the annual rental of the wire is $10, not including the cost of putting in, which, if the main line passes the door, should not exceed $5. This device, as will be seen, does away with cells entirely, as well as the time, trouble, and expense of keeping them in order, and I venture to express, as my opinion, that we have a current superior to any that it is possible to have gener-

ated from chemical action, besides economy of room, which is not a small item in cramped quarters.

A word regarding the danger from contact with the electric-light wire. The Thompson-Houston or the Edison incandescent system of an electromotive force of one hundred and ten volts, and of a strength of $\frac{1}{10}$ of an ampère is harmless, *and must not be confounded with the arc system of Brush and others, as the strength of the latter is six ampères, and of course dangerous and must* never *be used.*—*Medical Record*, March 31, 1887.

The Treatment of Flatulent Dyspepsia.—The *Journal de Médecine* of March 11, 1888, gives the following formula:

Bismuth. subnit.,	
Magnesiæ pulv.	āā gr. 30.
Belladon. pulv.,	
Zingib. pulv.	āā gr. 3.

Mix carefully and divide into ten powders.

A powder should be taken in peppermint water twice daily.

Hygrine and Cocaine.—Hygrine was obtained by Dr. Ralph Stockman from distillation of so-called amorphous cocaine with water. A drop of it placed on the tongue causes a burning sensation, and it is an extremely irritating substance. Without causing special symptoms, frogs died from the subcutaneous injection of a drop of hygrine mixed with water. Considerable irritation was caused at the seat of injection, while the muscles all over the body, the bowel, and serous membranes were studded with numerous minute hemorrhages, due evidently to the local irritation of the particles of hygrine. Hence the importance of being certain that any specimen of cocaine is free from hygrine. Indeed, this communication is very instructive and important in connection with the occurrence of accidents after the injection of cocaine. The benzoic ethers formed by decomposition of cocaine are also very irritating to the mucous membranes.—*Lancet*, March 17, 1888.

The Treatment of Tuberculosis of the Peritoneum and the Hectic of Tuberculosis.—Pribram, of Prague, regards tuberculosis of the peritoneum, when the disease is general and well marked in other organs, as symptomatic, and not requiring especial treatment. When the disease is purely peritoneal, the treatment first indicated is antipyretic, hygienic, and tonic. Adonis vernalis he regards the best diuretic; he advises inunction over the belly with sapo viridis. If the process is not arrested, and absorption does not take place, palliative incision is advised when interstitial ulceration is absent. In women the ovaries and tubes should be examined. A moderate degree of lung affection does not contraindicate incision. In a question of diagnosis between peritonitis and ovarian cyst, laparotomy should be performed. Regarding the pyrexia of tuberculosis, he advises differential diagnosis between tubercular diseases and fevers, the use of antifebrin and antipyrin, and especial attention to the patient's nutrition.—*Deutsche med. Wochenschrift*, March 8, 1888.

Traumatic Epilepsy cured by Incision.—An interesting case is recorded under the above heading by M. E. Müller in the *Gaz. Médicale de Strasburg.* A butcher ran a large meat-hook into the palm of his right hand between the second and third metacarpal bones at the junction of the lower and middle thirds. There was great pain at the time of the accident, and during the course of the same night the patient had an epileptic fit. He had never previously been epileptic, nor was there any history of the disease in any of his family. At the end of five months the fits recommenced, occurring on every tenth or fifteenth day. Latterly they became worse, and reoccurred as often as twice a week. Palpation of the cicatrix gave the sensation of hardness as if a foreign body were present, but exploration revealed nothing beyond a dense fibrous cicatrix. This was excised, and after two months had elapsed, the patient still continued well.—*Medical Press*, March 21, 1888.

The Treatment of Dentition and Stomatitis.—The *Revue Gén. de Clin. et de Thérap.* of March 15, 1888, gives the following useful formulæ for the treatment of dentition and stomatitis:

For local application during dentition.

Tinct. belladonn.	ʒ 2½.
Cocain.	gr. 8.

Also

Syrup. aurant. flor.	ʒ 5.
Cocain. hydrochlor.	gr. 3.
Tinct. croci	gtt. 20.

In stomatitis, with ulceration, Comly advises

Mel. rosæ,	
Glycerin.	āā ʒ 2½.
Potass. chlorat., or sodii borat. . .	gr. 20.

The affected parts should be touched five or six times daily with cotton dipped in this mixture.

The honey may be replaced by glycerine with advantage, if fermentation continues.

The Treatment of Icterus Neonatorum.—Jacobi writes as follows on this subject, in the *Archives of Pediatrics* for April, 1888:

A certain degree of yellowish discoloration of the skin is the result of the normal changes of hæmatin deposited in the skin during the rapid transition from fœtal to postnatal circulation. When by retarded separation of the newly born from the mother, and compression of the placenta, the amount of blood in the circulation of the infant is unduly increased, this form of hæmatogene jaundice is rather more developed. The simplest form of hepatogene icterus is produced by the sudden diminution of the blood circulating in the vessels of the liver, which encourages the exosmotic transition of bile into the adjoining bloodvessels. All of these forms of jaundice require no treatment. Duodenal catarrh will produce icterus in the newly born as it does in advanced age. Thus the feeding and the digestion of the baby must be carefully watched. The routine administration of syrup of rhubarb is a mistake on the part of the female busybodies which must be discouraged. Maybe some of them can be taught that acid cow's milk and indiscriminate feeding in general, and exposure, tight bandaging, and cold feet, can do still more harm than their medicines. Icterus resulting from congenital obliteration of the large biliary ducts, or congenital cirrhosis,

or acute fatty degeneration, or epidemic hæmoglobinuria is incurable. Icterus during septic infection is a bad symptom, and rarely terminates otherwise than in death. Icterus depending on congenital syphilis of the liver is grave, but I have met with several cases which recovered. A thorough and energetic antisyphilitic treatment is in such cases the only safeguard. It may prove unsuccessful, however, because the syphilitic process of the connective tissue is not confined to the liver but extends to the rest of the organs. Mercury must be administered for a long time, a twentieth or twelfth of a grain of calomel three times a day; careful inunction of a scruple of blue ointment daily; or one-thirtieth of a grain of corrosive sublimate in a one-fifth of a per cent. solution of distilled water for subcutaneous injection daily. In the beginning of the treatment two of these medications may be combined, or one of these together with the internal administration of from three to five grains of iodide of potassium. The internal administration of the bichloride of mercury is also well tolerated; one-hundredth of a grain may be given in a teaspoonful of water, or food, every two or four hours, and continued many weeks.

Phlegmasia Dolens and Œdema in Infants.—Dr. Leon Dumas, Professor of Clinical Obstetrics and Gynecology, Montpellier, has recently contributed to the *Annales de Gynécologie et de Obstétrique* a paper on the Probable Identity of the Œdema of Newborn Children and Phlegmasia Alba Dolens.. He concludes that this œdema is but one symptom of phlegmasia dolens developed in the course of the first few days after birth. Its causes, though very varied, are essentially of the same nature as in the adult, and may be divided into predisposing and determining. The principal determining cause is the incomplete establishment of respiration, including pathological and other obstacles which that function may encounter before arriving at its perfect state of efficiency. The symptoms of phlegmasia are the same in the newborn infant as in the adult, allowing for certain modifications in relation to the special physiology of the first days of life after birth. There is likewise the same pathological anatomy in both cases; but in the child the venous thrombosis is more often situated in the inferior vena cava. The treatment should be alike in both cases, and the same dangers are to be feared in the infant and in the adult, though the relative lesser vitality of the newborn child must always render the prognosis less favorable in its case than when its mother is similarly attacked. All the precautions by which impediments to the establishment of perfect respiration are overcome, including the avoidance of hasty and immediate ligature of the umbilical cord, together constitute the true prophylaxis against the affection in question.—*British Medical Journal*, March 24, 1888.

Tuberculous Contagion from Man to Dog.—Bourgangnon, in the *Journal de Médecine* of March 18, 1888, reports the case of a phthisical patient who was constantly attended by a pet dog. The animal often lay upon his master's bed, and shared at times his meals. Shortly after the patient's death the dog succumbed to a disease which possessed all the symptoms of tuberculosis. An autopsy confirmed the diagnosis. The most common avenue of contagion between man and beast is by the digestive organs of animals; they often swallow particles of sputa.

A Formula for Corrosive Sublimate Gauze.—Lübbert and Schneider in the *Centralblatt für Bakteriologie*, No. 12, 1888, conclude from a series of investigations on different solutions of corrosive sublimate, that the following solution is the best for making gauze, not excepting the recently advised solution of Laplace, containing tartaric acid. The present solution, the writers state, is unirritating:

Hydrarg. bichlor.	3 parts.
Sodii chlorat. crud.	100 "
Aquæ destillat.	600 "
Glycerin.	100 "
Spiritus	200 "

Dissolve the sodium salt in water; to the filtrate add the sublimate; to this solution add the glycerine, and then alcohol.

Gauze should be dipped in this, wrung out, and dried. Ordinary materials require one and a half times their weight of fluid to saturate properly.

The materials commonly used to color sublimate solutions are objectionable, as many of them contain fuchsin, which decomposes sublimate.

A Caution against the Common Use of Potassium Chlorate.—The *Medical Press* writes that chlorate of potassium is a very popular remedy; so much so, indeed, that the idea of its being poisonous in certain doses never occurs to anyone. Yet it is evident that if five-grain pellets be thoughtlessly sucked at intervals throughout the day, a very considerable and certainly injurious quantity will ultimately have been absorbed. In children it gives rise to cerebral symptoms, especially "night terrors," with more or less intense prostration. It would be well if the public were cautioned now and again that they cannot with impunity assimilate indefinite quantities of a salt which in anything like large doses is an unequivocal poison.

Menstrual Bleeding from a Laparotomy Scar.—At a recent meeting of the Kïew Obstetrical and Gynæcological Society, Prof. George E. Rein showed (*Vratch*, No. 7, 1888, p. 136) a menstruating woman from whom he had about three years before removed a cyst of the right ovary weighing thirty-seven pounds, fixing the pedicle in the abdominal wound. The patient soon recovered, and the wound healed, but at one part of the scar there remained a diminutive slough, which fell off just before the beginning of menstruation, its separation being followed by a constant flow of blood from the denuded surface during the whole catamenial period. The phenomenon had regularly recurred monthly ever since. As a rule, the scar begins to bleed somewhat earlier than the uterine flow makes its appearance. The menstrual blood from the cicatrix has a characteristic odor. It is difficult to explain such an occurrence. Possibly, a Fallopian tube or one of the uterine cornua had been stitched together with the pedicle into the abdominal wound. However, Prof. Rein hopes soon to ascertain the nature of this interesting and rare case, since the patient must undergo a second laparotomy for disease of the left ovary.—*British Medical Journal*, March 31, 1888.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, APRIL 21, 1888.

LIEBERMEISTER ON THE TREATMENT OF PNEUMONIA.

A FEW months ago we presented our readers with a full account of the methods of treatment in pneumonia followed in the chief American hospitals. The subject is one of such practical everyday interest that no apology is necessary in presenting the views of the well-known Tübingen professor, more particularly as his treatment in some points contrasts strongly with American and English practice.

In the *Deutsche medicinische Wochenschrift* he has been discussing the etiology and symptoms of inflammation of the lungs and pulmonary tuberculosis, and in No. 9 he gives his matured experience in the treatment of the former affection. The possibility of the discovery of a specific he thinks less probable in this than in other infectious diseases, and meanwhile he follows the expectant and symptomatic plan which is based upon a clear conception of the course and dangers of the disease. The majority of deaths occur from paralysis of the heart, in consequence of the increased labor, or from heart weakness, the result of the fever. We have here our indication for treatment; for the first, stimulation; for the second, antipyresis. Abstraction of heat by external cold is preferred to drugs, which are used only when hydrotherapy fails.

Liebermeister does not regard the fever as an unmixed evil, but inclines to the view that it is reactive and conservative, an expression of the struggle which is taking place with the microbes of the disease. He employs the bath in preference to other methods, and orders one whenever the temperature reaches 104° F.. The water may be at 68° F., in which case the patient remains only ten minutes, or the time may be prolonged if the water be lukewarm and gradually cooled. The baths are given preferably after seven o'clock in the evening, as in this way the spontaneous morning remission of fever is increased. During the day, if necessary, cold sponging is employed. Experience has proved to be groundless the fear of chilling and of increasing the inflammation; on the contrary, the patients breathe more deeply, the expectoration is freer, and the entire system is refreshed and stimulated. No recent statistics are offered, but he quotes his Basle records of 150 cases treated in this way, with a mortality of only 10.5 per cent., against an average of 25 per cent. under older methods during a period of thirty years.

Antipyretic drugs, quinine, antipyrin, and antifebrin, are seldom used, and then only to maintain the action of the bath. Digitalis, which for so many years was looked upon as a substitute for bloodletting, has its uses in reducing fever and supporting the heart. Alcohol is regarded as the most important remedy against the progressive heart weakness. Bloodletting is advised in œdema of the unaffected lung. Cupping is not thought to have any influence in the inflammatory process, but it relieves the pain, a result as well obtained by hypodermic injection of morphine, or by the application of cold.

While, then, on general principles, Liebermeister's treatment of this disease corresponds closely with that employed in our hospitals, his strong advocacy of hydrotherapy, and the striking results which he quotes, should challenge the attention of clinicians. That the method is troublesome and expensive to carry out, should not stand in the way of its adoption in our hospitals, and the recent statements of Brand, together with the experience of the Lyons School, in the treatment of typhoid fever, should arouse an active interest in the method, which heretofore has scarcely received the consideration it deserves at the hands of American physicians.

FLOATING KIDNEY.

STATISTICS are proverbially elastic: the numerical method as applied to the results of therapeutics too often misleading; the personal equation the cause of many false steps in medicine. Yet we would

know little of the natural history of disease without statistics. Such work as that of Louis in enteric fever and that of Flint in pneumonia marks epochs in the progress of scientific medicine, cuts open roadways through the jungle of traditional error.

Carl Schütze has recently published a brochure on floating kidney, which is of more than passing interest. It is a statistical study from the etiological standpoint. To ten cases personally observed in Zeulzer's Polyclinic in Berlin, he has added ninety of the more fully reported cases collected in the literature, and subjected the whole number to careful analysis.

The fact noted by Ebstein, that floating kidney was found only five times in 3658 necropsies (1 : 732) at the Charité in Berlin, affords no insight into the frequency of this anomaly. For, as Landau has pointed out, the movable kidney tends in the cadaver to settle spontaneously into its normal position, and may thus very easily be overlooked. The latter observer himself, in the records from 1870 to 1879, with about 6000 necropsies, was only able to discover the records of four cases.

The most common period of life is from the twenty-fifth to the forty-fifth year; ten cases are, however, noted in the first decade of life, and four in the seventh. The condition may be congenital. In 474 cases, 405, or eighty-five per cent., were females; 69, or fifteen per cent., males. The right kidney is much more frequently displaced than the left; the right, according to Schütze's observations, 65 times; the left, 18; both, 14. The statistics of Landau, Ebstein, and Hare are in close accord with these figures. Schütze's cases go far to support the opinion that laborious occupations and strong bodily effort are of less importance etiologically than is that general relaxation of the tissues which comes of an inactive and sedentary life.

The events of sexual life in the woman, menstruation, abortion, miscarriage, parturition, are of great etiological moment, and to this general category must also be referred dislocations and diseases of the uterus and its appendages. Pregnancy has been frequently accused of causing dislocation of the kidneys, but Fritze made it clear that the gravid uterus not only does not drag the kidneys from their normal position, but tends, on the contrary, to restore them when displaced.

Very important among causative agencies is the relaxation of the abdominal walls which follows frequent childbearing, and the pendulous belly resulting from this condition. Yet Schütze found among ten women suffering from wandering kidney only two cases of pendulous belly. Wasting diseases, violent concussions of the body, tight lacing, hydronephrosis, and secondary diseases of the kidney itself, are among the causes assigned. Especially frequent as a cause is rapid wasting of the body. The bed of fat in which the kidney lies is almost invariably wanting when this organ leaves its home.

Beumer collected, up to 1878, forty-eight cases of single wandering kidney. To guard against the surgical catastrophe of the extirpation of a wandering kidney whose fellow is functionally inactive or altogether absent, it is necessary, after other diagnostic methods are exhausted, and the case has come to operation, to determine, by internal palpation, the presence or absence of the second organ. H. Braun regards the presence of congenital defects or anomalies of the sexual organs as suggestive of congenital defect or absence of a kidney. In 13 females having a single kidney only, Beumer found 8 to present some developmental defect of the uterus, ovary, or vagina of the side corresponding to the renal deficiency.

Nephrorraphy is to be preferred to the extirpation of a sound kidney. S. W. Gross's early collection of 17 cases, with 9 good results, are cited in favor of the former operation. More recently Braun, Küster, Esmarch, and others have reported similar cases with a preponderance of favorable results.

CEREBRAL SURGERY.

We learn that Dr. W. W. Keen operated, April 12th, on a second brain case with a very speedy and thus far successful result. The patient is a young man from Kansas City, twenty-five years old, who fell eighteen months ago, and had a depression over two inches long on the right side of the head, over the supra-marginal and post-Rolandic convolutions. He had had paralysis of the left wrist and hand, and four epileptic attacks.

Dr. Keen made an opening 3¼ x 1½ inches, and removed the depressed bone and the underlying dura, which was diseased and had attached to its under surface a small fragment of bone. The brain tissue was found diseased throughout the length of the scar, and at the posterior end there was a small cyst. All of this diseased brain tissue was removed. The wound was entirely united at the end of three days, and the patient out of bed on the fifth day, no rise of temperature having occurred. The patient is practically recovered.

Two points in the surgical treatment of this case, one of which was indicated by Dr. Keen in our issue of last week, give promise of future usefulness, ergot was given instead of morphia, and cocaine was applied locally to the cerebral vessels with good results in controlling the hemorrhage. The dura having been removed the trephined button of bone could not be replaced on the brain surface, but it was secured to the under surface of the flap by a catgut ligature passed through two apertures made in the bone for that purpose.

Of course the remote result as to the epilepsy and, even possibly, as to the life of the replaced bone disk, must remain for the present undetermined.

TYPHOID FEVER AT THE CINCINNATI HOSPITAL.

An Appendix to the Report of this institution for 1887 contains the statistics of the cases of typhoid fever admitted during the year, with notes by the attending physicians on treatment. Memoranda of this sort are of great interest, and it would add very much to the value of the annual reports issued from the various hospitals throughout the country if the members of the staff would take the trouble to note in this way the special features of the year's work.

Typhoid fever was epidemic in Cincinnati last year, and 209 cases were admitted to the hospital, of which 34 died, a mortality of 16.2 per cent. In Dr. Forchheimer's wards, baths were systematically employed, when the fever rose above 103°. The water was used at the temperature of the body, and cooled gradually to 70° As many as ten or twelve baths were given, if necessary, in the twenty-four hours. 51 cases were treated with 5 deaths. In Dr. Carson's wards baths were also used, and of 62 cases 4 died. Dr. J. C. MacKenzie treated 81 cases with 5 deaths. Antifebrin was used with the greatest benefit, acting well in all cases. We cannot quite reconcile these special figures with the general summary, for the cases treated in the wards of Drs. Forchheimer, Carson, and J. C. MacKenzie, added together, number 194, with 14 deaths; while the total number treated for the year is stated to be 209, with 34 deaths.

The Committee having charge of the arrangements for the International Ophthalmological Congress to be held at Heidelberg from the 9th to the 12th of August next, announce that the following subjects will be discussed: "Glaucoma," to be introduced by Priestley Smith, of Birmingham, and Snellen, of Utrecht. "Cataract," by Gayet, of Lyons, and Schweigger, of Berlin. "Bacteriology," by Leber, of Göttingen, and Sattler, of Prague. On the evening of the 11th of August the members will take supper in the Old Castle, and on the afternoon of Sunday, the 12th, the city of Heidelberg will entertain the Congress at a fête champêtre in Ziegelhausen in the valley of the Neckar, with a boat excursion on the Neckar, and an illumination of the Old Castle after sunset.

MM. Foa and Bordona Uffreduzzi have communicated to the Italian Medical Association the result of their experiments, by which they have discovered that the microbe in cerebro-spinal meningitis (meningococcus) is identical with that which Sternberg obtained by the treatment of saliva, and which Fränkel described as the microbe of pneumonia.

The Anthropological Society of Vienna, by permission of the government, has appointed a commission composed of Professors Meynert, Kundrat, and Toldt, and Surgeon-Major Weisback, to measure and photograph the skulls of the great musicians Beethoven, Mozart, Gluck, and Schubert, and prepare casts of them for the museum of anatomy of the Vienna University. It is greatly to be regretted that the location of Mozart's grave is not exactly known.

The Orthopædic Hospital of Philadelphia is the subject of extended and favorable notice in the *Journal de Médecine* of March 25, 1888. The establishment of a similar institution in Paris is urged, and the value of such hospitals is thought to be proven by their successful maintenance at London, Birmingham, Stuttgart, Bologna, and Philadelphia.

The extraordinary demand for antipyrin has caused an undue pressure upon manufacturers, and in their haste to increase their output they have become careless, especially in regard to the later processes of purification of the drug. According to Dujardin-Beaumetz, benzine has not infrequently been detected in samples submitted for analysis. This impurity may account for some of the toxic symptoms which have been reported, such as gastric disturbance, cutaneous eruptions, and even grave cerebral symptoms, more particularly in the aged.

THE water-supply of growing cities is the subject for which a prize is offered for international competition in 1893. It is one of a series of annual prizes offered by the King of the Belgians, the value of which is 25,000 francs for each award. The essays of those desiring to compete must be addressed to the Minister of Agriculture, Brussels, before January 1, 1893. Here is an opportunity for one of our American water-engineers, so fertile and thorough in these public undertakings, to win a substantial purse and reputation at the same time.

SOCIETY PROCEEDINGS.

THIRD FRENCH CONGRESS OF SURGERY.

Held in Paris from March 12 to 17, 1888.

(Specially reported for THE MEDICAL NEWS.)

The third French Congress of Surgery was presided over by Professor Verneuil, assisted by Baron Larrey, Vice-President; and Professors Gavarret, Brouardel, Maurice Perrin, Ollier, President of last year's Congress, and Pozzi, Secretary, also took places on the platform.

Professor Verneuil opened the session and delivered the presidential address. After having welcomed the foreign professional visitors to the Congress, he developed with amplitude his favorite subject of the good of the conservative method as applied to the cure of surgical affections. He then replied to an attack which was directed against French surgery, by the eminent surgeon of Vienna, Billroth, some months ago.

Professor Verneuil then passed in review the operations which are undertaken daily, when it is well known the patient cannot survive. He then passed in review all the large operations which are undertaken when necessary, by French surgeons. He then said, if we compare, in its general tendencies, surgical therapeutics in France and in foreign countries, one can affirm, without fear of contradiction, that in no country is surgery more conservative than in France.

I shall not mention the questions for discussion in the order in which they were presented, but will give first the three questions which had been proposed long ago as principal subjects to be discussed.

ON THE VALUE OF THE RADICAL CURE FOR HERNIAS, WITH REGARD TO THEIR FINAL CURE.

DR. SOCIN of Bâle, Switzerland, said that according to the discussions which have lately taken place at the Société de Chirurgie, it appears that the radical cure for hernias has become a common practice among French surgeons. In regard to his own operations, he had operated 75 times for the radical cure of non-strangulated hernias and 85 times for strangulated ones. The first series had given him two deaths and the second eleven. He had seen after operation, about 133 of his 147 patients, some a few months later, others one year, and others at the end of nine years, which proves that cure is possible, while if the others have not been entirely cured, they have, at least, derived some benefit from the operation. This operation ought to be performed in every strangulated hernia, except in cases where the intestine ought not to be reduced.

The resection of the sac, instead of being a danger, offers a new chance of success; there is no doubt that the extirpation of the tissues which have been in contact with the intestines renders the wound much more simple. He also attributed a great part of his success to the use of antiseptic measures strictly carried out. He disinfects the intestine before returning it to the abdominal cavity.

The indications for the cure of non-strangulated hernias, he thinks, are in young subjects of either sex below twenty, in whom the classical treatment by bandage does not succeed in retaining the hernia reduced in a complete and absolutely permanent manner; in adults, when the bandage does not retain the hernia completely in an easy and non-painful position.

The chances of success are much greater when the subject is young and the hernia small and recent. This is easy to understand; in young subjects hernias are always congenital, that is to say, they are due to the persistence of the vagino-peritoneal canal, and this abnormal disposition constitutes the whole disease. Take away this canal, and the subject then finds himself well formed and the cure is really radical. This explains the success he had obtained in subjects below twenty-five, about 62 per cent. of complete recovery.

In elderly subjects the sac is not our only trouble, we must consider the lengthening of the mesentery, the adipose excess of the epiploon, the weakness of the walls and rings, all conditions which cannot be remedied by the extirpation of the sac alone. In this condition his successes above twenty-five years have been only 42 per cent.

The existence of a double hernia in a patient, or in the direct family, diminishes the chances of success. Hard physical work does not conduce to the return of the trouble. The application of a bandage after the operation is useless, often harmful. The operation is without danger in simple cases, the danger only appearing in very old subjects and when the hernial tumor is very large, so large that the skin is ulcerated.

The operation consists in the total extirpation of the hernial sac above its neck. Suture of the pillars of the ring is only exceptionally necessary. In longitudinal hernias sections might present difficulties, but succeed in the majority of cases. In case of testicular ectopia with atrophy, the testicle must be removed with the sac.

DR. THIRIAR, of Brussels, said that during the last two years he had operated upon 26 cases of hernia; 12 times for a strangulation, 14 times to take away the infirmity. Of his 12 kelotomies for strangulated hernia he has tried the radical cure in 7 cases. He had the statistics of 21 operations with one death, the patient, aged sixty-four years, died on the sixteenth day from alcoholic encephalitis. The peritoneal cavity was normal.

He has only seen four of those who were operated upon more than three months ago. The first man, sixty-three years of age, had two large irreducible inguinal hernias, he was operated on on both sides at the same time. On the right he had healing by first intention, on the left, suppuration occurred. The hernia has returned on the right side, on the left it is cured.

The second man, sixty-five years of age, had a large

right inguinal adherent hernia. Operation very long; has to-day a point of hernia easily reduced.

The third man, forty years of age, a voluminous inguinal, irreducible, and painful hernia. The sac contained the convolutions of the large intestine and the small intestine. The dissection was very difficult, the spermatic artery being cut. The patient actually wears no truss, appears entirely cured, but the testicle is atrophied.

The fourth, thirty-three years old, was operated on twice, the first time for a right enterocele and then for left adherent epiplocele, He is doing very well; cured.

He operates following the method of Lucas-Championnière. He always sutures the rings. He drains through the scrotum, and never has a bandage worn. He only operates when a hernia is irreducible or incoercible, when it is painful, when it is congenital and accompanied by testicular ectopia, or when it is maintained with difficulty by a truss and there is danger of strangulation. In these conditions he estimates the radical cure for hernias an excellent operation.

Dr. Leonté, of Bucharest, employs the following method: after incision of the sac and reduction of the intestine the internal surfaces of the sac as well as of its neck are exposed. He then incises in a circular manner the serous membrane on a level with the neck; immediately the two serous borders, the result of the incision, separate themselves, leaving exposed the subjacent cellular tissue. The serous layer of the superior border has even a tendency to recoil itself inwardly; he aids this inward recoiling by detaching and pushing this serous layer either with his nail or with his tissue-forceps. In this manner he obliterates the superior orifice of the hernial tract. To complete this obliteration he passes the catgut round all the surface which has been denuded of the serous layer, and drawing the two ends together the opening is closed like a purse. He does not extirpate the subjacent sac, but he scrapes its external surface, and adjusts with silver wire or silk the walls of the sac and those of the skin in the same suture.

After the cure he forbids the use of a truss. By this method he has had 7 successes out of 7 cases. He always obtained an immediate healing. As to a return of the trouble, he has not seen a sign in one case as yet. One of his patients was operated upon two and a half years ago. The conclusions are these: 1. The operation is shorter and less painful. 2. No danger of wounding the organs of the cord. 3. One reinforces the superior ring by uniting the walls of the sac, which by their adhesions give a true pillar sustaining the cicatrix.

Dr. Mollière, of Lyons, said that kelotomy is an operation without gravity by itself, if one has thought the contrary it is because he has confused the dangers of kelotomy with those of strangulated hernia. He operates as follows: 1. Isolates, without opening it, the hernial tumor. This dissection is easy, whatever the hernia might be, it is a little longer with inguinal hernias. In an umbilical hernia the navel must be cut away; without this precaution one could not isolate the sac. 2. The sac being isolated it is to be opened in its prominent part and the contained viscera examined. 3. To liberate the hernia an incision is made in the constriction outside the sac, and the neck dilated when the hernia is strangulated, with a blunt instrument, and the intestine reduced. 4. Finally, the sac is ligated with an elastic thread very tightly applied. In making this ligature one draws very strongly on the sac, so that the ligature catches the peritoneal cul-de-sac above it. He has verified, long after the operation, by autopsy, the radical cure of the hernia.

Dr. Routier, of Paris, had performed fourteen operations for the radical cure, and he advises the total extirpation of the sac, with a ligature applied at the base; the suture of the pillars appears to him useless. Out of the fourteen cases he has had fourteen cures; six patients only had been seen who had been operated on at least fifteen months before. All were cured; one only has a return, the sac, for certain particular reasons, had not been extirpated, but only scraped. Two cases were umbilical or para-umbilical hernias, and remained cured without the use of a bandage. The other twelve are inguino-scrotal hernias, some irreducible from adhesions, others incoercible.

He advises the use of a light truss, which acts as a preventive against the reproduction of a hernia, to which patients are always predisposed, on account of the nature of their abdominal walls. According to his practice, the operation is a successful one, and he recommends it, first, for any strangulated hernia in which the intestine can be returned; second, for any hernia that cannot be constantly, completely, and easily kept reduced.

Prof. Trélat, of Paris, said there would soon be an understanding on the question of radical cure for hernias, which term he condemns, as it leads surgeons to believe in an absolute cure, while only a simplified condition of the trouble is obtained; he prefers the words, operative or surgical cure.

As regards the indications for an intervention, he thinks that the easily reducible and maintained hernias ought not to be operated upon, for in forty per cent. of these cases the patient is obliged to wear a bandage after the operation. We must interfere only in those in which irreducibility in any form is present, however small the irreducible portion may be, should it only be a band which at the moment of the reduction carried with it the sac or the testicle; the operation is also indicated for the impossible or too difficultly maintainable hernias.

It is the simplification of complicated and adherent hernias which is the real conquest accomplished for the surgical cure of hernias; it saves individuals condemned to a certain death at a more or less distant time. He is convinced that intervention limited to this series of hernias would suffice to prolong notably the average lifetime of hernial patients.

In lucky cases one can obtain the total cure; it has been realized in sixty per cent. of the cases. But this probability plays a much less important part than the successful operative intervention: for a lecture, he had collected, in one evening, about 160 cases, without one death, nearly all done by foreign surgeons. There had been stated lately at the Société de Chirurgie, several very fortunate series, giving about 130 cases. Adding to those 17 operations made in his own wards, we get the respectable number of 307 cases without one death. This is not a statistical study; he had only picked like flowers the facts which offered themselves to him, and which really are surgical flowers. Uniting all these known facts, we arrive at a mortality of 0.04 per cent. Although death is possible in certain grave cases, yet he knows of no more successful surgical operation. This is the reason why the radical cure has been so rapidly admitted by the surgeons

of every country; it is an operation without gravity, without mortality; it does away with danger, and reduces to its minimum a disagreeable infirmity. He had himself resisted a long time, but he had finally been converted, and had abandoned the practice of progressive and laborious reductions of adherent hernias, which he to-day considered a bad practice.

This operation unites most of the conditions requested by Prof. Verneuil; if it is not always simple, it is successful if aseptic, and it will be efficacious every time one conforms to the rules laid down by M. Lucas Championnière; it replaces an infirmity by a hardly visible cicatrix.

Dr. J. Bœckel, of Strasbourg, had made twelve operations for the radical cure, which he had been able to see again. Five were non-strangulated hernias, three voluminous and incoercibles, and two partially irreducible, and seven strangulated hernias. His results have not been very encouraging; he lost two patients: one, on the fifth day, from acute septicæmia from gangrene of the scrotum; the other, from delirium tremens after the cure of the wound. Out of the ten surviving ones, two have had a return of their hernias—which, it is true, at the end of seven years, remained reducible and well maintained. An old man, having had a laparo-herniotomy performed, without a radical cure, had seen a point of hernia appear at the end of three years; another patient, operated on in the same condition three years ago, presented no return of the trouble; three have been without return after ten, twelve, and eighteen months; the last three have been seen without return in the last six or seven years. All wear trusses. After having tried, in numerous cases, all the other operative procedures recommended, he had finally adopted the one of M. Lucas Championnière.

Dr. J. Lucas Championnière, of Paris, made a great distinction between the operations for non-strangulated and strangulated hernias; the operations for strangulated hernias are done too rapidly, hence ought to be systematically excluded from the present discussion. He has made eighty-one operations for radical cure. The first two operations were done seven years ago, and the two patients need a truss: but one had not been operated upon according to the rules he follows now, and the other had an enormous hernia. One can judge at the end of the sixth week whether an operation will or will not be curative. As regards mortality, he had lost only the last patient on whom he operated, but this does not change his opinion in regard to the successful character of the operation—it was a voluminous tumor in an emphysematous patient, he operated away from his service, had not his usual assistants, so that the operation lasted two and a half hours. The patient was well for two days, but in the evening he was attacked by a pulmonary congestion, of which he died. If he had been closely watched, as he would have been in his wards, perhaps a great number of cups applied would have saved him. This case is not comparable to the others, and he might just as well have lost a woman upon whom he had operated for an umbilical hernia of thirty inches circumference. If there remains a large orifice, the bandage is quite necessary. In the other cases, it only serves to atrophy the cicatrix, and he only applies a truss above the hernial canal, which protects against any intestinal pressure.

He did not see why we should not also operate for radical cure, in those cases which are outside the rules laid down for intervention, as this cure can be obtained in favorable cases. He had himself operated upon several children, and he is certain he will have excellent results; the congenital hernia, in particular, is an absolute indication on account of the integrity of the rest of the abdominal walls, which can be fortified by special gymnastics.

Above all others, one must operate upon hernias which grow rapidly, for radical cure has three enemies: pulmonary congestion—very dangerous in old subjects and in large hernias; the large intestine, which renders the operation difficult and the return of the trouble certain; finally, the organic breaking down of old hernial patients who are troubled with albuminuria or glycosuria. He always operates upon small hernias before their volume renders these operations more dangerous and less efficacious.

Dr. Segond, of Paris, asked, Is the operation for hernia a radical cure, or not? He had made fourteen kelotomies for non-strangulated hernias, and thirty times for strangulated hernias. His forty-four cases led him to the following conclusion: As regards the successful character of the operation and the operative risks, he considers only his first fourteen operations. He had no deaths. When he analyzed his thirty kelotomies for strangulated hernias, he finds that five of his patients died: one, an old man, from pulmonary congestion; another from tetanus, and three as a result of the strangulation. This shows that the operation for radical cure does not increase the gravity of the intervention.

As regards the immediate results, all the patients are satisfied, and the relief they experience encourages them to ask a second operation when this becomes necessary. As to the definite value of the surgical cure, he had seen about one-half of his patients again. Two were definitely cured, while the others lost all the benefit which had been derived from the operation.

His indications are the same as those laid down by Prof. Trélat. He tries to apply a ligature as high up the sac as he can. The dissection is not always easy, where one wants to save the spermatic cord. He has been obliged on two occasions to give up a too timorous dissection.

The trusses he uses after the operation are very light and easy, and have nothing in common with those instruments of torture that are applied before the operation.

M. Schwartz, of Paris, had had occasion to treat one non-strangulated hernia: a man of thirty-six years, with signs of tuberculosis, having an inguinal hernia the size of a child's head, irreducible, and very painful. After he had incised the sac, he felt upon the large intestine the sigmoid flexure with its surrounding parts, which had acquired the volume of a fist, while the thickness of the intestinal walls measured more than one-third of an inch. There were no adhesions, and this increase in volume was the only cause of irreduction, so much so that he had to incise about 1½ inches of the hernial ring, which already admitted four fingers. As he was unable to place a ligature upon the sac, he applied sutures on the pillars. Although the patient wore a bandage, the cure only persisted three months; at the end of seven months the hernia had already a large volume. The patient died of tuberculosis, at the end of nine months.

Dr. L. G. Richelot, of Paris, admitted the conclusions of M. Championnière, and he divides hernias into three

classes: 1, simple hernias; 2, complicated hernias; 3, hernias of old age and cachectics. The simple hernias of young people ought not to return after the operation; there is a complete anatomical restitution.

Complicated hernias are usually old, with large rings, voluminous, irreducible, adherent. Radical cure is less certain, still we get definite cure. In complicated hernias, when the cure does not maintain itself, we always have a suppression of the accident. In complicated hernias, complete cure is often obtained; if it does not take place, the return of the trouble is only an insignificant, easily tolerated pointing.

In hernias of old people and cachectics, diabetes, albuminuria, etc., are contraindications to the operation; also in emphysematous old people with large tumors. He has, however, on two occasions, operated on a man of seventy years of age, who lived in his bed, without moving, with two enormous hernias. The first time he returned into the abdomen a mass of the small and large intestine; union took place immediately. Encouraged by this result, he operated two months later on the opposite side, without any local accident or trace of peritonitis, but a pulmonary congestion appeared on the third day, and killed the patient.

Dr. Le Bec, of Paris, has operated on a man sixty-five years old, having a fistula situated in the middle of the scrotum. He wears a bandage. The testicle appeared normal, but the cord was covered by a fistulous tract, which formed a mass of the volume of the little finger, resembling a tubercular, suppurating mass and part of the vas deferens. He decided to attempt the radical cure. After incising the skin, he found an elongated mass, of the volume of the little finger, appearing to be the spermatic cord thickened by inflammation. The spermatic vessels were dissected; he found the vas deferens enclosed in a mass of inflammatory tissue, but unluckily it broke, which decided him to take away the testicle. The patient being old, there was no great objection. In dissecting the inflammatory mass, he found that it was continuous with the sac, and extended to the external inguinal ring, and from there penetrated into the abdomen. It was the ileo-cæcal appendix, which was adherent to the sac. The rounded extremity being inflamed, and keeping up the fistula, he opened the sac on its lateral parts. The adherent and suppurating extremity was carefully detached and ligatured, the whole being returned into the abdomen. The patient was cured, and only had a small abscess under the cicatrix, owing to faulty drainage. He saw the patient five months later; he was wearing a truss, and felt perfectly well.

CHRONIC SUPPURATIONS OF THE PLEURA AND THEIR TREATMENT.

Prof. Le Fort, of Paris, thinks the Letievant-Estlander operation a very good one. If there exists a large suppurating cavity, the operation is not successful, even if a great number of ribs are resected. He remarked that when the operation of empyema was first resorted to, the persistent fistulæ was much rarer than it is in our day. At first, when the pleura was opened, it was washed out, and the opening kept patent with a piece of cotton. Since then, this cotton has been replaced by drainage tubes which help the evacuation of the suppuration of the pleura, but which, remaining open, allows the air to enter freely the thorax. Under such conditions, the aspiration of the thoracic walls can have no more action on the lung, which remains retracted, and its expansion, which is one of the conditions most favorable to obliteration of the diseased cavity, is rendered much more difficult. He thinks we would have more frequent cures of empyema if we could so arrange that after having placed drainage tubes we could prevent the air from going through them in the intervals between the syringing out.

One of his patients presented a singular phenomenon. He had a fistula admitting about 4 ounces of liquid easily. One day, after convalescence had set in, when no more syringing out was done, he injected 3 ounces of liquid. Immediately the patient had a syncope, and he feared very much for his life. Following this accident he had a paralysis of the extremities which passed very slowly away. He thought he must have had a medullary apoplexy the primary cause of which was unknown.

Dr. J. Thiriar, of Brussels, in the past four years had operated on thirteen patients suffering from purulent pleurisy with fistulæ. They had necessitated nineteen operations for thoracoplasty. Twice the costal resection had been the first step of pneumotomy, and once it was made according to the modifications brought about by Schede and Sprengel—that is, the old thoracic wall, except the skin, had been resected. Only one patient died from the effects of cold; eleven were cured, and one female patient had only a small fistula.

Of the ten cases, seven were operated upon once; a child of twelve years had been operated upon twice; a man of twenty, three times; a woman of twenty-nine years, also three times.

A man of twenty, had a left purulent pleurisy with fistula. On September 7, 1885, he resected from the fourth, fifth, sixth, seventh, and eighth ribs, about 1½ to 3 inches of each. At the second dressing he was told the drainage tube had fallen ont, and a drainage tube was presented to him as being the one. He left the hospital on October 11th apparently cured. Two weeks later a new abscess opened; the patient entered his ward in January, 1886, and he took away about 4 to 5 inches of the fifth, sixth, seventh, and eighth ribs. The patient left the hospital on May 26th, with a fistula. The patient was subjected to a third operation on October 26, 1887. To the five already resected ribs, he resected 1 inch of the second rib, 3 inches of the third rib, and 2½ inches of the ninth rib; the pleura was at the same time thoroughly curetted. In June, suppuration being still very profuse, he undertook the resection of the pleura and thoracic wall. After having dissected the skin, he took away with the ordinary costotome, a fragment of the thoracic cavity, starting at the tenth rib and extending to the clavicle. He then discovered a very large drainage tube, calibre No. 10, and 16 inches long. He took it away, and after a careful curetting of the pleura, especially below the clavicle, he sutured the cutaneous flaps. On August 30th, the man left the hospital, absolutely cured. He has seen him since; he is perfectly well.

After having tried different methods, he makes his costal resections with one single transverse incision; he can easily resect seven or eight ribs, and he obtains ordinarily union by first intention. The extent, length, and number of ribs to be resected are subordinate to the extent of the affection. He places his resections as far from the lung as he can—that is, in the anterior part of

the thorax. He does this to such an extent, that when he has cut the rib at its posterior part, he seizes it with a forceps and tears it from its anterior cartilaginous insertions. He tries to avoid injections in the pleural cavity, which he has thoroughly disinfected at the time of the operation, and he helps the restoration of the thoracic wall by the application of an elastic band.

DR. J. BŒCKEL, of Strasburg, has made twelve Estlander's operations; he has had nine cures and three deaths. The three deaths were, the first, tuberculous; the second, cardiac; and the third, suffering from albuminuria. The other nine operations give us, six complete cures, one temporary cure, two incomplete ones. Of the two incomplete cures, that is with fistula, one was in a child who died later on from phthisis; the other in an adult of thirty-five years, on whom he made a second operation.

Want of success is due to the fact of a too timid resection; this was his weakness in his first operations. If it is necessary to obtain a falling down of the chest to resect the rib above and behind, one is justified in resecting the scapula. In certain cases incision and excision of the pleura become necessary.

DR. VIEUSSE, of Toulouse, has made three operations; one died in forty-eight hours after the operation of septicæmia; the two others were cured. In one of the cases the fistula was at the angle of the rib.

DR. DELORME, of Paris, finds that amongst the causes of non-success is the too great limitation of the costal resection, which renders it impossible mechanically for the suppurating cavity to close. The thoracic cavity, to take the position of the *chord* of the excised costal arc, only needs to be depressed 1¼ inches, which demonstrates that a cavity more than 1¼ inches deep cannot be closed by the sole retraction of the thoracic walls deprived of its skeleton. It would be quite different if to the bony excisions one would add the resection of the soft tissues vertically, as high up as the cavity, and that afterward the flaps should be pushed in contact with the opposite parietes of the cavity. If the cavity should extend beyond the limit of the excision, one could obliterate the lateral cul-de-sac with the folding in of the parietes, fixing it there with catgut.

The inconvenience of this traumatism, which cannot be very extensive, cannot be compared to the danger of persistent suppuration of the pleural cavities. The obstacle to the cure can come from the tuberculous nature of the pleural lesion. In those cases one must curette the cavity. But this curetting must not be the irregular, insufficient, uncertain, dangerous curetting, which consists in thrusting the curette through the fistula, and moving it in different directions. It must be done openly, so as to destroy the secondary diverticula which may exist.

DR. BOUILLY, of Paris, had operated thirteen times; twelve times on patients from twelve to thirty years old; the other case was a man over forty. Youth gives the greatest chance of success on account of the elasticity of the thoracic walls. The oldest suppurating cavity had been twelve years; the most recent one, one year old. He divides his cases into four groups: 1st, large suppurative cavities, the lung being thoroughly compressed and irremediably lost; 2d, large cavities, but the lung still good; 3d, medium cavities, in which the lung is compressed in a cup-like shape of four inches broad; 4th, fistulous tracts, more or less deep and oblique.

The pleura is sometimes an inch thick, and requires excision. In other cases the pleura may be soft and friable, which indicates a breaking down of the patient. In very large cavities, he thinks better not to interfere. The large cavities may be attempted if the subjects are less than twenty-two years old, and if the cavity does not extend too high or too far back. The fistulous tracts should be well scraped and touched with chloride of zinc. Out of thirteen operations he reports eight definite cures: one persistent fistula; one result incomplete, and three deaths; one by septicæmia on the third day; one during the operation; the last one from hectic after six months.

DR. BERGER, of Paris, had had two deaths and thinks the operation a serious one. One patient was tuberculous who had an operation for empyema performed four years previously, having had a fistula since, through which he would bleed very much, a regular hemoptysis. It was very difficult to explore the chest. He then made a resection, a very laborious one, but when the patient became conscious he suffered from severe dyspnœa, and died four hours later. The cause of the death was due to his having resected the last rib. These last ribs give attachment to the digitations of the diaphragm, and sustain the phrenic centre, and their suppression produces a loss of equilibrium in the respiratory play, which is still more favored by the bad condition of the lung. If there be a tendency or signs of tuberculosis or of amyloid degeneration of the viscera, one must not operate; but if the suppurating cavity is the only cause of hectic the suppression of the suppuration will restore the patient.

DR. KIRMISSON, of Paris, had only one case, which, however, he followed for four years. In 1884, a man, nineteen years of age, suffering from chronic left purulent pleurisy with a fistula below the nipple, consulted him. After having opened the eighth interspace he excised two or three inches from four ribs. The general condition of the patient became better, he went home, but returned later to have a second operation performed, this time eight ribs were excised. The patient was cured with a very small fistula.

DR. FAUVAL, of Havre, presented a patient on whom he excised respectively, 4, 5, 5, and 3 inches of the fifth, sixth, seventh, and eighth ribs; the cure was complete.

DR. OLLIER, of Lyons, said that in children he recommends very small excisions, whatever may be the size of the pleural abscess, relying upon the elasticity of the thoracic walls, for large excisions would produce deformities of the vertebral column. In adults, large excisions are necessary. The excisions must be done on the lateral parts of the thorax, the nearer you go toward the anterior portion of the rib the more you compromise its further osseous development, for it is always by its anterior part that the development proceeds. If the fistula be nearer the sternum, resect only on the side, the immediate results will be sufficient, the later results will be much better. He made these observations on lambs when he made his experiments on the sub-periosteal reproduction of bone. One must be very careful in young subjects to take away carefully the costal periosteum, or else we would have a rapid osseous regeneration which would interfere with the success of the operation; the scraping of the periosteum is not sufficient. This precaution is not necessary in elderly persons.

DR. LEVRAT, of Lyons, mentioned the history of a

case on which he performed costal excision three times. In his two last attempts he met with real bony plates very extensive, the ablation of which was very annoying. The destruction of the periosteum by dissection or with the thermo-cautery would prevent such formation.

Dr. Ollier said that these bony plates are found especially in old inflammations of the pleura, they are ossifications due to the presence of the periosteum on neighboring inflammatory tissues. In one case he had great difficulty, the pleura was lined with a calcareous layer, which prolonged itself in inaccessible culs-de-sac. He took a great part of it away, but was compelled to leave the rest, which kept up a small fistula not dangerous to health.

Dr. Duret, of Lille, communicated a case of excision in a child four years old. The suppuration, which was very extensive, had lasted eighteen months and had reduced the little patient. He excised from four to five inches of five ribs. The cure was complete, and the lung returned to its function. He concludes that in children this operation will sometimes give excellent results.

ON THE RETURN OF EXTIRPATED NEOPLASMS.

Dr. Cazin, of Berck-sur-Mer, gave the results of his practice from September, 1862, to 1886; he had extirpated 564 malignant tumors. The diagnosis of the tumors he had treated had not always been made before intervention, but the post-operative examinations have always settled the question. These tumors were myxomas, chondromas, sarcomas, epitheliomas, carcinomas. He would only take, for example, the scirrhus and encephaloid.

He had operated upon 102 *scirrhus* of the breast; 60 complicated by ganglionic extension, 42 without it. In the first 60 cases he obtained 7 definite cures, 48 returned, 3 died, and 2 results unknown. With the 42 others he had 8 absolutely cured, 28 returned, 2 died, and 5 results unknown.

He operated on 120 *encephaloids;* 80 with ganglionic involvement and 40 without. In the first 80 he had had 5 cures, 67 returns, 4 deaths, 4 results unknown. In the 40 others 8 definite cures, 26 returned, 1 death, 5 unknown.

The returns he had observed have commenced from three months to seven years after the operation. He attributes the proportion of his successes to his adhering strictly to these precepts; very extensive extirpation, without occupying himself with the immediate union of the wound, even when the lymphatic glands appear normal; he extirpates the lymphatic vessels between the tumor and the lymphatic glands.

Prof. Verneuil, of Paris, said that in the great majority of cases cancer is a constitutional disease; the beginning may be a local trouble, which once developed will infect for ever the system, and never is cured. There can only be occasional arrests in the development of the tumor. He had seen in a lady, a cancer return on a cicatrix of the breast thirty years after the primary operation, with histological characters exactly similar to the first tumor. In another case he saw a ganglionic return six years and a half after the extirpation of an epithelioma of the neck of the uterus. To explain this first fact, we might say that there is a new determination of the diathesis on the cicatrix, which is a place of less resistance; he preferred the idea of morbid latency, which explains also the glandular return of the trouble. It is certain, that where the return took place there must have been already some morbid elements there at the time of the operation. As to the microbic character of the cancer, it is not yet established. What do we do to prevent the return? We make our patients follow a treatment for six months. He thought, however, that these germs, in an embryonic state, so to say, can be destroyed or influenced by the medicines which are powerless on the declared cancer. He always prescribes after an operation a permanent arsenical and alkaline treatment. He orders $\frac{1}{25}$ grain of arsenic a day, and a teaspoonful of magnesia every night before going to bed. Under the influence of this treatment he had seen a lymphatic gland remain stationary for more than one year after he had amputated the breast; he absolutely condemned the iodide of potassium. One must also prescribe a vegetable diet; for he thought that since our peasants have taken more meat during their meals the number of cancers has also augmented.

Dr. Poncet, of Lyons, read the statistics of his operations: Out of seven primary epitheliomas of the scalp, all died after one or more operations; on the contrary, two epitheliomas, which had begun in an old sebaceous cyst, extirpated, gave him two good results. The skin epitheliomas on cicatrices of burns returned very rapidly. Eight epitheliomas of the tongue all died from a return of the trouble within two years; on the contrary, he had two lasting cures for epitheliomas of the floor of the mouth; in one case, the cure is due to a very extensive ablation, favored by the ligature of both external carotids and the excision of the inferior maxillary. He concludes, 1st, that a return of a neoplasm is almost certain in subjects presenting a direct cancerous heredity; 2d, when the glands are involved, the tendency to the return of the disease is much greater; 3d, the best prophylaxis is found in the rapid and broad extirpation; 4th, one must also not operate when we find very unfavorable conditions; great numbers only demand a palliative intervention.

Dr. J. Bœckel, of Strasbourg, said that out of 103 operations for cancer, he had had 89 cures, and 14 deaths. Out of the 89 cures, 12 only can be considered as permanent; 32 have been lost sight of after two to four years; the 45 others had a return. Among these returns, one came six years later (rectum), and three from eleven and a half to twelve years (lips, rectum, and tongue).

Dr. Pollosson, of Lyons, said that out of 7 cases of diffused myxomas of the extremities, which were apparently completely extirpated, all have returned within the year, and have required the amputation of the limb. In presence of these myxomas one must not hesitate to sacrifice the limb as early as possible.

Dr. Labbé, of Paris, said that it is sometimes a difficult matter to obtain from the patient the authorization to sacrifice a limb for an apparently local trouble; this had happened to him lately, a patient suffering from a diffuse myxoma of the arm, refused to let him disarticulate his shoulder; he returned a few days ago, but too late to be operated upon. But there are some benign tumors, which are very interesting to consider, the adenoid tumors of the head, which have a tendency to return. The classical operation for these tumors is simple enucleation; it is absolutely insufficient, and it is necessary to

extend beyond the capsule of the tumor. In addition, when these tumors are very large, the whole breast must be extirpated, and search for the rest of the gland must be made which has been pushed eccentrically and flattened, and which is difficult of recognition. We shall in that manner prevent the six or seven successive returns of this variety, of which we have examples. He is a firm believer in immediate autoplasties, especially of the face, when we extirpate large tumors. For limited epitheliomas of the face he had always been satisfied with the use of the caustic, which gives results superior to the use of the knife. He also believes, like Verneuil, that a post-operative treatment is necessary. He would add to the medicines employed and mentioned by Prof. Verneuil, the tincture of condurango, which has also been used by Nussbaum.

DR. G. RICHELOT, of Paris, remarked that total hysterectomies gave as many or more returns than partial hysterectomies. This is due to the fact that complete hysterectomy is only undertaken when the cancer is very extensive, and extends beyond the uterine limits. He presented 13 new cases of vaginal hysterectomy, 2 must be deducted, for extension to the broad ligament was recognized, and the operation was not completed. Out of the 11 others he has had 5 returns, and 6 cures, 55 per cent. But 11 cases are very few to establish a mortality, and 2 of his cases are only seven or eight months old. It is in the first six months that the return of the neoplasm is to be feared; it is rare to observe it after two years. All his patients were operated upon early; four times he had an intra-cervical cancer, and twice a little more extensive growth on the neck of the uterus. To diminish the chances of return, he resected a band of the vagina. This is especially useful in the cauliflower epithelioma of the neck of the uterus, which has a greater tendency to propagate itself to the vagina. The cases must also be well watched for six months, and the least return of the trouble must be destroyed. He has employed the secondary interference in two cases, and the cure maintains itself. There should be no operative interference when the broad ligaments are involved.

DR. CASTEX, of Paris, presented a case with autopsy, in which there was, on the patellar cartilage, the propagation of a sarcoma by the bloodvessels; there existed in the middle of this cartilage, which was normal, a sarcomatous colony in relation with the degenerated synovial membrane through vessels of new formation. The histological examination has shown the migration of these sarcomatous elements through vessels of new formation.

DR. SABATIER, of Lyons, recommends to attack malignant tumors by their periphery, and not to tear them, so that none of this pathological tissue may become grafted on the fresh bleeding surfaces. The union by first intention is a danger, for such little pieces, which may be left behind, will be the source of a new development, hence union by second intention is to be recommended.

DR. MOLLIÈRE said if the patient is young the return of the trouble is almost certain, and it becomes a question whether to operate or not. After fifty years one can hope that no return of the trouble will take place. After seventy years one is almost sure it will not reproduce itself.

DR. GALEZOWSKI, of Paris, said that the malignant tumor of the eye develops generally in the anterior segment of the eye, which he explained by the great nutritive activity at the sclero-corneal junction. In melano-sarcomatous tumors the epitheliomas do not appear to reproduce themselves through the bloodvessels or lymphatic vessels, for they remain localized where they first broke out. The malignant tumors of the eye he finds now much more common than twenty years ago. The mechanism of direct inoculation explains the propagation of the neoplasm, the epitheliomas, which, beginning in the globe of the eye, inoculate the palpebral border. In other cases, the propagation takes place by the lymphatics. In melanotic epithelioma the implantation takes place in the corneal border.

PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, March 26, 1888.

THE PRESIDENT, S. WEIR MITCHELL, M.D., IN THE CHAIR.

DR. S. WEIR MITCHELL read a paper on

LOCOMOTOR ATAXIA CONFINED TO THE ARMS: REVERSAL OF ORDINARY PROGRESS.

(See page 428.)

DRS. CHARLES K. MILLS and W. C. CAHALL reported

SIX CASES OF EPIDEMIC CEREBRO-SPINAL MENINGITIS.

(See page 429.)

DR. WILLIAM OSLER said that it was interesting to note that in this city cerebro-spinal meningitis had been endemic for so many years. Dr. Stillé states that every year since 1863–64, deaths from this affection have been reported. Many of the cases were probably not cerebro-spinal meningitis. Mistakes in diagnosis were very common in this affection. Three or four instances of this had come under his observation. One case of small-pox was diagnosticated as cerebro-spinal meningitis. Cases of what the French term the cerebro-spinal type of typhoid fever, were frequently diagnosticated as cerebro-spinal meningitis, and at the post-mortem the brain was deeply congested, while the intestines exhibited the characteristic enteric lesions. The fifth case reported by Drs. Mills and Cahall resembled typhoid fever with severe cerebro-spinal manifestations. In certain of these cases he did not think that it was possible to make a positive diagnosis, unless the base of the brain was involved.

DR. MILLS said that the fact that in the fifth case the patient became blind was a strong point in favor of cerebro-spinal meningitis.

DR. H. A. HARE spoke with reference to the use of salicylic acid and quinine in cerebro-spinal meningitis. He had always understood from his reading and teaching and had found it practically correct, that these drugs are contraindicated in inflammation of the meninges of the brain and of the brain itself on the ground that they produced congestion of these parts. Studies have shown that in animals killed with quinine intense inflammation of the meninges of the brain was the typical post-mortem lesion.

DR. WILLIAM W. WELCH had been much pleased in listening to what had been said. It was, he said, shortly after the war that he first saw in this city cases of cerebro-spinal meningitis, and they answered to the description

given that evening. Since then he had only occasionally met with a case. He was inclined to agree with Dr. Osler that not unfrequently a mistake in diagnosis was made in regard to this disease. He had seen more than one case of smallpox mistaken for cerebro-spinal meningitis. About a year before, a young Swedish girl, suffering from this disease, had been brought to the Municipal Hospital from a ship arriving at this port. Of course he did not see her early in the disease nor was he able to obtain any history, but when admitted there was cephalalgia, hyperæsthesia, and marked stiffness of the neck and along the spinal column. She was totally deaf and in the course of the disease a purulent discharge came from the ears. For a time she seemed to improve, but finally lapsed into coma, and finally died after being in the hospital thirty-six days. No post-mortem was made. There had been under treatment in the hospital two cases which came from the locality mentioned by Drs. Mills and Cahall. These cases were not sent to the hospital until they had been sick about two weeks. He learned, however, that in both cases the sickness came on suddenly with a chill followed by fever, nausea, headache, intolerance of light, delirium, and stiffness amounting to rigidity of the cervical muscles. On admission most of these symptoms continued. It was about seven weeks since the attack occurred; in one case there was apparent improvement, but the condition of the other was still critical. The convalescence from this disease is always protracted. Indeed, he had sometimes questioned whether in severe cases perfect recovery ever takes place.

NEWS ITEMS.

New Quarantine Stations.—Dr. John B. Hamilton, Supervising Surgeon-General, Marine-Hospital Service, recommends to Congress the erection and thorough equipment of seven quarantine stations in addition to the one already provided for at the mouth of the Mississippi River, as follows: Delaware Breakwater; Cape Charles, Va.; Sapelo Sound; Key West, Fla.; San Diego, Cal.; San Francisco, Cal.; and Port Townsend, Oregon. The estimated aggregate cost of construction and equipment of these quarantine stations, including the one at the mouth of the Mississippi River, is $489,500, and the estimated aggregate annual cost of maintaining them is $93,000. "Believing, as the committee does, that it is the duty of Congress so to regulate commerce as to prevent the introduction of contagion from foreign countries into the United States, the bill is reported, with the recommendation that it pass," is the concluding sentence in the Senate Committee's report.—*Sanitary News*, April 7, 1888.

An Appropriation for the College of Physicians and Surgeons at Baltimore.—The *Maryland Medical Journal* of March 31, 1888, states that a bill has passed the House of Delegates of Maryland appropriating $10,000 for the use of the College of Physicians and Surgeons, of that city, to be used in the erection of a building adjoining the City Hospital on Calvert Street. The bill provides that the College shall support one free bed for each County in the State.

An Epidemic of Typhoid Fever in a College.—The *Sanitary News* writes that St. Stephen's College, near Poughkeepsie, N. Y., has been closed on account of an outbreak of typhoid fever among the students. The trouble is attributed to the drinking water, which is obtained from a well at the bottom of the hill on which the college buildings are situated. It is claimed the drainage from them enters the well.

The Cremation of Hospital Garbage.—The offensive refuse from Cook County Hospital is now being burned in the Chicago garbage crematory.

Boards of Health in Ohio.—A new and very important law has just been passed in Ohio, whereby a board of health is established in each city or village containing five hundred or more inhabitants.

The Manufacture of Cognac.—In a recent report from Mr. Vice-Consul Warburton, some suggestive statements are made as to the condition of the brandy industry in the department of the Charente-Inferieure, from which, before the vine failure, a considerable portion of the brandy exported to this country (England) was derived, although much also came through Cognac, which is the headquarters of the trade. Mr. Warburton states that in 1875 the department produced 200,000,000 gallons of wine, a great part of the surplus over the local consumption being converted into brandy. In consequence, however, of the ravages of the phylloxera the produce has gradually fallen off, until in 1886 it was reduced to 13,000,000 gallons. As the local consumption of wine in the department is estimated at 12,000,000 gallons, it will be seen there must have been comparatively little left for brandy making. In fact, Mr. Warburton says that pure brandy has become very scarce and difficult to get in the department, most of what is sold being mixed with beet root or cheap German spirit, while the latter is very often sold as cognac without any mixture at all. Mr. Warburton significantly adds that the supply of "cognac" is very limited and must diminish every year, ss that if the trade in the reputed article continues to go on much the same as it did before the failure of the vines, it will be evident that fraud is on the increase.—*Pharmaceutical Journal.*

Cremation in Italy.—The *British Medical Journal* writes that cremation in Italy has not, for the last two years or so, made so much headway as at first. The example at Milan in 1876 soon found many imitators, especially in the northern and central provinces of Italy, and there are now something like thirty-two societies and committees for favoring cremation, though they have not all got crematories of their own yet. The number of persons burnt last yeai was only 165, as against 181 in 1886. The Pisa Society, however, has not yet sent in its statistics for last year, and crematoriums will be opened in the course of the present year at Turin, San Remo, Verona, Bologna, Pavia, and one or two other towns. Of the total number of 952 cremations that have occurred in 17 cities in Italy, since 1876, as many as 518 have taken place in Milan, and 155 in Rome. The new crematorium at Milan is situated at the extreme end of the Campo Santo, just outside the walls of the city. The temple, as it is called, is a building in the Doric style, constructed of stone, and having an open façade supported by columns, from behind which rises a tower which, as seen

from the outside, looks as if it formed part of the temple, although in reality it stands quite by itself, and is the chimney. The inside of the building is divided into several rooms, in the first of which the religious rites are performed; its walls are lined with funeral urns containing the ashes of many of those who have been cremated at Milan. There is a separate room in which the bodies are placed pending cremation, and a third in which the relatives and friends spend the two hours occupied by the cremation itself. There are two furnaces—one being for general use, and the other for the bodies of persons who have died of contagious diseases and are not natives of Milan. The body is not visible to the onlookers when being put into the furnaces, nor are the ashes afterward.

Inconsistent Anti-vivisectionists.—Professor W. Mattieu Williams convicts the enemies of physiological experiment of inconsistency by showing that all male animals that come fully grown to market, as they must know, are subjected to one of the most painful mutilations that can be performed, merely to improve the flavor of their flesh. "A prominent member of the screeching sisterhood," he says, "has been seen lounging in her carriage drawn by a pair of horses that have been thus tortured for her luxurious convenience. To this she is supremely indifferent, but raves most virtuously against those who puncture the skin of a dog or rabbit in order to save thousands of human beings from cruel disease."—*Popular Science Monthly.*

The Removal of Dr. Thomas Keith to London.—Dr. Thomas Keith, the distinguished ovariotomist of Edinburgh, has made arrangements for removing to London in a short time. The Edinburgh School and the Royal Infirmary will sustain a great loss in Dr. Keith's change of location.

Recent Deaths among Medical Men in Paris.—Dr. Blot, a well-known obstetrician; Dr. Constantin James, a writer on the mineral waters of France; Dr. Martineau, a well-known gynecologist; and Dr. Brochin, the principal editor of the *Gazette des Hôpitaux*, are among the number of medical men recently deceased in Paris.

ORIGINAL LECTURES.

INVESTIGATIONS RELATING TO THE ETIOLOGY AND PROPHYLAXIS OF YELLOW FEVER.

An Address Delivered before the College of Physicians of Philadelphia, April 21, 1888.

BY GEORGE M. STERNBERG, M.D.,
MAJOR AND SURGEON U. S. ARMY.

GENTLEMEN: You are aware that I have been engaged during the past year in an investigation of the methods of inoculation practised in Brazil and in Mexico, by which it is claimed that protection against yellow fever is afforded. The subject is one of such great interest to the medical profession everywhere, and of such importance with reference to the sanitary interests of that portion of the United States subject to invasion by the disease in question, that Congress provided for an investigation of the methods of inoculation practised in Brazil and in Mexico, in the Act providing for the civil expenses of the Government for the year ending June 30, 1888.

Having been selected by the President to make the investigation referred to, in compliance with my instructions I first proceeded to Brazil for the purpose of investigating the methods of Dr. Domingos Freire, of Rio de Janeiro, and after my return from that country went to Mexico to make a similar research with reference to the value of the method of inoculation practised by Dr. Carmona y Valle. My detailed report was submitted to the President about a month ago, and by his permission I am now authorized to make public the conclusions reached. As I am about to go to Havana for the purpose of continuing my researches with reference to the etiology and prophylaxis of yellow fever, I am glad to avail myself of the kind invitation of the College of Physicians of Philadelphia, and to present to you, and to the profession generally, the conclusions which I have reached up to the present date.

These conclusions are given as follows in my report, above referred to:

"Facts relating to the endemic and epidemic prevalence of yellow fever, considered in connection with the present state of knowledge concerning the etiology of other infectious diseases justify the belief that yellow fever is due to a living microörganism, capable of development, under favorable local and meteorological conditions, external to the human body, and of establishing new centres of infection when transported to distant localities.

"Inasmuch as a single attack of yellow fever, however mild, protects, as a rule, from future attacks there is reason to hope that similar protection would result if a method could be discovered of inducing a mild attack of the disease by inoculation or otherwise.

"The hypothetical yellow fever germ, multiplying external to the human body in unsanitary places in tropical regions where the disease is endemic, or during the summer months in the area of its occasional epidemic prevalence, establishes infected localities, and susceptible persons contract yellow fever by exposure in these infected areas. We infer therefore, *a priori*, that the yellow fever germ invades the system by the respiratory tract, by the alimentary canal, or from the general surface of the body; and it should be found in the blood and tissues, or in the alimentary canal, or upon the surface.

"Another possibility presents itself, viz., that the germ multiplying in insanitary localities external to the body produces a volatile poison which contaminates the air, and that an attack is induced by the toxic effects of this potent chemical poison. The more or less prolonged period of incubation—two to five days—in numerous cases in which the attack has been developed after removal from the infected locality seems opposed to this latter hypothesis.

"In the light of what is known of the etiology of other infectious diseases, the hypothesis that the germ really finds entrance to the body of the person attacked and multiplies within it, is that which presents itself as most probable, and it hardly seems worth while to consider any other unless this is proved by a complete investigation not to be true. In the latter event we would have to consider the possibility of absorption through the respiratory tract of a volatile toxic agent, or through the skin of a poisonous ptomaine formed upon the surface of the body by a specific microörganism which does not itself penetrate to the interior.

"Naturally the attention of investigators has first been given to a search for the 'germ' in the blood of those attacked, and in the blood and tissues of the victims of the malady.

"*The researches made up to the present time have failed to demonstrate the constant presence of any microörganism in the blood and tissues of those attacked.*

"*My own researches, recorded in the foregoing report, show that no such microörganism as Dr. Domingos Freire, of Brazil, has described in his published works, or as he presented to me in his yellow fever germ at the time of my visit to Brazil, is found, as he asserts, in the blood and tissues of typical cases of yellow fever.*

"*There is no satisfactory evidence that the method of inoculation practised by Dr. Domingos Freire has any prophylactic value.*

"*The claims of Dr. Carmona y Valle, of Mexico, to have discovered the specific cause of yellow fever have, likewise, no scientific basis; and he has failed to demonstrate the protective value of his proposed method of prophylaxis.*

"It is highly important, in the interests of science and of public health, that further investigations be made by more exact methods, which have been perfected since Drs. Freire and Carmona made their researches, and with which they were evidently not familiar.

The failure thus far to find a specific microörganism

in the blood or tissues, makes it desirable that a thorough research should be made with reference to the microörganisms present in the alimentary canal, for it is possible that in yellow fever, as in cholera, the disease is induced by a microörganism which multiplies in this situation. Additional researches are also required before we can say definitely that there is no germ demonstrable in the blood and tissues. Having exhausted our researches by the method of direct examination, and by cultures from blood drawn during life, it is highly desirable that various culture media should be inoculated with material taken, with proper precautions, from the various organs, and at the earliest possible moment after death.[1]

I cannot attempt to give you in detail, at the present time, the evidence upon which the conclusions above stated are based, but it is recorded, *in extenso*, in my Report to the President, and will no doubt be published in due time. I shall, however, take advantage of this occasion to call your attention to some of the principal facts upon which I base the unfavorable opinion expressed with reference to the claims of Dr. Domingos Freire, of Brazil, and of Dr. Carmona y Valle, of Mexico. Both of these gentlemen, as you are aware, have laid claim to priority in the discovery of the specific germ of yellow fever, and both have practised inoculations with material supposed to contain their "microbe," having in view the production of a mild attack of the disease, and subsequent immunity as a result of this attack.

Dr. Freire has, however, made the greater number of inoculations and owing to his numerous publications and very positive assertions, his claims have received the most attention. My conclusion, that these claims are without scientific foundation, may seem to you almost incredible, in view of the extended researches which Dr. Freire has made in a locality where yellow fever is endemic, and of the very favorable statistics which he has published in support of the value of his method of inoculation. But I need scarcely remind you that the astonishing development of our knowledge relating to pathogenic microörganisms, which has occurred during the past decade, has been accompanied by numerous announcements of pseudo-discoveries in this field of research, and that much confusion has resulted from the premature publication of experimental researches made by enthusiastic investigators not familiar with the exactions of modern science, or with the exact methods by which alone security is offered against such pseudo-discoveries.

Dr. Freire insists in all his published works that his *cryptococcus xanthogenicus* is present in great numbers in the blood and tissues of yellow fever patients. In his principal work, *Doctrine Microbienne de la fièvre jaune*, published in 1885, he makes the following statement:

"The microbe xanthogenicus is a cosmopolitan; it does not select its domicile in any organ and has no preference for any organic liquid. We have encountered it with the same characters, the same opulence of proliferation, in the brain, in the muscles, in the liver, in the spleen, in the kidneys, in the lungs, in the blood, in the urine, in the bile, in the vomit, and even in the cephalorachidian fluid. However, it is necessary to establish a well-drawn distinction as to the blood; the blood of the general circulation shows itself much less charged with the microbes than the blood of the capillaries. Thus, if I could admit any preference on the part of the microbe xanthogenicus I would say that it pleases itself better in the blood of the capillaries, in the blood which bathes immediately the anatomical elements.

. . . . . .

"The occasion seems to us a favorable one in order to call attention to some indispensable precautions when the microbes of yellow fever are to be sought in organic solids and liquids. While it is extremely easy to perceive the presence of the microbes of yellow fever in the urine and the bile, for example, by placing a drop of these liquids upon a glass slide, covering it with a thin glass cover, and examining it with a power of 450 to 740 or 780 diameters, this proceeding cannot be employed when the blood is to be examined. If we proceed in this manner the globules will hide nearly all of the microbes, and the observer will wrongfully conclude that they are very rare in this organic liquid. Not only does the form of the microbe offer a certain resemblance to that of the red corpuscles, but these latter in adhering together envelop 'the microbian cells, and, on the other hand, cast upon the cells a jet of light which makes them disappear from the field of the microscope.'

"But if we dilute a little drop of blood in a pure solution of sulphate of soda and place it under the objective, the microbes become visible and will appear in considerable quantity,

"It is likewise necessary to make a preparation previously for the examination of the cerebral mass and of the muscles. They should be triturated in a sterilized mortar and mixed afterward with distilled water entirely deprived of organisms, filtered through fine linen which has been passed rapidly through the flame of an alcohol lamp, and afterward a drop of the filtered liquid should be placed upon a glass slide. If we withdraw a little piece of brain or of muscular fibre, even triturated, we will not perceive anything abnormal under the microscope unless it be the anatomical elements more or less deformed by trituration.

"It is not the same for the liver. It suffices to withdraw a bit of this organ and to crush it between two glass slides; upon observing it under the microscope we perceive at once a multitude of microbes. This is because in the muscles the microbes are lodged between the fibrillæ and in the substance which surrounds them; and in the brain they are found in the interior of the nerve cells which must first be destroyed by trituration in order that their parasitic hosts may become visible."

Having made extended researches in Havana in 1879, and during the past year in Brazil and in Mexico, I am able to assert most positively that no such microörganism as Dr. Freire has described is to be found in the blood and tissues of yellow fever patients. I have examined blood from numerous cases, drawn from the finger during life, both in the fresh condition, in preparations stained by various aniline colors, and by culture methods, and I have studied with great care a large number of thin sections of the liver and kidney, stained by the most approved methods, from a considerable number of typical cases of yellow fever, without having encountered the *cryptococcus xanthogenicus*.

As Dr. Freire asserts that his microbe is especially abundant in the capillary vessels, it should be easily demonstrated in thin sections of the various organs made *secundem artem*.

As a matter of fact, my researches show that, as a rule, no microörganism demonstrable by known methods of

[1] The writer went to Brazil and to Mexico fully prepared to make these experiments, but, unfortunately, was unable to secure any autopsies in either place, and the limit as to the time fixed by his orders made it necessary to return to the United States without having made these important researches.

staining, is to be found in such sections. But, here I must state that in certain cases microörganisms have been found. The one to which the most interest attaches is that described by Babes. This was discovered in 1884, in material sent to Paris from the laboratory of Dr. Lacerda, in Rio de Janeiro. At the time of my visit to Brazil, my friend, Dr. Aranjo Goes, gave me material from nine cases,[1] which had been preserved in Dr. Lacerda's laboratory since the epidemic of 1884, and after my return to Baltimore I examined sections stained by Gram's method, and with Lœffler's alkaline solution of methyline blue from all of these cases. I quote from my report as follows:

"In two of these cases I find in the capillaries of the liver and of the kidneys an organism which has been described by Babes and by Lacerda, who found it in material collected at the same time, and probably from the very same cases as those in which I now find it. This organism is a short bacillus, which occurs in chains, as seen in Fig. 2, Plate IV.

"In certain places, especially in the kidneys, it is found in the capillaries in great numbers, massed together; in other places it is distributed more sparsely, as seen in the figure." Careful examination of specimens stained with Lœffler's solution shows that the separate elements in these little chains vary considerably as to their length, and that the ends are more deeply stained than the centre. This appearance was no doubt observed by Babes, who first described the organism in question, but he has interpreted it differently. He says:

"The filaments appear united and homogeneous with an amplification of 600 diameters, but with a high power ($\frac{1}{12}$th hom. im., or No. 12 of Verick, which corresponds with the $\frac{1}{18}$th of Zeiss) one can assure himself that these filaments are composed of elliptical grains, almost cylindrical, arranged in pairs, forming little groups in which they are united by an intermediary pale substance. The filaments are thus composed of diplococci, or, if one wishes, of very short rods with terminal spores." (Op. cit., p. 522.)

Dr. Lacerda has described the organism referred to as in filaments which branch dichotomously, and believes this branching to be a constant and distinctive characteristic of the parasite which he accepts as the veritable yellow fever microbe. He is without doubt mistaken. The apparent branching of the filaments which he has described and drawn, and which he showed me in some of his preparations at the time of my visit to Rio, is due simply to the accidental juxtaposition of the torula-like chains. He is also mistaken in supposing that this organism is only to be satisfactorily demonstrated by Gram's method of staining. My friend, Dr. Goes, shared this belief at the time of my visit to Rio, but I demonstrated to him the facility with which the organism may be stained with a solution of methyline blue, upon sections which he made for me from material in Dr. Lacerda's laboratory. Since my return to Baltimore I have made numerous sections from the same material (two cases out of the nine) and find no difficulty in staining the organism present in the tissues, with methyline blue or with fuchsin. Dr. Goes also supposed that his failure to find this parasite in all of the tissues which he had preserved since the epidemic of 1884 was due to the fact that the tissues had been kept too long. He thought that it was most easily stained in recent tissues, and anticipated that when he had again an opportunity to make autopsies he would encounter this microorganism in the tissues. I shall await with interest his report of his recent researches.

As already stated, I have not been able to find this microbe of Babes in the tissues of six undoubted cases of yellow fever sent to me from Havana, and examined most carefully within six months of the date of the autopsies. Babes, himself, has renounced the idea that this microörganism bears an etiological relation to the disease under consideration. In the second edition of *Les Bacteries* he says:

"Since these researches we have had the opportunity to examine several series of sections from yellow fever: First, the liver and kidney of two individuals dead from this malady, collected by Dr. Alvarez, were examined in the Laboratory of Pathological Anatomy of the Faculty of Paris, without any bacteria having been found; second, material from three cases of yellow fever which Koch was kind enough to confide to one of us. In these three last cases, notwithstanding the most scrupulous research, and notwithstanding the advice of Koch, it was impossible to find the little chains in the brain, the kidneys, the liver, and the spleen. We must suppose, then, that in yellow fever, as in other infectious maladies, microbes are only found in the parenchymatous organs in certain cases, and not in all. The question whether these microörganisms really constitute the cause of the malady, or simply a complication, is consequently not resolved.

"We would remark that in view of the negative results attending Babes's more recent researches, and our own extended study of the tissues from six typical cases occurring in Havana, there is no good reason for supposing that the above-described microörganism bears an etiological relation to yellow fever. On the contrary, it seems probable that its presence in material from a limited number of cases occurring in Rio, is either entirely accidental, or is due to a secondary complication, perhaps to some form of septicæmia."

From what has been said, and from Dr. Freire's own account of his method of triturating fresh tissues to demonstrate his cryptococcus, the inference seems unavoidable that in his researches made by this method he has mistaken broken-up blood corpuscles and the granular *débris* of the tissue elements for microörganisms.

In his culture experiments he has, owing to a defective technique, encountered micrococci of various kinds, and one of these, which he brought back with him from Paris in an agar-agar culture, he presented to me as his yellow fever germ.

I brought a pure culture of this micrococcus with me to Baltimore, and have cultivated it during the past winter in various media. It does not correspond in its morphology, or mode of development, with the *cryptococcus xanthogenicus*, as described by Dr. Freire in his various published works, and, as stated, is not found in the blood or tissues of yellow fever patients.

In his principal work, published in 1885, Dr. Freire gives the following account of the morphology of his cryptococcus:

[1] In December last, having received a request from Dr. Frank Billings for some yellow fever material, I sent him a fragment of liver and one of kidney from one of these cases. It so happened that it was one in which the Babes organism was present, and Dr. Billings has since published an account of his examination of this material in a paper entitled, "Southern Cattle Plague and Yellow Fever."

"When we follow with care and attention the march of the development which characterizes the germs which produce yellow fever, we acquire the certainty that, commencing to present themselves under the form of little points almost imperceptible, they afterward gradually increase in diameter, until they attain considerable dimensions; so that these little beings, which, at the outset, had the aspect of very little grains of sand, not measuring more than 0.001 millimetre to 0.002 millimetre in diameter, arrive, little by little, to such a development that they reach the dimensions of 0.005, 0.007, 0.008 millimetre, and sometimes even more in certain conditions. When they have attained the adult age these cells are broken at divers points, and discharge their contents, composed of spores already formed, mixed with a viscous substance of a yellow color, composed of a pigment and protoplasmic substance, and of the liquids elaborated by the cells."

Even so recently as last year, in an address delivered before the Dosimetrique Society of Paris, Dr. Freire repeats this account of the mode of development of his cryptococcus; he says:

"Each adult cell is ruptured in one or several points, and allows to escape its contents, composed of germs which are to perpetuate the species, and two pigments, one yellow, destined to infiltrate all the tissues, and to produce the icterus color which has given name to the malady; the other, black, insoluble, and destined to be carried along by the circulatory current, producing either capillary obstructions, or blood stasis in the parenchyma of the organs."

Now this mode of multiplication is not known among the bacteria, and does not occur in the micrococcus which Dr. Freire placed in my hands as his yellow fever microbe, which multiplies by binary division, and does not differ in its morphology from a variety of microorganisms of the same class, which are extremely common in all parts of the world.

According to Dr. Freire's statement, the agar culture brought by him from Paris came originally from the blood of a patient with yellow fever at the point of death.

Now, as heretofore stated, I have demonstrated by the microscopic examination of numerous specimens, that, when proper precautions are taken, no microörganisms are found in blood drawn from the finger of yellow fever patients, and that no development occurs in culture media inoculated with such blood. I infer, therefore, that the micrococci, etc., found by Dr. Freire in his cultures, are due to the accidental introduction of microorganisms from without, and especially from the surface of the finger during the collection of the blood. I may remark here that Dr. Freire's cultures in liquid media, which were made before he went to Paris, and which were placed in my hands for examination, were all impure, and contained several different microörganisms. I suppose that the micrococcus brought back from Paris was isolated while he was there from one of these impure liquid cultures, for I found no evidence that solid culture media had been used in his laboratory in Rio prior to the date of his visit to Paris.

Nor did he use, to any extent at least, the well-known methods of staining bacteria which are recognized by bacteriologists as so essential in the study of these minute microörganisms. This is shown by the following quotation from his address, delivered in Paris, to which reference has already been made, he says:

"We know that in order to color a microbe it is necessary first to kill it and then to wash the little microscopic cadaver, by means of reagents possessing the power of dissolving all matters foreign to its skeleton. At the outset I applied myself to the study of the yellow fever microbe in a fresh state. I fed it with the best food—*les meilleurs engrais*—for the purpose of surprising the different phases of its evolution from its birth to its death."

"Nevertheless, in fault of other accusations, some authors have reproached me with not having colored my microbe. Alas! what a miserable objection. Is it necessary in order to affirm the existence of a microbe which swarms by millions in the urine, in the bile, in the blood, in the tissues, etc., is it necessary to mass them, to disguise them under a costume of carnival, in order to please certain microscopists? M. Pasteur has never colored his microbes, and nevertheless every one admits the existence of the bacillus of charbon, of the corpuscles of pébrine, of the micrococcus of fowl-cholera, etc.

"Do not think, gentlemen, that I fear the application of coloring processes to the search for the microbe of yellow fever. Far from it. In order to show you that the criticism which I have just made is not due to prejudice, I will say to you that such processes have recently been employed upon the yellow fever microbe with complete success."

A character upon which Dr. Freire insists, even in his address delivered in Paris in April, 1887, is the formation of two kinds of pigment, one yellow and one black. From the first he has affirmed that the black color of the characteristic "black vomit" is not due to the presence of blood changed by the acid secretions of the stomach, as has been generally believed by those physicians who have studied the disease, but that this color is due to a pigment produced by his cryptococcus. Now, I have had the coccus which he gave as his yellow fever germ under cultivation in various media, during a period of several months, and no black pigment has been produced. On the contrary, the colonies in Esmarch tubes, and stick cultures in gelatine, or in agar all have a milk-white color. In morphology this micrococcus does not differ from some well-known and widely distributed species. It liquefies gelatine quite slowly, grows readily at a temperature of 18.20° C. (64.4°–68° F.), and, as stated, forms no pigment.

The supposition that the microörganisms present in Dr. Freire's blood cultures, and in those of various other observers who have discovered yellow fever "germs" came from the surface of the body and not from the blood is sustained by recent experimental researches upon the sterilization of the hands, made by Kümmell[1] and by Fürbringer.[2]

These experiments show that it is not an easy matter to destroy all microörganisms upon the surface of the body by means of a disinfecting solution, and that a simple washing with bichloride solution of $\frac{1}{1000}$th does not usually insure sterilization of the hands. Fürbringer, after repeated experiments, recommends the following procedure: 1. Remove all visible dirt from the nails. 2. Scrub the hands with soap and water by means of a brush. 3. Immerse them for one minute in strong alcohol—at least eighty per cent. 4. While still wet im-

[1] Wie soll der Arzt seine Hände Desinficiren? Deutsche med. Wochenschr., 1886, No. 32, p. 555.

[2] Untersuchungen und Vorschriften über Disinfection der Hände des Arztes, etc. Wiesbaden, 1888.

merse them for one minute in a two per cent. solution of mercuric chloride.

Less thorough treatment did not in Fürbringer's experiments absolutely insure sterilization. In the case of patients in hospital, the difficulty is often increased by the fact that their hands are horny and begrimed with dirt which can only be removed by long scrubbing.

With reference to Dr. Freire's experiments upon animals, I can only say that those performed in my presence failed entirely to demonstrate that the micrococcus brought from Paris had any specific pathogenic power, and that I find no satisfactory evidence in the record of similar experiments contained in his various publications that it has ever transmitted yellow fever to rabbits or to guinea-pigs, as claimed.

I shall quote here a single experiment in which a fatal result occurred, and in which, as usual, Dr. Freire ascribed death to yellow fever resulting from the injection, notwithstanding the fact that the material injected (blood) had been subjected to a boiling temperature for some minutes. My own numerous experiments show that all known micrococci are quickly destroyed by a temperature much below the boiling point of water.[1]

Dr. Freire's account of this remarkable experiment is as follows:

"We must note that the microbe of yellow fever offers a remarkable resistance to heat. The following experiment furnishes a demonstration of this:

"On the 17th of April, 1883, we subjected to ebullition for several minutes, a gramme of blood containing the microbes. We injected it afterward into a guinea-pig, which had a temperature before the experiment of 38.5° C. (101.3° F.) in the axillary region. The temperature followed this march the following days:

April 18th	39° C. (102.2° F.)
" 19th	39°
" 20th	39.1°
" 21st	39°
" 22d	38.7°
" 23d	37.4° C. (99.3° F.)

"The animal died during the night of the 23d. Its autopsy showed the characteristic lesions.

"It is necessary to push the temperature beyond 200° C. in order to destroy the toxic energy of the microbe. As we have seen, its virulence resists simple ebullition. The microscope has shown that notwithstanding the boiling the microörganisms retained their ordinary form and continued to execute all of their movements, a proof of their complete vitality. (Op. cit., p. 217.)

"I may remark here that the micrococcus presented to me by Dr. Freire as his yellow fever germ is killed by exposure for ten minutes to a temperature of 60° C., and that it has no proper movements."

Dr. Freire's protective inoculations.—Having demonstrated that Dr. Freire's claim to have discovered the specific cause of yellow fever is without scientific foundation, it may be thought that no further demonstration is required in order to show that his preventive inoculations are without value; for these inoculations are said to have been made with cultures containing the attenuated microbe of yellow fever. These inoculations have, however, been made upon so large a scale, and the statistical results, as presented by Dr. Freire, appear so favorable to his method that it becomes necessary to analyze these statistics; and if, as he claims, they establish the fact that the mortality from yellow fever is very much less among those who have been inoculated by him than among non-inoculated persons exposed in the same way, we shall be obliged to concede the value of his method, although the rationale of the protective influence may not be apparent. In my detailed report I have reviewed at length Dr. Freire's statistics in the light of the facts developed by my personal researches in the city of Rio de Janeiro where the inoculations were made. I cannot attempt to bring the evidence before you at the present time, and I have already stated to you my conclusion with reference to the matter. In support of this conclusion I shall, however, quote a few extracts from my report.

In 1884, Dr. Freire inoculated 418 persons whose names, ages, place of residence, and length of residence in Brazil are given in an appendix to his principal work, published in 1885. In regard to the evidence afforded by these inoculations, I have written as follows:

"We remark, first, that in selecting foreigners and preferably those who had recently arrived in Brazil for his first experimental test as to the efficacy of his protective inoculations, Dr. Freire has given evidence of his confidence in the method of prophylaxis proposed and of an honest desire to demonstrate its value, and nothing could be more fair than his full publication of the names and of the essential facts with reference to these persons.

I must object, however, to his including in his statistics the names of thirty-seven persons residing in Vassouras, a village, which is some fifty miles distant from Rio de Janeiro. Even if these persons had occasion to visit Rio during the epidemic season, as is stated by Dr. Freire, it is probable that they would remain as short a time as possible, and there is no evidence that they were fairly exposed to the epidemic influence. Moreover, if any of these persons had contracted yellow fever as a result of a visit to Rio their names would not appear in the mortality list of this city, but in those of Vassouras, which are not given. The latter objection applies also to fourteen persons among the vaccinated whose place of residence is Nictheroy, a town upon the bay of Rio de Janeiro, which is the capital of the province of the same name; two persons vaccinated at Tijuca, and one on board the bark "Flive," two at Pavina, and three at Serraria must also be excluded. This reduces the number of vaccinated persons within the city limits to 355; and, of this number a certain proportion no doubt left the city soon after being vaccinated, and before any exposure, worthy of consideration in a test of this kind, had occurred."

Dr. Freire admits that "during the epidemic season a great number of the vaccinated were attacked by the malady," but claims that these attacks were of a mild character; yet he gives us the names of seven vaccinated persons who died from the disease. This list has been added to by some of Dr. Freire's confrères, as will be seen by the following translation of a letter published in one of the newspapers of Rio, and bearing date May 5, 1887. This letter is signed by Dr. Aranjo Goes, at present a member of the Central Board of Health, and a gentleman whose statements are worthy of the fullest confidence:

"My letter to the Imperial Academy of Medicine having been published, it now behooves me to publish

[1] The Thermal Death Point of Pathogenic Microörganisms. Amer. Journ. of the Med. Sci., July, 1887, pp. 146–160.

the statistics relating to the vaccinations on Morro da Viuva.

One fact seems to me to be definitely demonstrated, that is the *worthlessness of Dr. Freire's vaccination*, as is well known to the medical profession of this city.

A year ago I wrote the following:

"The want of skill which he displayed in his first experiments, the false conclusions which he has drawn therefrom, and the thoughtless precipitation with which he has hastened to make known incomplete results without accompanying them with a single qualifying remark vitiate all the methods to which he may hereafter resort to corroborate his statements." (*Journal do Commercio*, April 20, 1883.)

"The mortality among the persons vaccinated on Morro da Viuva furnishes one more proof that I was right in saying this, as I now proceed to demonstrate.

"There were vaccinated in this district sixty persons.

"Sixteen removed shortly after the commencement of the epidemic, and forty-four remained exposed to its influence. Of these twenty-two had yellow fever, nine of whom died.

"The following is a list of the vaccinated persons who had the fever, the names of those who died being marked with an asterisk:

"*Antonio de Oliveira.
"Antonio Bento da Silva.
"Albino Francisco Maia.
"Jose da Silva.
"*Joaquin Pereira da Souza.
"Joaquin Gomes de Azevedo.
"Joaquin Ferreira Tolho.
"Jose Seabra dos Santos.
"Jose de Sonza Ferreira.
"Jose Gomes de Azevedo Junior.
"Jose Farinha.
"Manoel Joaquin Percira Lopes.
"Manoel Gomes de Azevedo.
"*Manoel Antonio.
"Seraphim Goncalves Raymundo.
"*Manoel Simoes.
"Thome Simoes.
"*Manoel da Silva Alves.
"*Antonia Percira Neves.
"*Joaquim Martins Pinheiro.
"*Joaquim Antonio dos Santos Cardoso.

"Consequently, of the 44 vaccinated persons who remained in the locality 22, that is 50 per cent. had the yellow fever!

"Of the 22 patients, 9 died, that is 40.9 per cent.!

"In the Jurujuba Hospital, which receives scores of patients already dying or in the third stage of the disease, the mortality is only 21 per cent.

After reviewing all of the evidence obtainable relating to the inoculations practised in 1883 and 1884, I say:

"The evidence above recorded seems to the writer to be convincing as to the complete failure of Dr. Freire's proposed method of prophylaxis as practised in 1883 and in 1884. We cannot, however, leave the question here, inasmuch as a modification of the method was adopted in 1884, and a large number of persons have been since inoculated by this modified method. Dr. Freire says in his report under consideration: 'I have employed in nearly all of the vaccinations the endermic method, and it is only recently that I have injected into twenty persons the same cultures by the hypodermatic method. . . . I shall hereafter give the preference to the last mentioned method, because one is more sure that the liquid employed goes to exercise its preservative influence.'

In 1885, Dr. Freire resumed his inoculations on a larger scale, but instead of selecting unacclimated strangers, those inoculated were for the most part natives of Brazil or Portugese who had lived for a number of years in Rio and who had passed through one or more epidemics. A considerable number of negroes were also inoculated and included in the statistical tables. With reference to Dr. Freire's statistics for the year 1885 I quote from my report as follows:

"Dr. Freire has omitted to state one very important fact with reference to the vaccinations practised during the period included in this tabular statement. The date of the vaccinations is not given. Fortunately I am able to supply this omission from his journal containing the names of the vaccinated, which he kindly placed in my hands during my stay in Rio. I find from this record that the inoculations were practised as follows:

January	392
February	342
March	611
April	139
May	273
June	813
July	481

"Now it is well known that June and July are months during which yellow fever does not prevail in Rio, and that in fact the month of May furnishes, as a rule, but few cases.

"The exposure even in an epidemic year amounts to very little during the months of May, June, and July, and may be considered practically *nil* in a year like 1885, when the whole mortality was only 278 in a city of 400,000 inhabitants. But Dr. Freire has included in his list 1294 persons who were vaccinated during the healthy winter months of June and July, and who presumably had been exposed during the preceding comparatively unhealthy months of January, February, March, and April. If these 1291 individuals were protected from an attack of yellow fever by the inoculation practised in June or July, what protected them from being attacked during the preceding months when yellow fever was prevailing to some extent?

"We remarked with reference to those persons selected for vaccination in 1883 and 1884 that 'in selecting foreigners and preferably those who had recently arrived in Brazil for his first experimental test of the efficacy of his protective inoculations, Dr. Freire has given evidence of his confidence in the method of prophylaxis proposed and of an honest desire to demonstrate its value.'

"In his inoculations practised in 1885 we no longer find any evidence of such selection, and so far as we can judge the vaccinated persons simply represent the average population of the city of Rio. It is well known that this population includes a large number of persons of foreign birth and especially of Portugese. The whole foreign-born population probably does not fall below 100,000 persons, but I have not been able to obtain any exact statistics with reference to this point. Dr. Freire vaccinated 2186 natives and 865 foreigners. Let us assume for the present that the 1760 persons vaccinated by him during the months of January, February, March, April, and May, were comparable so far as susceptibility to yellow fever is concerned with 300,000 of the population of Rio. In this estimate we exclude 100,000 of the population on the supposition that this number may have enjoyed immunity as a result of having suffered an attack of the disease, 278 deaths in a population of 300,000 gives less than 1 death per 1000, and there should not

have been over 2 deaths among the 1780 persons inoculated by Dr. Freire during the months of yellow fever prevalence.

"Let us look at the matter in another light. Dr. Freire gives the following table showing the length of residence in Brazil, of the foreigners inoculated in 1885:

For a few days	26
For a few months	71
From one year to one year and a half	69
Two years	107
Three years	98
Four years	126
Five years	103
On board ship (de passage)	9
More than five years	256
Total	865

"These figures also include the foreigners vaccinated in the healthy months of June and July, and those temporarily in the city (a few days 26, on board ship 9), but they will serve our present purpose, which is to call attention to the fact that 759 of the total number given had been in Brazil (and presumably in Rio) more than a year and a half, and had consequently passed through the preceding epidemic year (1884) without contracting yellow fever. If these persons resisted yellow fever during an epidemic, in which the number of deaths amounted to 1597, how can it be claimed that they are protected by a vaccination made in 1885, when only 237 deaths occurred, scattered about (sporadic) in a city of 400,000 inhabitants? the same argument applies with greater force to the 359 foreigners inoculated who had resided in Brazil for five years and above (five years 103; more than five years 256). Unless the list includes persons who had already suffered an attack of yellow fever, these individuals had passed through the epidemic of 1880 (1623 deaths) as well as that of 1883 and 1884, without contracting the disease, and we can hardly ascribe their immunity in the comparatively healthy year, 1885, to Dr. Freire's inoculation."

I pass now to the year 1886, during which Dr. Freire inoculated 2763 Brazilians and 710 foreigners, again including in his statistical tables those vaccinated after the epidemic season had passed. In reviewing these statistics, I remark as follows:

"We have quoted this last report of Dr. Freire *in extenso* in order to do him full justice by allowing him to state his own case. We shall now proceed to show that his statistics are fallacious, and that the percentage of mortality among the vaccinated, which he finds to be ten times less than among the non-vaccinated, results from a misuse of the statistical method and from a number of factors, which are favorable to Dr. Freire's statistics as he has stated them, but not to a fair test of his method of prophylaxis.

"In the first place, we would call attention to the fact that while during the comparatively healthy year, 1885, the immunity among the vaccinated of that year is said to be complete (see report of 1885), the number of deaths during the epidemic year which followed is stated by Dr. Freire himself to have been eight. Taking all of the vaccinated of the two years, and without making any allowance for the considerable number of persons vaccinated who had, no doubt, left the city before the epidemic of 1886 occurred, Dr. Freire with a total of 6524 vaccinated, and a total of 8 deaths, makes the proportion one per thousand. This is equivalent at the outset to an addition of 1476 persons to the number vaccinated, who being imaginary persons and not having been exposed to the epidemic influence simply aid in rounding up the general percentage of mortality in Dr. Freire's favor to the even figure of one per thousand. This is but one of many factors which go to make up this favorable showing. Reference to Dr. Freire's MS. Journals, which he kindly placed in my hands, shows that of the total number vaccinated during the two years, 4465 were vaccinated prior to the epidemic of 1866, that is to say, before the 1st of January, 1886. How many of these left the city before the outbreak of the epidemic, how many were only temporarily in the city when vaccinated, how many died from other diseases, I cannot say; but it is a significant fact that of the 3051 vaccinated prior to August, 1885, Dr. Freire has only one fatal case to report, while out of 460 persons vaccinated in January and February, 1886, he reports five deaths, a mortality of more than one per cent., which he gives as the general mortality among the non-vaccinated. This is not apparent from Dr. Freire's own statement of the case, but is nevertheless true, as I shall proceed to show. In his report which we have just given in full, he does not give the date of the vaccination of these individuals, but upon referring to his MS. Journal for 1886, I find that No. 3 of his list, Jose, son of Jose da Costa Vieira, was vaccinated February 12, 1886; No. 4, Paschoal Ruffino, on the 6th of February, 1886; No. 5, Henri Constance, on the 1st of January, 1886; No. 6, Fernando Argenteiro, on the 20th of February, 1886; and No. 7, Antonio Saraiva, on the 12th of February, 1886. The same MS. Record for 1886 shows that during these two months—January and February, 1886—the total number vaccinated by Dr. Freire was 460. That is to say, the mortality among those vaccinated during these two months was more than one per cent. On referring to the mortality lists of the city for the same two months, I find the total number of deaths to have been 369, which in a total susceptible population of 160,000 (Dr. Freire's estimate) would give a mortality of one in 436."

Time will not permit me to extend any further this analysis of Dr. Freire's statistics, and I must refer you to my complete report for additional details, and for an account of my personal investigations in Rio de Janeiro. Nor can I occupy any further time in an account of the inoculations practised by Dr. Carmona y Valle, of Mexico, and of his alleged discovery of the specific cause of the disease under consideration. A simple perusal of Dr. Carmona's published work is sufficient to convince any competent bacteriologist that owing to a defective technique and inexperience in bacteriological researches, he has fallen into serious errors of observation and of inference, and that his supposed discovery has no scientific basis.

From what has been said, it will be seen that the question of yellow fever etiology is still unsettled, and that it remains, in fact, just where it was left by the Commission sent to Havana in 1879 by the National Board of Health. The researches made by myself as a member of that Commission, showed that in yellow fever there is no microörganism present in the blood of the sick demonstrable by the highest powers of the microscope. This

conclusion is supported by my more recent researches by the method of cultivation. Before, however, abandoning all hope of finding a specific "microbe" in the tissues, I desire to make cultures from the various organs, obtained at the earliest possible moment after death. Unfortunately, the opportunity did not offer itself for this important experiment during my visit to Brazil and to Mexico last year, but I hope to have the desired opportunity in Havana during the present summer, and shall also give special attention to a search for the yellow fever germ in the alimentary canal, where it may possibly be located, as is the case in cholera. It is true that the clinical history of the disease does not especially point to this location, but in a research of this nature, it will not answer to reject any possible hypothesis, because of preconceived opinions; and inasmuch as the present state of science justifies a belief in a specific microorganism, as the essential agent in the etiology of this disease, it is imperative that the investigations be continued until success crowns our efforts.

ORIGINAL ARTICLES.

EXPLORATORY LAPAROTOMY.

By J. M. BALDY, M.D.,
of Philadelphia.

The whole subject of exploratory laparotomy is daily assuming such increasing importance that it is becoming necessary to have some exact data from which to judge of the propriety of this procedure. There is little doubt in the minds of most operating surgeons as to the importance of a complete and intelligent exploration of the abdominal cavity in all cases of obscure abdominal troubles of a serious character, which threaten life, and which refuse, within a safe amount of time, to yield to medicinal treatment. The active hostility to operative procedures about the abdomen comes, in great part, from so-called surgeons, men who have either had little or no practical experience in these matters, or who have had some very unfortunate results. Again, a quiet but determined opposition is often to be found amongst physicians. It is hard for these gentlemen to overcome the dread of interference with the peritoneal cavity, a dread which has been so thoroughly instilled into the professional mind that it will take, I fear, many years of patient work to overcome it. Even in cases in which the diagnosis is easily made, and in which every moment lost is of the gravest importance, men still hang back from a surgical procedure, apparently in the hope that something almost supernatural will intervene to save the patient. Where a doubt rests on the diagnosis, this reluctance becomes almost a dread, and generally calls forth an ill-timed opposition, until eventually the operation must be made, only to be found to be too late, or perhaps it is not made at all.

The fact cannot be too constantly kept before the profession that an exact diagnosis in abdominal diseases is very often impossible. This is the expressed opinion of the great majority of abdominal surgeons to-day, and it is the exception to find one bold enough to claim otherwise. In the words of Thomas, "he who declares that he does not frequently err belongs to one of two classes: that of those who lack the intelligence to appreciate their shortcomings, or the courage to confess them, or to that of those who by *suppressio veri* or *suggestio falsi* are shortsighted enough to hope to deceive the community which watches their careers." When such men as Tait and Thomas boldly acknowledge our lack of diagnostic precision, it is time for us to lay off timidity and embrace every means at our command to overcome the difficulties of the situation.

If it were certain that a band was binding a loop of intestine down, and strangulating it, or that there was a purulent peritonitis, or one of a dozen other conditions present, even a physician would not hesitate to have the abdomen opened, and the strangulation relieved, the peritoneal cavity washed out and drained, or whatever else might be found necessary. The risk to life which the operation itself might bring would be unhesitatingly accepted by any intelligent thinker, and would not have very much weight against an operation which offered such positive chances of relief and cure. But when a case is presented in which there is a very grave doubt as to the diagnosis, especially when the patient seems to be in pretty good general condition, and with the hope of something turning up constantly leading one on, the temptation to wait becomes great. This is the more so because there is a decided feeling of uncertainty in the minds of the profession at large, excluding operating surgeons of experience, as to the amount of risk to life the patient will be exposed to from an operation *per se*, provided nothing of a dangerous character be found to exist after the operation has been made.

It is with the hope of adding something to the literature of the subject, which may at least be a beginning toward a final settlement of this question of danger, that I have collated the following statistics.

I am fully awake to the fact that conclusions drawn from statistics are often misleading, and can at best be but approximate; and yet withal they have their place and serve their object. I have been at some considerable trouble to make this list as reliable as possible, but realize that some errors have probably crept in, and that some cases must have been included which should not have been. However, I do not think there are enough of them materially to alter the results. I have not used any journal cases, excepting in such instances as the operator has directly referred me to them. I have excluded all such for the obvious reason that the case might be only one of many done by the same operator, and

it would be manifestly unfair to include his favorable and not his unfavorable ones, or *vice versa*. All cases used have been those of American surgeons; they have been obtained directly from the operator himself, and presumably include all such operations done by him during the past five years. Such cases only as have had the abdominal cavity opened and no operation or extensive separation of adhesions done inside the peritoneal sac, whether the diagnosis had been made before the operation or not, have been admitted, so far as I have been able to judge. Cases of simple irrigation or drainage have been included for the reason that they are often almost of necessity part of an exploratory operation, and do not complicate it to any great degree.

A careful analysis of the list develops many interesting features. There are in all 154 cases, representing the work of 46 operators, many of whom will be recognized as men of prominence. As reported, the list is classified as follows:

	Cases.
Carcinoma	3
Papilloma	5
Malignant	8
Sarcoma	12
Cancer	33
Pregnancy	3
Peritonitis, acute, chronic, suppurative	11
Peritonitis, tubercular	17
Uterine fibroids	16
Diseases of the uterine appendages	10
Diseases of the liver, gall-bladder, and their ducts	9
Cysts of kidney	2
Pelvic or iliac tumors	8
Pelvic abscess	2
Purulent fluid in peritoneal cavity	2
Abscess of ovary	1
Suppurating sinus	1
Cellulitis of broad ligament	1
Perimetritis	1
Acute micrococcal development	1
Hyperæmia of the pelvic peritoneum	1
No disease found	3
Penetrating stab-wound of abdominal wall	2
Penetrating gunshot wound of abdominal wall	1
Not stated	1

The total number of deaths is 25, making the general mortality somewhat over 16 per cent. At first sight this death-rate is appalling, and would naturally stop all talk of exploratory operations, but when we come to analyze further the deaths and their causes, this will be considerably modified. The list is considered in two divisions; malignant, 61 cases; and non-malignant, 93 cases.

Among the malignant cases age does not seem to have differed more than in malignant disease in other parts of the body. The mortality between the ages of twenty and thirty years is over 33 per cent.; from thirty to forty it drops to almost 19 per cent.; but between forty and fifty it again rises to over 33 per cent., only to drop back to 18 per cent. between fifty and sixty. Of the 55 recorded cases, 40 occurred between the ages of thirty and sixty years. The extremes were five and seventy-four years.

Of the 87 recorded cases of non-malignant disease, 71 occurred between the ages of twenty and fifty years, with a mortality ranging from 6 to 16 per cent. The mortality of those from one to ten, and above sixty years of age is from 50 to 100 per cent. I take it that these results are not very far from those of any other major operation.

The number of females far exceed those of males; the mortality amongst the males is, however, very much the highest. There are 61 recorded malignant cases; of these, 57 are females and 4 males. The female mortality is over 21 per cent., the male is 50 per cent. Of 93 recorded non-malignant, 83 are females and 10 are males; the female mortality is over 8 per cent., the male is 40 per cent.

At the time of the operation the condition of the patients varied greatly. Of 33 recorded malignant cases, 7 were in good or fair condition, 19 in bad, and 7 in very bad; of 76 recorded non-malignant cases, 25 were in fair or good, 34 in bad, and 17 in very bad condition.

The length of time that the disease had existed before the operation was in 32 recorded malignant cases, under one month, 1; from one month to a year, 23; over one year, 8. Of 62 non-malignant, 11 had existed under one month, 25 from one month to a year, and 26 over a year.

Of 32 recorded cases of malignant disease which recovered from the operation, 2 lived under one month, 15 from one to six months, 15 over six months; of 61 non-malignant, 2 lived under one month, 9 from one to six months, and 50 more than six months.

An analysis of the effects of the operation on the condition requiring it presents some very remarkable facts. 27 malignant and 52 non-malignant cases are recorded. Of the malignant, there was more or less improvement in 14, and no improvement in 13 cases; of the non-malignant, there was no improvement in 12, but there was improvement in 40 cases. The change for the better in some of these amounted to an absolute cure, and in many others it was very great, as well as permanent. This is all the more remarkable when it is remembered that nothing could be done for the patient's relief after the abdomen had been opened, but the wound had been closed with everything left as it had been found. This bears Tait out well in the statement he made some years ago, that the mere handling of the abdominal contents seemed in many cases to give relief. The modus operandi is, I think, beyond explanation, but the bare fact still remains, to which I can personally bear testimony.

14 malignant and 11 non-malignant cases died. Of the malignant, 1 died within a day, and 13 from one to seven days; of the non-malignant, 3 died

within a day, 6 from one to seven days, and 2 lived over a week. The causes of death in the malignant cases were:

	Cases.
Exhaustion	4
Peritonitis	2
Shock	1
Intestinal obstruction	1

with six cases unrecorded.

Of the non-malignant:

	Cases
Collapse	1
Shock	1
Tetanus	1
Peritonitis	2
Heart clot	1

with five unrecorded cases.

I have already stated that there were 25 deaths. If we examine these deaths we find that 14 of them were among the malignant cases, making a death-rate of 22 per cent. In other words, the mortality of the malignant is just twice as great as that of the non-malignant. Palmer has stated "that patients with internal cancer have little vitality and a small amount of shock is liable to shorten life, if not prove fatal." The results here obtained would seem to verify his statement.

Death in three of the malignant cases cannot be attributed to the operation, and probably if fuller particulars had been given in the other 11, most of them could be eliminated. As it stands, about 18 per cent. of these deaths were hastened by operation. Here, however, we must take into consideration that the death of all was only a matter of time, and possibly a very short time. The operation was left in most of them, as usual, until the last moment, and when the condition of the patient was, as recorded above, either "bad" or "very bad" in 26 out of 33 cases.

A much more pleasing picture presents itself in many ways when we consider the non-malignant cases, but here, too, we find a lamentable lack of determination and pluck on the part of some one—either the patient or the physician. Had an operation been undertaken earlier most of the deaths could probably have been avoided. There are in all 11 deaths, a mortality of over 11 per cent. Of these, I think we can, in all fairness, eliminate seven from the list of those in which death was hastened by the operation, leaving four cases in which the death was either hastened or caused by the surgical interference, a mortality of over 4 per cent.

Of these 4, 1 was a case of perimetritis, which died in nine hours; 1, a case of tubercular peritonitis, which died in ten days of acute peritonitis; 1, a case of hobnail liver, which died in forty-eight hours of shock; the last 1, a case of uterine fibroma, which succumbed in ten days to tetanus. The following are the 7 cases which I would eliminate:

1, Purulent peritonitis (dying); death in a few hours.

2, General peritonitis (very low); death in five days.

3, General peritonitis (almost in collapse); death in two days.

4, Suppurative peritonitis (very bad); death in four days.

5, Ruptured tubal pregnancy (in collapse); death in twenty-four hours

6, Turbid serum in peritoneum (almost moribund); death in four hours.

7, Solid tumor of liver; death in two days.

This last operation was performed as a last resort at the express desire of the friends.

The whole number of deaths hastened by operation, in both malignant and non-malignant disease, is 15, a death-rate of 9 per cent.

There are 16 cases of uterine fibromata with only 1 death, and this from a cause which is as likely to complicate any other surgical procedure as the one under consideration. Furthermore, the prevention of tetanus is, as far as we know, entirely beyond our control. An operation to remove the ovaries or the tumor itself in the case of a uterine fibroma, which results in being able to do nothing, is probably as typical a case of exploratory laparotomy, in its results, as we can cite in judging of the danger of exploration. Another class which is just as typical and which occurs frequently, is disease of the uterine appendages. There are ten cases of this disease without a death. In fact, it seems to make little difference in this class whether the disease is removed or simply explored; one can be done with almost as much impunity as the other.

The penetrating wounds, 3 in number, all made good recoveries.

8 pelvic or iliac tumors, which could not be differentiated, all got well, as did also 2 of the 3 cases of pregnancy. The third was a ruptured tubal pregnancy, and the patient was almost dead when operated on. The 2 cases which recovered both aborted. 22 per cent. of the diseases of the liver, gall-bladder, and their ducts succumbed to the operation. I can only explain this on the ground of late operation.

The cases of peritonitis are among the most interesting and instructive on the list. I find 2 of chronic, 6 of general acute, and 3 of suppurative peritonitis, a total of 11 cases, with 4 deaths. 2 of these deaths were from suppurative and 2 from general acute peritonitis. 36 per cent. is a very large mortality, but the great death-rate of this disease where no operative interference has been practised must be remembered as well as the fact that all 4 deaths were almost certain at the time of operation, and would undoubtedly have occurred in any event. It is only another warning against the dangers of an expectant treatment in abdominal troubles. If we wait, and operate, as has been the custom too often, only as a last resort, we can never expect to render our results better than they have been in the past.

Probably the most remarkable class here recorded

is that of tubercular peritonitis. In a paper read before this Society last year, a case of tubercular peritonitis was reported, where the abdomen had been opened and death had followed. In commenting on that case, the reporter, on that occasion, a prominent physician of this city, said: "Incision should be avoided in tubercular peritonitis, unless the inflammation is purulent. Not only so, but where the tubercular process is present, even paracentesis should be practised only in those cases in which dyspnœa, from over-distention of the serous sac with fluid, threatens life. The danger of operative interference in tubercular inflammation of serous sacs is that the inflammatory process nearly always becomes purulent." In the discussion which followed, operative interference was generally condemned for various reasons. These opinions I have found to be pretty general among medical men. The facts are a decided contradiction of this, however, and in view of our rapidly accumulating experience, this subject will have to be very carefully reconsidered. Kussmaul reported 30 collected cases of operations on this disease to a recent Congress of German Surgeons. During the discussion of his paper 6 additional cases were reported, making a total of 36. There were in all 6 deaths, 4 of which were from general tuberculosis, and 2 were attributable to the operation. Many of the cases were encysted, and most of the patients were operated on under the supposition that there was an ovarian tumor or other cystic trouble present. I am now able to add 17 cases to this list, with but 1 death, the cause of death being general peritonitis. Thus we have a total of 53 cases with a death-rate of somewhat over 5 per cent. The 17 cases I have collected resemble in many respects those reported in Germany. They were for the most part cases of misdiagnosis or pure explorations for diagnosis. The manner in which they were dealt with varied. In some the ascitic fluid was simply evacuated, and the abdominal wound closed. In others a drainage-tube was inserted. Again, some were irrigated with water, or with water medicated with bichloride of mercury, and in still others iodoform was dusted into the peritoneal cavity. But there does not seem to have been any better result from one line of treatment than from another. The simple opening of the serous sac, with the evacuation of the ascites, probably supplemented by drainage, appears to be as beneficial as any. It is interesting to note that the patients not only did not die from the operation, but most of them had more or less permanent relief. Of the 16 cases of recovery, 5 are reported as cured, 4 as much improved, 2 as improved, and 4 as having no return of the ascites. In but 1 case did the ascites reaccumulate, and still the patient was alive sixteen months after the operation. Some of the patients have now remained well sufficiently long for us to be able to speak of their recovery with certainty. The amount of time now passed since the operation has been in 1 case over three years, in 2 cases over two years, in 5 cases over one year, the others varying from three to six months. The condition of 13 of the patients at the time of operation was either "bad," "low," or "apparently dying." Four only were in good condition. The case of death is reported as being very low, and a point of probable interest is that it is the only male in the series. It would seem then that operative interference in tubercular peritonitis is not attended with the risks attributed to it; but, on the contrary, is in a great majority of cases positively beneficial. There is a decided growing opinion among surgeons as to the propriety of adopting operative measures for the relief of this disease. Only within the past few months this subject was discussed in England by Mr. Knaggs and his colleagues with the result of reporting a number of additional cases, and the whole discussion taking a turn favorable to a further trial of operation.

To recapitulate, we have here a total of 154 cases of exploratory laparotomy, with a death-rate of over 16 per cent. By eliminating such cases of death as were very evidently not due to the operation itself in any way, the mortality becomes somewhat over 9 per cent. If we throw out the malignant and consider only the non-malignant cases, we find a death-rate of over 4 per cent. I think it fair to ignore the malignant and judge only from the non-malignant cases, because the operation in cancer is almost always a late one.

Even the mortality of 4 per cent. which we give to the non-malignant patients, is deceptive. For instance, of the 4 deaths, 3 are reported as being "very low" at the time of operation, 1 case of perimetritis, 1 of tubercular peritonitis, and 1 of hobnail liver. So in reality, although the operation directly hastened death, it probably only did so on account of the bad condition the patients were in, and should, therefore, not be taken into account in judging of what would be the result in a case operated on early in the attack, and which was still in good condition. What surgeon would expect to lose a case of simple exploration, of a patient suffering from a hobnail liver, from shock, under ordinary circumstances? The fourth case died of tetanus. This case was one of uterine fibroma, and was in very poor general condition, having suffered from the disease for over ten years. It is the only one I am inclined to give much importance to, and the only one which, after careful consideration, seems to me to have been a legitimate death from operation. Looking at the subject from this point of view, the death-rate falls at once to between one and two per cent., and this is, I think, about what it should be. Here is where Tait left it some years ago. In

his first 1000 cases of abdominal section, he had 93 exploratory with 1 death, and even this death was in a broken-down woman of sixty years, who died really of prolonged sickness after the anæsthetic.

These tables, I must admit, at first sight do not show what I should wish them to. But by considering only the non-malignant cases and by a fair exclusion of such deaths as cannot in justice be attributed to the operation alone, the results are not very far from the truth. I do not personally think there is any considerable amount of danger attached to a simple exploration of the abdominal cavity. A general mortality of over 16 per cent. as here shown can only mean that most of the cases had been undertáken when the patients were in such a low condition that the slightest shock would turn the balance against them. This is only too well shown to be true by reference to the condition of the patients before operation, as reported in this list. There is altogether too much waiting and expecting. If there is sufficient abdominal trouble of an obscure nature, to endanger life, which will not yield in a reasonable time to the ordinary methods of treatment, do not wait until the patient is worn out and in a condition in which no one would attempt any other major operation, but make a careful and complete exploration of the peritoneal cavity. It will be an exceptional case in which any harm will be done, and many an obscure case will be cleared up and many a life saved.

This line of treatment is growing more and more into favor with surgeons, and when the physician joins hands with the surgeon on this common ground the profession will no longer have to reproach itself for such a death-list as Treves reports for England, viz., over two thousand deaths every year from intestinal obstruction alone.

Note.—I wish to express my indebtedness to the following gentlemen for cases, many of which are as yet unpublished: Drs. William Goodell, 14; John Homans, 17; G. J. Englemann, 4; Paul F. Mundé, 3; H. P. C. Wilson, 4; W. W. Keen, 2; Henry O. Marcy, 8; C. D. Palmer, 5; R. B. Maury, 2; T. G. Morton, 3; R. S. Sutton, 1; Joseph Eastman, 1; Joseph Price, 7; Howard A. Kelly, 9; James B. Hunter, 6; John A. Wyeth, 3; R. F. Morris, 1; W. O. Werder, 1; William C. Wile, 1; John Scott, 1; Paolo De Vecchi, 1; George W. Porter, 2; W. B. Bontecou, 2; F. W. Rockwell, 1; J. R. Weist, 2; E. J. Beal, 1; Clinton Cushing, 4; T. A. McGau, 1; J. M. Barton, 1; Ap. Morgan Vance, 1; Donald MacLean, 1; Henry Beates, 4; John B. Deaver, 2; E. E. Montgomery, 5; Mordecai Price, 5; Harris A. Slocum, 1; W. C. Goodell, 1. I have received many others, but have been unable to use them, as they have been in one way or another somewhat more than simple exploration, at least as I have classified the list.

328 South Seventeenth St.

ACUTE EXOPHTHALMIA.

By RICHARD H. DAY, M.D.,
of Baton Rouge, La.

Under this heading, it is my privilege to report a very interesting case of sickness which recently came under my observation and treatment.

The subject is a colored boy, born December 6, 1872. His parents are still living and enjoy good health. The father is eighty years of age, his mother much younger. The boy is of medium size for his age, well built, and since infancy has enjoyed fairly good health. No constitutional taint that I can detect; yet his home surroundings, especially as to sleeping apartments, are very unfavorable and well calculated to engender systemic impairment and deterioration of the vital fluid.

I was requested to visit this boy, Abe W., on the morning of the 27th of January, 1888. The day before he had been out all day hunting in a cold, drizzly rain. When he returned home about dusk he was in his usual health, but fatigued from the day's hunt, and after eating his supper went to bed. Sometime during the night he became restless and complained of intense pain in his head. When daylight appeared his parents discovered that his left eye was very much swollen, and concluded that he had injured it the day before while hunting; but he insisted that he had not, and I am quite sure that he was correct, for there was an entire absence of any appearance or symptoms of traumatism. I found him with a moderate grade of fever, temperature 103° F. The bloodvessels about the temples were distended and hard. He complained of great pain through the temples and post orbital region of the left eye. The eye was pushed forward from its socket and protruded fully one-half to three-fourths of an inch beyond its normal site, presenting a strange spectacle, indeed, looking as though it would drop out at any moment. The lower lid was stretched as a tight cord across the lower segment of the sclerotica, while the upper lid was pushed forward and did not reach the upper corneal edge. The pupil was dilated, sight slightly impaired, but I could discover no cloudiness nor abnormal condition of the aqueous or vitreous bodies; though the globe seemed to be much distended and more conical than its fellow. I had no ophthalmoscope with which to examine the chambers and the posterior tissues of the eye, and hence am unprepared to say what abnormalities, if any, existed there, except as revealed by the symptoms and the subsequent history of the case.

Dunglison defines exophthalmia, "A protrusion of the eye from its orbit, occasioned by an abscess or tumor in the cellular texture of the orbit."

The suddenness of the attack and the rapidity with which the globe was thrust forward from its socket in this case, excluded the growth of a tumor, or phlegmon, or exostosis. I diagnosed the lesion to be excessive vascular congestion of the numerous and tortuous bloodvessels in the posterior orbit; and perhaps infiltration of serum or blood, from

rupture of some of the venous capillaries, in the connective tissue and Tenon's capsule behind the soft elastic fatty pad on which the globe rests, thus pushing the whole eyeball forward.

I visited my patient daily for six or eight days, watching his case very closely and with great interest, for the case was a novel one to me, and the first of the kind I had ever seen.

I kept him on small doses of calomel and ipecac for forty-eight hours and purged him with senna and epsom salts. Locally I instilled into his eye at intervals four or five drops of the following solution:

℞.—Sulph. zinc. . . . . gr. j.
Sulph. atropia,
Sulph. morphia . . . āā gr. ij.
Aquæ destil. . . . . ℥ j.—M.

And a soft muslin bag containing infused tea leaves was laid over the eye. On the third day, his bowels having been well evacuated, I left off the calomel and gave him quinine in five grain doses every four hours, and applied behind his left ear a small blistering plaster, which drew a good blister. I could now begin to discern some recession of the protruded organ, but even up to the end of the eighth day it was still prominent above the bridge of the nose and the supraorbital brow. The local treatment was continued, and a tonic pill composed of quinine, pulvis ferri, āā grs. ij, pulv. digitalis j, was given three times a day.

When the eye had sufficiently receded to lessen the tension of the lower lid, so that I could depress or draw it down, I discovered an ecchymosed condition of the sclerotic, or what in common parlance is called a *bloodshot* appearance, which would seem to strengthen the theory of the extravasation of blood in the deep tissues in the bottom of the orbit, as the true pathological lesion.

I saw and examined this boy again on the 1st of March. The eye had quite receded to its normal position, and his sight, so far as I could judge, was not impaired, and he could distinguish the different colors. The globe had lost its distended and conical appearance, and I thought was somewhat flatter in its general aspect than the other eye.

I have looked in vain over my standard authors for light upon this unique case. They all treat of exophthalmic goitre, several cases of which I have seen in the course of my professional life; but these differ from my case in every characteristic, except only in the protrusion of the eyeball.

My patient had no affection whatever of the thyroid gland, no heart failure, and was not anæmic or chlorotic. The case was not chronic in origin, but was sudden and acute; was not protracted in character, but sharp and violent, and quickly yielded to medical treatment.

It occurs to me that within the last six or eight years I have read in medical periodicals, reports of cases somewhat similar in character to the one I now report, having occurred somewhere in the West, but I find it impossible to recall to mind the history of the cases or the journals in which they were published.

If any medical gentleman reading this report can supply the information, I shall be very thankful; or if similar cases have been witnessed by others and not yet made public, I hope they will be written up and published for my own enlightenment and the benefit of the medical profession.

A CASE OF SYMMETRICAL GANGRENE.

By M. A. BEADER, M.D.,
of Lyons, N. H.

The following case presents several interesting features and appears worthy of record:

The patient, a vigorous man, about forty years of age, appears in perfect health. His complexion is fresh and ruddy and his muscles extremely well developed. All the functions are normal, save only that he has a peculiar weakness causing a slight halting in his gait. He drags one foot slightly, as though unable to control its movements perfectly. He states that this defect became apparent about six years ago. It began soon after he had experienced "a stroke" or fainting fit, which he had attributed to drinking largely of cold water whilst overheated. He recovered soon and perfectly from this attack with the exception of this imperfection in his gait, which seems to be of a paralytic nature.

About eight months ago dark spots, resembling bruises but more clearly circumscribed, appeared just below the knee on both legs. They were painless but gradually became of a deeper color, the skin over them being smooth and glossy. They were not attended by heat or swelling, but in the early stages were indistinguishable from well-defined patches of purpura. At a later period ulceration began, the skin breaking down and leaving dark, purplish excavations. This process extended in an irregular way, whilst healing progressed imperfectly in the centre of the diseased area. The new skin over the parts that were healing was almost black and was very smooth and glossy. There was no hemorrhage at any time, no secretion of pus, and scarcely any odor. A slight watery exudation forming a glazing over the diseased surface was the only discharge apparent.

The ulcerations were of a gangrenous type without any active granulation process or formation of the red line, the entire course of the disease being extremely indolent. The margins of the ulcers were not elevated or hardened and did not present a punched-out appearance. Their color resembled very closely that of a sloughing bedsore. There were no varicose veins in the vicinity. No history of syphilis could be traced. Thoroughly well nourished, with sound teeth and healthy gums, the patient did not present any of the marks of scurvy. He had not taken ergot or mercurials, so far as could be learned. In fact, he had been in good health in every way with the exception of the imperfection of gait above mentioned.

Upon the first appearance of the spots he imagined

that they might be bruises caused by placing his knee against the stick while sawing wood. But when the disease appeared on both knees and persisted and increased month after month in spite of the greatest care, it became evident that it was not the result of injury. The lesions were symmetrically located about three inches below the patella on each leg. The diseased patches extended almost completely across the anterior portion of the leg, but the ulcerations were deepest just below the condyles of the tibia well around toward the sides of each leg. The right limb was considerably more affected than the left, the largest diseased portion being on that side and located on the external aspect of the tibia, a space between three and four inches in diameter being involved.

The symmetrical distribution on both limbs, as well as the superficial character of the ulceration and the way in which it spread on each limb, indicated that it could not have been the result of embolism or thrombosis. It is noteworthy that the lesions were in close relation with like portions of the same nerves in each limb. The patient had been under the care of a physician recently deceased, and could not give any trustworthy account of the treatment that had been employed, except to say very positively that it had been entirely ineffectual.

When I first saw him he had been using an ointment of some kind which apparently had been somewhat irritating. I directed a simple protective dressing of carbolated vaseline to be used after the ulcers had been very lightly cauterized with strong carbolic acid. Occasionally they were to be dusted also with iodoform. Under this treatment healing progressed slowly but better, according to the statement of the patient, than it had under the more irritating treatment that had evidently been employed previously.

At the outset, in this case, it is evident that there was a failure of the capillary circulation over the small spots first affected. There was no extravasation of blood, the spots remaining well defined, and the skin in their vicinity not undergoing any changes of color as it does when bruised. At this stage the lesions were simply purpuric. Subsequently the nutrition of the parts having failed, ulceration resulted and became extremely indolent. There was some attempt at repair in the central portions of the diseased areas, but it was very imperfect. The symmetrical distribution of the lesions on both limbs points to a central origin. The fact also that the patient had a paralytic disorder may be significant in this connection.

It would seem, in this case, that the vasomotor nerves controlling the circulation and nutrition of the parts affected were primarily at fault. The succession of events indicates the existence of a disorder of the same type as Raynaud's disease or symmetrical gangrene. I have not been able, however, to find any description of a case in which the lesions were situated in the particular locality which they occupy in the case under consideration.

MEDICAL PROGRESS.

The Ligature and Dressing of the Umbilical Cord.—JACOBI, in the *Archives of Pediatrics* for April, 1888, describes his method of treatment as follows: If the ligature be thin, it is liable to cut through the walls of the blood-vessels prematurely; if too thick, it may not suffice to compress them satisfactorily. It ought to be applied at a distance of from one and a half to two and a half inches from the abdominal wall. Not nearer, in order to avoid the effect of the immense muscular power of the umbilical arteries inside the abdominal cavity. A second ligature is placed about an inch from the first, and the cord cut between them. It is a good rule, which must surely be adhered to in every case of thick cord, to apply an additional ligature between the first and the abdominal wall, to avoid hemorrhage from the insufficiently compressed arteries, which may take place after the cord has commenced to shrink. The abdominal end of the cord is then wrapped up in a dry and soft piece of linen, lint, or cotton, placed on the left side of the abdomen, and fastened, by means of a soft flannel bandage, which is wide enough to cover the larger part of the chest and all of the abdomen, so as not to slip.

In wrapping up the end of the cord no oil must be used. Warmth and dryness favor mummification; moisture and exclusion of air, gangrene. This holds good also for the cord when it is separated from the living baby by an additional ligature, and in the dead. Thus, the former forensic axiom, that a dry cord proved life, which prevailed for decades after Meckel had demonstrated its fallacy as early as 1853, is absolutely worthless. Thus, fatty substances, and moisture of any kind, must be avoided as much as possible. Powdered subnitrate of bismuth, or oxide of zinc, or iodoform, or salicylic acid, one part with ten parts of starch, may be dusted round the insertion of the cord and over the stump daily. The latter application is not necessarily useless (from the point of view of antisepsis), for the separation of the cord is a gradual one, and not uniform through the whole thickness of the amnion and the three bloodvessels.

Creasote, Deeply Injected, in Phthisis.—DR. ROSENBUSCH gives an account in a Polish medical journal (*Przeglad Lekarsi* of February 4 and 11, 1888) of the cases of nine phthisical patients whom he treated by injecting creasote into the tissue of the lung. The results he obtained were excellent. The injections, which were given at intervals of two or three days, caused the cough almost to disappear and the quantity of sputum to diminish. In those cases which were not very far advanced the patients gained flesh, the dyspnœa and sweats ceased, the body weight increased, and frequently spots which had been dull on percussion cleared up. The temperature decreased from five to eight hours after the injections, the fall continuing at first for ten to twelve hours, a permanently normal temperature being subsequently registered. The injections were made into the affected portion of the lung, which was usually, of course, the apex. The in-

strument employed was an ordinary Pravaz syringe, with a needle from two to three inches in length. About eight minims (half a syringeful) of a three per cent. solution of creasote in almond oil were injected in each of two spots, the piston of the syringe being pressed down slowly. The patient was told not to breathe deeply, and after the injection to lie quite still for a few minutes. When the needle was not inserted deeply enough, some lancinating pain was apt to be produced by the irritation of the pleura. This, however, did not last long. No hemorrhage was ever observed after the injection, though in the case of one patient, who was subject to hæmoptysis, a slight coloring of the sputum was observed for a short time. If the injections were made into a cavity, or into one of the large bronchi, the patients said they could smell creasote when they coughed, and this substance could be detected in the sputum by chemical means. Of course, great care was taken to perform the operation under aseptic conditions, the skin, the needle, and the syringe being previously carefully washed with an antiseptic. The creasote used was the *creasotum e bitumine fagi*, or beech creasote. The writer promises a subsequent communication on the effect of these injections on the number of Koch's bacilli.—*Lancet*, March 31, 1888.

Putrid Bronchitis Successfully Treated by Inhalations of Corrosive Sublimate.—Korányi, of Buda Pesth, is quoted by Betz's *Memorabilien*, Band 32, Heft 7, as having treated successfully a case of putrid bronchitis, complicated by pleurisy and mitral disease, with inhalations of corrosive sublimate, as follows:

Hydrarg. bichlor. corros. . . .	½ gr.
Aquæ destill.	3⅛ ℥.

Of this solution, five drachms were inhaled morning and night.

Six days of this treatment resulted in a diminution of fever, and in a great improvement in the character of the sputa and the general condition of the patient.

The Antiseptic Treatment of Smallpox.—Cavaillon is quoted by the *Gazette de Montpellier* of March 3, 1888, in his account of the following method of treating smallpox by local antiseptics:

He opens the pustules as soon as they are full of purulent matter, and presses out their contents upon cotton. The pustules are then touched with cotton dipped in the following mixture:

Benzine.	15 ♏.
Water	10 ℥.
Pure alcohol	30 ♏.

This application is renewed until the crusts appear. When no more pus is found beneath the crusts an oily dressing is applied. If pus does not form freely the pustules are sprayed with the solution of benzine. After the twelfth day the following ointment is used:

Naphthol	75 grs.
Vaseline (with benzoin or oil of bergamot)	25 ℥.

Idiosyncrasy to Antipyrin. — Taylor reports, in the *British Medical Journal* of March, 31, 1888, the following case: I administered to a lady on two different occasions eight grains of antipyrin for attacks of migraine, and on each occasion, very shortly after taking it, a tight feeling of constriction was felt across the chest, with a burning sensation in the pharynx. These symptoms were immediately followed by sneezing, by intense suffusion of the eyes, and by quantities of mucus flowing from the nose, giving her all the appearances of having a severe attack of coryza; there was also great irritation in the larynx, causing severe fits of coughing, but unattended with expectoration. After a quarter of an hour these uncomfortable symptoms gradually subsided. There was no urticaria. I followed it up on each occasion with an equivalent dose of antifebrin (three grains) which (with one repetition in the course of an hour on the first occasion, but which was not required on the second) completely relieved the severe hemicrania, as it has done on subsequent trials without using antipyrin at all. It appears, therefore, that antifebrin may be used equally with antipyrin in migraine as in febrile conditions, and may replace it with advantage where the latter disagrees.

An Accident from Antipyrin in the Treatment of Rheumatism.—Giguel, in the *Gazette Hebdomadaire* of March 23, 1888, reports the case of a woman of nervous temperament, the subject of herpes and suffering from rheumatism in the right shoulder. He prescribed forty-five grains of antipyrin, to be taken in three doses, during twenty-four hours. Ten minutes after the first dose was taken the patient experienced sensations of great irritation about the upper and lower jaws, sneezing followed, and persisted for a quarter of an hour. A sensation of pricking was felt at the thyroid cartilage, and the voice became hoarse and rough; the temples throbbed, and the nares were occluded by mucus. The painful shoulder, however, was free from pain, and could be moved freely. Five hours after the drug was taken only a slight roughness of the voice remained. A second dose of four grains was followed by the same effect, at the same time, in less degree. During the effect of the drug the side of the head and neck were intensely congested.

"Imitative Tetanus." — Dr. Vicente G. Gáunchez, writing in the *Revista Científica de la Universidad Central de Venezuela*, records a case of "neurosis tetanica," or "imitative tetanus," which occurred in a native of Caracas, a young man who had always enjoyed good health. The patient began to complain of pain in the calves of his legs which caused him considerable difficulty in walking. There was no fever, but the pain increased, and some contraction of the flexor muscles of the leg occurred, rendering the man incapable of walking. Indeed, on the second day of the attack he could not turn in bed without a good deal of pain. He was unable to sleep, and suffered from mental anxiety. It was then elicited that his brother, who lived at a little distance, was suffering from tetanus, and that the patient, who went frequently to see him, had appeared to be greatly affected at the sight of his brother's spasmodic attacks, and had declared that he himself would die of the same malady.

Dr. Guánchez, however, attributed the pains to rheumatism, which was common enough at the season when this occurred. He treated the man with anodyne lini-

ments and jaborandi internally. No effect was produced, as intense rigidity of the legs, simulating ankylosis, came on, the patient obtaining no sleep whatever and the pain being still very severe. A purgative was prescribed, but the trunk muscles became affected and clonic spasms began to show themselves. Bromide, chloral, narcein, and codeia were prescribed, but none of these arrested the rapid progress of the affection. The convulsions increased, opisthotonos and lastly trismus occurred, and the man died on the sixth day. In this case the mode of invasion was different from that usual in true tetanus, which commences by affecting the muscles of the face and chest; again, there were no remissions, as in ordinary tetanus, but the disease progressed steadily and more rapidly than is usual in tetanus. As to treatment, Dr. Guánchez, who has had some experience of ordinary tetanus, has found mercury and opium sometimes successful, and in one notable case the cure appeared to be due to the constant and careful administration of curare. —*Lancet*, March 31, 1888.

The Treatment of Retained Placenta and Membranes, in Breisky's Clinic.—Bloch reports the treatment followed in Breisky's wards as follows:

1. Disinfection of the genitals.
2. Slow dilatation, with careful disinfection of the tents or instruments employed.
3. Disinfecting the interior of the womb, and intra-uterine examination by the finger.
4. Removal of retained membranes or placenta with polypus forceps, and intra-uterine disinfection.—*Centralblatt für die gesammte Therapie*, April, 1888.

Oertel on Diphtheria.—The *Lancet* summarizes Professor Oertel's conclusions regarding diphtheria, recently published, as follows:

In a few pages Professor Oertel alludes to the clinical and therapeutical bearings of these considerations. In the first place, the false membrane must no longer be regarded as the first pathological and pathognomonic sign of diphtheritic infection, and it is not surprising that energetic measures toward its removal are followed by fresh formation, since the morbid process is going on in the mucous membrane. Still, local treatment should aim at thorough disinfection of the buccal and pharyngeal cavities, which will at least prevent secondary infection of the stomach and intestines, and this is best effected by the frequent use of disinfectant spray. How far the disease is spreading may be judged by the degree of lymphatic gland swelling; and the degree of fever may bear upon the extent of general infection. When we know more of the influence of drugs upon ptomaines, in preventing their formation or hastening their conversion into innocuous material, we shall be better able to prescribe general remedies—such as quinine, mercury, or arsenic—with confidence; but meanwhile the chief hope lies in prophylaxis and the maintenance of the body in a state of nutrition, so that its cell elements may be able to resist successfully, and annul, the virus against which they have to contend. That this is possible is evident from what we know respecting other poisons and individual capacities of resistance.

In conclusion, Professor Oertel points out that the whole subject, from the first migration of leucocytes into the infected epithelium to the formation of necrobiotic foci in the spleen, proves the important part played by cells in the disease. It shows, he considers, that we must still go back to the cell theory if we would explain morbid action, and he puts forward his work as a contribution to Virchow's doctrine of cellular pathology, which is by no means so effete as some declare.

Formulæ for the Use of Digitalis.—Huchard, in the *Revue Gén. de Clin. et de Thér.* of March 22, 1888, gives the following formulæ:

Digitalis with bromides:

Tinct. digital.	♏ 30.
Potass. bromid.	℥ 5.
Aquæ destill.	℥ 9½.

Dose, one to three tablespoonfuls daily.

Digitalis and trinitrine

Tr. digital.	♏ 45.
Alcoholic solution of trinitrine, 1 to 100	gtt. 30.
Aquæ destill.	℥ 9½.

Dose, from two to six teaspoonfuls daily.

Digitalis and iodide of sodium:

Sodii iodid.	℥ 1.
Digital. pulv.	gr. 30.
Glycerin.	q. s.—M.

Ft. pil. 40 in num.

Sig.—Three or four pills daily, for five or six days.

The Effect of Cooking upon Starch.—In a graduation dissertation for the degree of M.D. in the Military Medical Academy of St. Petersburg, Dr. N. Butiagin gives an account of some experiments he has been carrying out with the view of determining the effect of cooking on the digestibility of starchy foods. He found that the activity of the saliva does not differ much amongst healthy persons, but that when people are badly nourished and weak, and especially when in addition to this they are suffering from disease of any kind, their saliva has a very perceptibly diminished power of dissolving starch. When starchy substances are subjected to prolonged cooking they become more easily digestible, and in this way compensation can be provided for the inactivity of the saliva of weakly persons. Thus, rice and peas were found to require three hours' cooking in order to render them as easily digested in the saliva of a badly nourished, nervous, hysterical woman (which had previously been found to possess only 88 per cent. of the normal activity), as they were with a single hour's cooking by the saliva of healthy persons; and generally it was found that in the case of weakly or diseased persons starchy food must be cooked twice or thrice as long as in the case of healthy persons in order that it might be equally acted upon. Again, when starch has been cooked for a long time there is less difference between the effect of healthy and unhealthy saliva upon it; this is specially remarkable in the case of millet—which, after one hour's cooking, showed a difference of 12.89 per cent. in favor of the saliva of healthy as against that of diseased persons, but after three hours' cooking a difference of 5.77 per cent. only.—*Lancet*, March 31, 1888.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, APRIL 28, 1888.

YELLOW FEVER INOCULATONS.

Many recent bacteriological investigations have illustrated how sadly truth may suffer at the hands of incompetent, yet earnest, observers. Enthusiasm without judgment and observation without scientific training have been, and doubtless will continue to be reponsible for many errors, and it is unfortunate that a great part of the labor in any research is in separating the wheat from the chaff and determining just how much of the work done has been reliable.

The assertions and claims of Domingos Freire, of Rio Janeiro, that he had discovered not only the germ of, but a vaccine against, yellow fever, have naturally attracted special attention in this country, and we have, on several occasions within the past few years, noted the course of his investigations. The publication of his work on the disease enabled experts to determine how unsatisfactory were the methods which he followed, and the germ, *cryptococcus xanthogenicus*, which he described could not be classified with any known forms. More important by far, however, were his claims that he had found an efficient vaccine which had been tested in hundreds of cases. The interests involved were important enough to justify the President in sending Dr. Sternberg to investigate these methods, and we give in this issue the preliminary results of his studies as presented in a paper read before the College of Physicians of Philadelphia.

From the limited time allotted, Dr. Sternberg could not, unfortunately, secure any autopsies, and the chief value of his present investigation lies in the careful criticism and analyses of Freire's work. So far as we know, this has not before been attempted by any acknowledged expert. That Freire's claims have not stood the test will not surprise those acquainted with modern methods, and the extracts given in Dr. Sternberg's lecture suffice to show that his work lacks scientific precision, and is totally untrustworthy. It was quite possible that, missing the germ, he might still have discovered a protective virus, and the figures of successful vaccinations published within the past few years have given color to the belief that there was some truth in his statements. The figures presented, however, by Dr. Sternberg justify his conclusion that there is no satisfactory evidence that the method of inoculation has any prophylactic value. We have not the slightest doubt that in this opinion the leading bacteriologists of the world will concur.

Dr. Sternberg has been ordered to proceed to Havana for the further study of the disease, and we sincerely trust that with the elaborate and accurate methods now at command he may reach positive conclusions regarding this most formidable of tropical plagues.

BACTERIA IN THE URINE.

Though the influence of bacteriology in furthering the study of hygiene and pathology is manifest to all, it is evident that the hopes of clinical medicine have not been fulfilled to the extent anticipated by many in the earlier days of that science. Thus, so far as practical medicine is concerned, examination of the sputum for tubercle bacilli is about all that has been definitely gained.

It is slowly being learned that those hopes were based on false conceptions of the true nature and mode of action of the various morbific agents. A study of the results of the bacteriology of the urine is exceedingly instructive, for it not only shows us the possibilities and limitations of such investigations, but also renders more comprehensible some fundamental truths about infectious diseases.

Numerous experimental and clinical studies have been made in this field during the last few years, and in a valuable series of articles in the *Berliner klin. Wochenschrift*, Nos. 7, 8, and 9, 1888, Dr. H. Neumann, of Berlin, has published a critical analysis of the most important contributions of other writers, besides adding some observations of his own.

The valuable information furnished by the routine

examination of urine, led to the belief that with the aid of simpler means, such as we now possess, much practical information might be obtained as to the nature and course of infectious diseases by a bacterioscopic examination of the urine. This partial truth was based on a widely spread error. It was part of the belief that the atmosphere is "pregnant," as has been said by some, with germs; that these were constantly being swallowed or inhaled, taken into the circulation, and, like the urine salts, "sieved out" of the economy by the kidneys. As a deduction from this bizarre and unfounded idea, it was supposed that in microbic diseases the blood "swarmed" with the specific germs, and, arrived in the renal circulation, they were in turn "sieved out."

Among the first to show the erroneousness of these views was Leube, who found that the urine in health contained no bacteria. More recent observations by Lustgarten and Mannaberg, confirmed by Neumann, show that though this is true of urine in the bladder, the urethra always harbors germs which contaminate it more or less in passing. These bacteria, however, are few in number, and, with one exception, non-pathogenic. The exception is the staphylococcus aureus, and in investigations it can be excluded by the use of sterilized catheters.

Knowing that the urine in health is germ-free, it remains to be seen what changes, if any, occur during infectious disease. At the risk of causing some confusion, it is well to digress here, and consider first the modes of distribution of bacteria in the organism, premising that much of the information on that topic has been gained through studies of the urine.

We already know that in infectious diseases we have to distinguish between local and general infections. Thus in many diseases the germs not only penetrate by the most direct route to the organs concerned, but remain and vegetate there. So in Asiatic cholera, the spirilla remain in the intestine, and no matter how severe the infection, search for the germs in the circulation must be in vain.

Bacterial invasions of the general organism occur in various ways, but for the present purpose may be divided into three groups. In the first the bacteria cause a local infection, and then gain access in a more or less direct manner to the circulation. This has been proven in some cases in suppuration, pneumonia, tuberculosis, and erysipelas. In the second group a lesion is caused in the skin or mucous membrane, and through it an organism which was not the original cause of disease arrives in the circulation. This is a frequent accident in diphtheria, variola, and scarlatina, and in such cases the newcomer is usually a strepto- or staphylo-coccus. In the third group the bacteria course from the beginning in the circulation, or gain access to it at certain periods of the disease. This occurs in recurrent fever, endocarditis, sepsis, glanders, and typhoid fever.

A separate class under this group might include such rare cases as those in which an organism which usually causes only a local infection occurs in the circulation; such cases as those in which the diplococcus pneumoniæ of Fränkel caused meningitis or endocarditis. In such cases it would be fallacious, probably, to infer from an examination of the urine that a latent pneumonia was in progress.

Finally, all kinds of combinations and sequences of these groups may occur in the individual, so that at the same time typhoid bacilli and erysipelas cocci, for example, may be circulating together.

We are now in a position to examine the condition of the urine in cases of blood infection, and first to ascertain if the healthy kidney permits a passage to the bacteria. Notwithstanding many affirmative answers, both clinical and experimental evidence seem rather to deny such an occurrence. Thus, Kannenberg could find spirilla recurrens in urine only after hæmaturia had set in, and numerous culture experiments with the urine of typhoid patients have been negative, though if present the recovery would have been attended with no great difficulty.

A valuable fact that has been learned in this connection is that not all lesions of the kidney occurring in the course of infectious disease are bacterial. According to Neumann's results, severe albuminuria may occur in typhoid fever without bacilli appearing in the urine, and in cases of suppuration even acute nephritis developed with urine examinations negative. These lesions can be explained on the supposition that the excretion of ptomaines causes the nephritis, as Koch has shown possible in the case of the "cholera-kidney."

In order that bacteria be excreted from the kidneys it is necessary that they have accumulated in those organs in large numbers, as happens in glanders, typhoid fever, and pyæmic diseases. Embolism of small vessels or capillaries takes place and then changes occur in the surrounding tissue, varying with the nature of the infectious agent. These

changes are but little understood, though it is clear that multiple emboli, even when accompanied by necrosis and inflammatory foci, do not necessarily lead to inflammation of the whole organ and its corresponding phenomena. Thus, in osteomyelitis with bacteria and round-cells in the urine, albumin and casts were absent almost constantly. In typhoid fever, too, along with bacilli there is sometimes only temporary albuminuria, at others, casts and albumin in large amounts are present.

Existence of bacteriuria may in some cases be recognized without a microscopic examination. Thus, in typhoid fever and some other diseases the bacteria appear to increase in the bladder, the urine when passed appears cloudy and remains so after repeated filtration, and is usually less acid than normal.

The diagnostic importance of bacterioscopic examinations of the urine, aside from cases of primary bacterial nephritis, which we have purposely not considered, depends on the recognition of the time at which bacteriuria appears. On this point but little is known. The ability to show the existence of a "mixed infection" may assume greater clinical importance than it now has.

In typhoid fever, although these examinations have shown nothing positively new, they have confirmed some earlier ideas. Seitz and Neumann found typhoid bacilli in the urine in cases where the eruption was most intense, and they infer, with much ground, a relation between the number of foci of disease and eruption. As far as the diagnosis of typhoid is concerned we are not very sanguine, since there are few doubtful cases in which culture experiments could give the desired information before either the clinical course or autopsy decided the question. As the bacilli remain present in the urine for some time, the diagnosis of a case coming under observation at a late stage might be made from such an investigation.

For prognosis, the ability to discover a renal complication, or a secondary infection, may become very important.

An important practical conclusion may be drawn from the knowledge of the infectiousness of urine in many cases of typhoid fever, and that the source of danger may remain for many months.

Slight as are the clinical gains so far acquired in the lines thus indicated, it must be remembered that the whole subject is a new one, that we are just coming into possession of practical methods, and, bearing in mind the limitations we have made, there is reason to look for greater progress in the future.

On Tuesday evening, the Alumni and students of the Medical Department of the University of Pennsylvania gave a reception to Dr. D. Hayes Agnew, in commemoration of the fiftieth anniversary of his doctorate. Addresses were made by Provost Pepper, Dr. S. W. Gross, Mr. Lincoln (on behalf of the undergraduates), and Dr. Agnew. Subsequently a handsome collation was served. There was quite a large gathering, including a number of the Alumni from a distance. The Provost announced that the University authorities had determined to confer its highest academic honor upon Dr. Agnew at the ensuing commencement.

We are informed that the place of meeting of the American Gynecological Society has been changed to Washington, so as to conform to the meeting of the Congress of American Physicians and Surgeons in that city, on September 18th, 19th, and 20th.

We are in receipt of a circular from Mr. George S. Davis, publisher of the *Index Medicus*, stating that this periodical is not self-supporting and needs a larger measure of aid from the profession than it has yet attained to place it upon a permanent basis. This journal occupies a unique position as a means of research, and the best interests of the profession demand that it be sustained.

The appreciation of its value has extended to Europe, and recent foreign periodicals note with regret that it is in need of aid, and are united in expressions of its great value. We sincerely hope that the American profession will not incur the reproach of neglecting this most important instrument in the promotion of medical research, and we would especially urge every medical society in the country to subscribe for at least a single copy.

We are informed that a national association under the title of "The American Association of Obstetricians and Gynecologists," was formed at Buffalo, on April 19th. It is to be composed of obstetricians and gynecologists, and those surgeons who are interested in the abdominal surgery connected with those specialties. The list of foundation members numbers thirty-four, and includes men from all parts of the country. The initiative meeting was held at the Niagara House, seventeen members being present. The business consisted of the adoption of a Consti-

tution and By-Laws, the election of officers, and the appointment of the place of the annual meeting.

The officers elected were as follows:

President.—W. H. Taylor, M.D., of Cincinnati.

Vice-Presidents.—Drs. E. E. Montgomery, of Philadelphia, and J. H. Carstens, of Detroit.

Secretary.—W. W. Potter, M.D., of Buffalo.

Treasurer.—X. O. Werder, M.D., of Pittsburg.

Executive Council.—Drs. Thomas Opie, of Baltimore; J. H. Etheridge, of Chicago; C. Cushing, of San Francisco; Melancthon Storrs, of Hartford; and Byron Stanton, of Cincinnati.

Delegate to the Congress of Physicians and Surgeons.—James P. Boyd, M.D., of Albany.

Alternate.—Hampton E. Hill, M.D., of Saco, Me.

Place of meeting, Washington, D. C., September 18 to 20, 1888, during the session of the Congress.

During the day the new Association became the guest of the Buffalo Obstetrical Society at a luncheon. The meeting is said to have been a most successful one, and it is the opinion of its founders that the Association is strong, and destined to be a working body, and take high rank among the societies of America.

The Seventh International Congress of Chemistry and Pharmacy will meet at Milan in September, 1888.

Surgeon-General Moore, of the Army, and Surgeon-General Browne, of the Navy, were entertained at dinner at the University Club last Saturday evening by the Practitioners' Society of New York City.

The Society of Apothecaries of London have determined to permit female students of medicine to come up for examination. A movement is on foot to organize a "Ladies' University."

Dr. Edward C. W. O'Brien, of Buffalo, has been nominated by the Governor of the State of New York for the office of Health Officer of the Port of New York.

The country practitioner of Great Britain is threatened with a horse-tax of five dollars for each animal he uses. As he is already the subject of a levy upon his carriages, in about an equal sum, this threatened imposition is highly unpopular with a profession which believes itself to be already overburdened.

Smallpox was exported from New York City to the Clyde, on the "Circassia," arriving out March 22d. There were five cases, all among the crew. The sick were removed to Greenock Hospital; vaccination and fumigation were thoroughly performed. The steamer was then allowed to proceed to Glasgow. No subsequent cases have been heard from.

SOCIETY PROCEEDINGS.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, April 16, 1888.

The President, J. R. MacGregor, M.D., in the Chair.

Dr. Joseph E. Janvrin read a paper on

THE PRIMARY REMOVAL BY ABDOMINAL SECTION OF THE TUBE AND ITS CONTAINED FŒTUS IN CASES IN WHICH PREGNANCY HAS BEEN DIAGNOSED, BEFORE RUPTURE OF ANY PORTION OF THE TUBE HAS OCCURRED.

The operation referred to, he said, was one performed with the expectation of delivering the tube and its contained fœtus intact, and done before the end of the fourth month of gestation. In a paper read by him before the American Gynecological Society, in 1886, he had advocated early laparotomy, as a rule, in cases of tubal pregnancy in which hemorrhage had occurred (instead of resorting to the use of electricity), thus removing all possible danger of further hemorrhage. In December of that year he reported, at a meeting of the New York Obstetrical Society, a case in which he had diagnosed tubal pregnancy at the fifth week, and in which death had occurred at the end of the seventh week from a second hemorrhage from a ruptured artery on the peritoneal surface of the sac; the first hemorrhage, which was extremely small, having occurred from this same artery some days previously, and galvanism having in the meantime been employed to destroy the fœtus.

At that time, he said, he was convinced from this case, and from three other similar cases, that the time to operate was when preliminary or partial rupture occurred, as indicated by the first hemorrhage; the primary collapse symptoms constituting an almost certain indication both of the pathological condition and of the need of immediate interference. In speaking of the symptoms of tubal pregnancy, he had stated that he believed it was easier to recognize this condition than a case of hydrosalpinx, and that the presence of an irregular decidual discharge in a woman who had missed a period, associated with the normal signs of pregnancy, and an enlarging, fluctuating, and exquisitely sensitive mass on one side of the uterus, and followed subsequently by symptoms of shock, could hardly be referred to any other condition even as early as the fifth week. In a case of this kind he had also said that he would certainly perform laparotomy whenever the first symptoms of internal hemorrhage occurred.

Again, in a discussion at the January meeting of the Obstetrical Section of the New York Academy of Medicine, in 1887, he had stated that in any case in which from the rational and physical symptoms he became convinced that tubal pregnancy was present, even

before symptoms of a rupture of the peritoneal covering of the tube occurred, he would most earnestly urge laparotomy, and perform it if he could obtain the consent of the patient.

Dr. Janvrin then went on to say that up to the present time he had been able to find but one case on record in which the operation was performed prior to a laceration, or partial laceration, of the tube, and before the fourth month of gestation. This was one reported by Dr. Joseph Price, of Philadelphia, in the *Annals of Gynecology* (Boston), for March, 1888, and in a recent letter to Dr. Janvrin, Dr. Price had said concerning it: "The history was simply that of delayed bleeding two weeks, and constant pain and nausea. I operated for extra-uterine pregnancy or pus tube." He next referred to cases of laparotomy performed in tubal pregnancy, after one or more decided hemorrhages, reported by Lawson Tait, Martin, of Berlin, and others in Europe; and by Drs. A. W. Johnstone, of Danville, Ky.; Joseph Price, of Philadelphia; S. C. Gordon, of Portland, Maine; Wm. Gardner, of Montreal; G. M. Tuttle, of New York; and Charles B. Penrose, of Philadelphia.

All such operations, performed after there had been a rupture of some part of the tube, he thought should be classed as *secondary* operations. So far as he knew, the credit of first advocating the propriety of performing abdominal section and removing the ruptured tube with the fœtus and blood-clots, was due to an American surgeon, the late Dr. Stephen Rogers, of New York, who, as long ago as 1867, urged the claims of this operation in such cases.

The advisability of enlarging this field, and removing the tube with its contained fœtus before rupture has occurred, and during the early weeks of gestation (instead of employing electricity for the purpose of destroying the life of the fœtus), Dr. Janvrin said he had advocated on every possible occasion during the past year and a half. Until very recently he believed that he stood almost, if not quite, alone on this point; but during the last few weeks he had found that other gynecologists also had come to the same conclusion. Thus, in the *American Journal of Obstetrics*, for April, 1888, Mr. Lawson Tait said that, although he had never as yet been called upon to operate until after the sac had ruptured, if in any instance there was a reasonable supposition that there was a tubal pregnancy which had not yet ruptured, he should recommend immediate operation. Drs. Joseph Price and Howard A. Kelly, of Philadelphia, he believed were also in accord with this proposition. In a recent letter to Dr. Janvrin, Dr. Kelly said: "The history of fœtuses which have been destroyed by faradization has frequently been associated with protracted suffering to the mother, and with conditions of chronic invalidism."

Dr. R. P. Harris, of Philadelphia, in the *American Journal of Obstetrics* for August, 1886, referred to several cases in which attacks of peritonitis have occurred (where the fœtus had been killed by electricity) several years subsequent to the death of the fœtus, and due to its presence in the abdominal cavity. Mr. Tait also has very recently (*American Journal of Obstetrics* for April, 1888) pointed out the danger of the placenta going on developing enormously after the fœtus had died from natural causes.

Up to the present time, however, the weight of opinion among American gynecologists is decidedly in favor of destroying the fœtus by electricity in some form, in cases in which a diagnosis has been made prior to the fifth month of gestation, and in which there has been no decided hemorrhage from the sac wall. Among the advocates of this measure stand Thomas, Garrigues, Lusk, Mundé and others, of New York, and M. D. Mann, of Buffalo, and each of these, as well as others throughout the country, have had excellent results with it. In the *Annals of Gynecology* for February, 1888, Dr. Mann stated that Dr. Janvrin was able to find only three cases in literature, including his own, where rupture of a vessel caused death without rupture of the sac. Since the publication of his paper before the American Gynecological Society in 1886, however, he had seen another case in which this condition was fully demonstrated at the autopsy. Two other important specimens he had recently seen in cases in which abdominal section was performed. In one of these the fœtus had died, from pressure of blood-clots, at about the end of the third month, and several other attacks of hemorrhage had occurred between this date and the seventh month, when the tube, fœtus, clots, etc., were removed. In the second case, where laparotomy was performed at the seventh or eighth week, there was a history of slight hemorrhage from the sac wall and slight peritonitis for a week or ten days prior to its removal.

In the paper before referred to, Dr. Mann, of Buffalo, had expressed the opinion that if rupture has not occurred electricity should always take the precedence of laparotomy. To this proposition Dr. Janvrin said he would assent, provided an experienced laparotomist could not be found to operate, but not otherwise. With a capable operator at command, he would urge abdominal section just as soon as the diagnosis has been made, and before any hemorrhage from the sac, with its subsequent attacks of peritonitis, could take place. These frequently recurring attacks of slight hemorrhage are exceedingly dangerous to the life of the mother, and when they have occurred, and the time comes when laparotomy *must* be performed, the patient is in bad condition for operation, while the procedure itself is much more complicated than at an earlier period. The same could be said in reference to waiting to perform laparotomy until serious symptoms have supervened, after the fœtus has been killed by electricity. Here, too, there will be more or less adhesions to deal with, and the work to be done will be much more complicated than the removal of a simply enlarged and still unruptured tube containing the fœtus, with no products of inflammatory processes to interfere with its easy extraction.

Dr. W. T. Lusk said that he wished he could be convinced by the arguments advanced in the paper, that the time had come for the doing away with galvanism in the treatment of tubal pregnancy. It would certainly be very gratifying if one could always perform laparotomy as soon as this condition was diagnosticated, as the operator would thus secure any amount of *éclat* which is not possible when electricity is employed. Destruction of the fœtus by the latter is a far less brilliant method of procedure, and when it is attended with successful results the medical attendant is not infrequently subjected to insinuations that extrauterine pregnancy has never existed at all. At the same time he was so thoroughly convinced that these cases can be efficiently and safely treated with galvanism after the

appearance of the characteristic colicky pains, that he did not as yet feel justified in abandoning so satisfactory a method. The operation is a very simple one, requiring no special skill, so that it can be practised by any one, and, as a rule, the results are all that could be desired.

Dr. Lusk went on to say that he had had two of his cases, occurring in private practice, under observation for a long period, one of them for six years, and the other for four years. At the time the first of these patients was operated on it was thought that she was dying. After consultation with Dr. Thomas it was decided to employ electricity, and the result had been entirely satisfactory. There had never been the slightest bad effect, and at the present time the mass remaining was about the size of a pigeon's egg. In the second case, in which there had been the colicky pains and other usual signs of tubal pregnancy, the tumor was now about the size of an English walnut. Since the operation the patient had given birth to a living child, and there had been no trouble whatever at the time it was born.

Now, if we have such an efficient method which is perfectly safe in the great majority of instances, he could see no good reason for giving it up. Even if inflammation, suppuration, or ulceration should ensue, we can usually perform laparotomy then with satisfactory results. He was, therefore, convinced that in the present state of our knowledge this is the best plan of proceeding. As to performing laparotomy after rupture of any portion of the tube has occurred, the difficulty of diagnosis at this time is exceedingly great, and Lawson Tait had told him personally that he did not feel able to make it; or, at least, this was what Dr. Lusk understood him to say.

In regard to the other five cases which he had treated with electricity, he could not speak with the same confidence as of the two just mentioned. The results were satisfactory at the time, but as the women were hospital patients, he had not been able to follow up their subsequent history. If he could be convinced that laparotomy is just as safe as electricity, he should certainly join the ranks of those who advocate this procedure. As to the danger of the growth of the placenta after the fœtus had been destroyed, this seemed to him to be very slight, and he questioned very much whether such a danger really exists at all.

DR. GEORGE T. HARRISON said that his experience with galvanism had been very favorable. He had certainly destroyed the fœtus by this means in three cases. He had examined one of these patients two years after the operation, and had found the sac much shrunken. Since then the woman had given birth to a child in a normal manner. There had also been no evil results in his other cases. Notwithstanding this, however, he thought the experience of the profession is at present too limited to enable us to arrive at any definite conclusions, and the teaching of modern gynecology is undoubtedly to advance in the line indicated by Dr. Janvrin.

The results obtained by some of the German operators especially, have been such as to have great weight in convincing him of the practicability of laparotomy in this connection. Still, at the present time he was not quite willing to declare himself in favor of the general adoption of the procedure in this class of cases. The statement of Dr. Janvrin in regard to the constant occurrence of extreme sensitiveness in the tumor of tubal pregnancy he thought should be somewhat modified, as he had observed instances in which this was not present.

DR. ANDREW F. CURRIER said that such remarks as he had to make on this subject were largely theoretical in character. After a careful consideration of the matter it had seemed to him that it was one of the inconsistencies of modern gynecology, that while the abdomen is constantly being opened for the removal of tumors which may be doing the patient no injury, operators should refuse to do the same for the relief of a condition which, if uninterfered with, is absolutely sure to prove fatal, and should leave the case to the uncertainties of a method like electricity; although in many cases, perhaps most cases, the latter has proved successful. Men, he thought, are apt to be influenced by their surroundings, and if some of those who are the strongest advocates of electricity had met with a fatal result in any of their cases, they would not, perhaps, be so enthusiastic in its favor. Several years ago the late Professor White, of Buffalo, had advanced the proposition (which he thought was a very sound one), that whenever there is in the abdomen an extraneous body which is liable to cause fatal results, the proper surgical course is to open the abdominal cavity and remove it. Again, the possibility of the subsequent growth of parts connected with the fœtus ought not to be ignored, since such men as Tait and Knowsley Thornton have spoken of it as a very serious danger.

When gynecologists perform laparotomy so frequently for ordinary pyosalpinx or hydrosalpinx, why should they hesitate to open the abdomen for so grave a condition as tubal pregnancy? Probably the reason why this matter has not attracted more attention than it has, is because these cases are so seldom seen. If this were the case, it showed the importance of manfully warning those who were to become family practitioners, as well as those who were to become mothers, of the dangers of such an accident, and the necessity for the early recognition of the condition. So far as he was aware, but little attention is paid to the subject in the medical schools.

A. PALMER DUDLEY said that the all-important point seemed to him to be the matter of diagnosis, and he should very much like to know how to make the diagnosis. Even Mr. Tait, according to Dr. Lusk, had confessed his inability to do this before rupture had taken place. If the diagnosis be once established, the treatment is sufficiently easy, whether electricity or laparotomy is resorted to. Under the circumstances referred to by Dr. Janvrin, laparotomy is a comparatively simple operation, and no more dangerous than when it is done for hydro- or pyo-salpinx.

Dr. Dudley then related a case which, he said, showed the difficulty of making a correct diagnosis. The patient was a married woman of seventeen, who was irregular in her monthly periods. She had already had one child. The cervix uteri was soft, and she suffered from nausea and vomiting. There was a pulsating soft tumor, extremely sensitive to the touch, which Dr. Dudley thought was probably due to tubal pregnancy. He proposed laparotomy, but this was opposed, and the patient passed from observation. Two months afterward she returned to the hospital clinic, still suffering from nausea and vomiting, and this time she consented to the operation. This was performed two weeks ago. On opening the abdominal cavity he found pyosalpinx on the

right side, while the tube was twisted around so that its fimbriated extremity was attached to the bladder, behind which the ovary was lodged. The fimbriated extremity of the other tube was attached to the rectum, while under the pyosalpinx was a parovarian cyst. There was a frightful hemorrhage during the operation, but the patient is now recovering. Here, then, was a condition other than tubal pregnancy giving rise to the symptoms mentioned by Dr. Janvrin. In conclusion he said that he would not hesitate to resort to laparotomy early if he was able to make the diagnosis of tubal pregnancy.

Dr. Lusk said that in considering laparotomy in connection with pyo- or hydro-salpinx and with tubal pregnancy, we must remember that there is this difference, that while the former conditions cannot be removed by electricity, it is, as a rule, quite possible to put an end to tubal pregnancy by this means. If this were practicable in the case of pyosalpinx also, we would not resort to laparotomy until after electricity had been tried. He then spoke of the importance of arriving at a correct diagnosis in many cases, of making a thorough examination of the patient under ether, and referred to two cases in his own experience illustrating this point.

Dr. Dudley stated in reply to a question by Dr. Janvrin that in the case which he had related he had not observed an irregular decidual discharge.

Dr. Janvrin said that he regarded this as the most important point in the diagnosis of tubal pregnancy. If the symptoms which he had mentioned (leaving out those of shock, which is due to rupture) were noted in any case, he thought there would be no difficulty in making out the diagnosis before rupture of any portion of the tube had occurred. These, it should be remembered, are the presence of an irregular decidual discharge in a woman who has missed a period, associated with the normal signs of pregnancy and an enlarging, fluctuating, and exquisitely sensitive mass on one side of the uterus.

Dr. Lusk had stated that after the employment of electricity there is very little danger of ulceration and other bad effects. This is no doubt true, as a rule, but certain cases have been reported in which it was followed by evil results. Thus, Dr. Mann has published in the article referred to in the *Annals of Gynecology*, two such cases after the use of galvanism. As to Mr. Tait's views on the diagnosis of tubal pregnancy before rupture, in the very last number of the *American Journal of Obstetrics* (April, 1888) he stated that he had never been able to make the diagnosis at this time because he had never been called in any case until after rupture had occurred. The German cases referred to by Dr. Harrison were all secondary operations, and, so far as he was aware, the only primary operation which had as yet ever been performed was that of Dr. Joseph Price, of Philadelphia, which was done in September last.

THIRD FRENCH CONGRESS OF SURGERY.

Held in Paris from March 12 to 17, 1888.

(Specially reported for The Medical News.)

(Continued from page 446.)

EXCISION OF THE WRIST FOR ANKYLOSIS.

Dr. Ollier, of Lyons, reported two excisions of the wrist for ankylosis. These operations would never have been undertaken, he said, had the antiseptic methods not been used, and a sufficient functional restitution of the part assured. It would not have been accepted a few years ago, when ankylosis was the ideal result sought for in excisions. Langenbeck had tried it twice, but in one case he had pyæmia and in the other a return of the ankylosis.

At the present time, after the excision of the carpus in an isolated manner or associated with that of the metacarpal or ulnar-radial extremities, one can obtain excellent functional results, far superior to those obtained by Lister in 1865, which, however, showed already at that time a marked improvement. One of the most important results obtainable is a joint movable by communicated movements, and also self-moving; we arrive at that by respecting the motor-tendons of the wrist, radial and ulnar, which were formerly sacrificed. Of course, the articulation has not its normal freedom, but it will have movements of at least 40 to 45 degrees, which is quite sufficient for the ordinary use of the wrist. Having seen, four or five years later, two autopsies of resected patients, he found between the extremities excised an osteo-fibrous cushion with synovial interstices, giving a good functional condition to the articulation.

The possibility of writing is not a good test, for one with stiff fingers can do this; all his patients can hold their arms out with a weight of 10, 24, and 36 pounds while moving their wrists, the movements of abduction and adduction of the thumb are also well restored. In cases of ankylosis the operation is always a delicate one, especially when the wrist is S-formed. The carpal bones must then literally be carved with the chisel and mallet with great care not to wound any arterial or nervous trunk. In rheumatic patients, on account of a certain degree of tendinous ankylosis, one must take a good portion of the bone away. The operation, if the trouble is not accompanied by tuberculous lesions, must also be absolutely without subsequent fever. The first case he operated upon was a young woman who had already a double osseous ankylosis of the elbow, and he excised the carpus and about one-third of an inch of the bones of the forearm to allow her to play her piano, which she now does very readily. His second case was of ankylosis giving a bad position to the hand, rendering it absolutely useless. The functional result obtained is a perfect one.

EXTIRPATION OF THE LARYNX FOR CARCINOMA.

Dr. Demons, of Bordeaux, did not think that on account of its difficulties and the rapid return of the disease, if the patient does not die from the operation, this operation ought to be disregarded. He reported two cases. The first case, man, aged forty-four years, had presented for one year signs of cancer of the larynx. He had an epithelioma which started at the epiglottis, then invaded the base of the tongue and the pharyngeal wall with bilateral glandular swellings. Tracheotomy had been performed, and the patient asked for a radical operation. He first took away, by a transverse incision below the level of the hyoid bone, the epiglottis and the base of the tongue, then by a median vertical incision, the left lateral half of the larynx. At the end of nine months the disease returned at the base of the tongue. The second case, man, aged fifty-seven years, had had for one year laryngeal symptoms, and presented a limited

epithelioma on the right vocal cord. This operation he made last May. The epithelioma was found limited to the larynx without any lesions of the cartilages or lymphatic glands. He first made a transverse incision below the hyoid bone from the middle of which he started a vertical incision down to the larynx. He incised the thyroid cartilage vertically and finding the left side also slightly involved, he extirpated the whole larynx. A month later the patient was cured, and for ten months has felt perfectly well, and there is no sign of the return of the trouble. The diagnosis was confirmed by the microscope. He concluded, that if the affection takes a rapid course we should refuse to operate, but, if, on the contrary, the disease is limited, we should not hesitate to use the knife.

DR. DUPONT, of Lausanne, drew attention to a modification of the operation. The principal danger of the operation being the introduction of blood into the air passages, the Trendelenburg canula is used by some operators. He separates the trachea from the œsophagus and brings it forward, fixing it at the inferior angle of the wound. In that manner the trachea is no longer in the direction of the inferior extremity of the larynx, and the blood falls behind it.

DR. MOLLIÈRE, of Lyons, had extirpated the larynx in a man of sixty-eight years, for an epithelioma of the arytenoid region. He excised the posterior one-third of the larynx and the greater part of one of the vocal cords, which he then tried to restore by sutures. He then finished by suturing the epiglottis to the cutaneous wound. To prevent the passage of food into the larynx, Trendelenburg's canula was used with good success, and was left ten days in the wound, until it was cicatrized. It has been much better borne than the ordinary canula on account of its not moving and being elastic. The patient was nourished with the œsophageal sound for two days and ate alone on the third day. He left the hospital at the end of one month.

WHAT TO DO IN GUNSHOT WOUNDS OF THE VISCERAL CAVITIES.

DR. CHAUVEL, of Paris, said that on this subject the profession is divided into two camps: the temporization party and the intervention party; but the introduction of antiseptic surgery ought to modify the old views. In the cranium and chest the infection of the wounds of the serous cavities can only come from the exterior; in the abdomen it comes from the wounding of the abdominal organs, which pour their products into the peritoneum. For the past hundred years immediate intervention has been defended by Thomassin, Dufouart, Baudens, Legouest, Otis, etc., but their precepts were not followed. In France the opinions are varied, the abstentionists are represented by Professors Tillaux and Vernenil; the moderate interventionists by Professors Trelat and Reclus, who operate as soon as signs of peritonitis appear, and indicate a peritoneal effusion of some kind; to these later views adhere also MM. Bouilly and Le Fort.

Hamilton and MacCormac recommend immediate laparotomy, and he adheres to these later views. He thought that any wound of the abdomen should be followed by an immediate enlarging of the wound, exploration of the parts, etc. Gunshot wounds are almost always mortal, if we rely on expectation. Dr. Nimier in his statistics had found the mortality to be variable; in certain cases ninety-five per cent. die, while others lose about ten to fifteen per cent. He has collected five thousand and three cases, the mortality of which was eighty per cent. In gunshot wounds of viscera, the line followed by the bullet is always a direct one, and the wounds are always according to a direct line from the wound of inlet to the one of outlet.

Intestinal movements may produce a slight deviation from this line, but not a considerable one; this enables us to find out more easily the injuries sustained.

At the beginning the two pathognomonic signs are very obscure, the appearance of the intestinal contents at the wound and visceral hernias are rare; still, one cannot await the general symptoms. Death usually occurs by hemorrhage or by septic peritonitis. The hemorrhage may be due to a large vessel or again to the tearing of small arterioles. Septic peritonitis is the result of the presence of intestinal matters in the peritoneum. Hemorrhage and peritonitis being the principal causes of death, is it not natural that these should be prevented by the ligature of the wounded vessel, and by the cleaning out of septic matter?

Out of forty-one cases of laparotomy for gunshot wounds of the abdomen by small bullets since 1880, one finds twelve cures and twenty-nine deaths. If one should eliminate the cases in which the operation had been undertaken too late, the proportion of cures would be much greater.

The washing out of the peritoneum, proposed by Nimier, cannot replace laparotomy. This operation must be done in the median line, and as rapidly as possible. The extraction of foreign bodies, ligature of vessels, suture of intestine before or after excision of the same, the washing out of the cavity, the extirpation of certain organs, will be practised by incision in the median line. Finally the medical treatment: absolute rest, opium, fasting, will help the surgeon. One must then reject systematic expectation, and operate immediately.

DR. E. DE LORME, of Paris, said that direct surgical intervention in intestinal wounds by gunshot is a very rational operation, but practically immediate intervention for gunshot wounds of the abdomen on the battlefield is not at all to be recommended. These operations could only be undertaken in fixed ambulances which are not obliged to follow the army.

The principal contraindications are: 1. The wounds produced by voluminous pieces of shell, which produce very extensive damage which can hardly be remedied by surgical aid. 2. The multiplicity of the wounds of the small intestine by bullets which penetrate the abdomen; still this is a less serious objection on account of the progress made in intestinal suture. From a series of experiments on cadavers, he has found that in transverse perforations of the intestine the intestinal lesions are much more numerous than in antero-posterior perforations. 3. When the bullet has a very great speed, the frequent extension of the lesions contributes to an unfavorable prognosis, and renders less certain direct intervention.

Gunshot wounds of the abdomen in a campaign are in a bad condition for laparotomy. The operation cannot be performed in the field ambulance, and when the wounded are admitted to a permanent hospital it is too late.

DR. PONCET, of Paris, said that in the time of Larrey cannon balls were round, and would produce by rub-

bing against the abdomen severe bloody effusions in the abdominal cavity. Later, in 1855, the explosive shells produced contusions without ecchymosis of the parietes, but intestinal lesions. He had seen during the siege of Strasburg, cases in which contusion of the abdomen produced by large pieces of shell would only present symptoms of intestinal perforations by sloughing at the end of the seventh or eighth day. Formerly the shells were made to explode according to certain lines, indicated by weak points at the time of the manufacture of the shell; but one of the shells in present use will explode in four or five hundred pieces; in addition we have the metallic dust which accompanies such explosions, and which is capable of penetrating the tissues to the depth of four inches. These are only the effects of our cast-iron shells. But what will the wounds be produced by steel shells; they are still more dangerous and produce terrific wounds. All the splinters of the shell are each like a knife cutting on both sides, which are thrown on the human body with such force that they are found at three hundred and fifty yards behind, or nine hundred and fifty yards in front of the point of explosion, and so hot that they cannot be touched. Such are the shells which will produce the wounds of the next war; as to say what kind of wounds they will be and what to do, we must wait experience. In every case of immediate perforation laparotomy ought to be performed, and suture and excision of the intestine made. If there is a consecutive perforation after elimination of a suture, a secondary laparotomy will have to be performed.

Dr. Reclus, of Paris, said that American and English English surgeons whenever they find themselves in the presence of a perforating wound of the abdomen produced by a revolver, make an immediate laparotomy. For them intestinal perforation is a necessity to a perforating wound, and death is inevitable if an intestinal wound is left to nature. He accepted the first proposition, for in only one case out of thirty-seven had he seen a gunshot wound of the abdomen not followed by perforation of the intestine. But he did not admit the second proposition that perforation of the intestine always causes death. This opinion has been established in two ways: 1. The confusion which has been established between revolver wounds and those produced by war rifles, which last are much more dangerous. 2. The results of experiments on dogs. All the animals on which Parkes experimented died. But the dog is not in the same condition as man, on account of the shortness of the intestinal canal, and of the relatively larger size for him of a revolver ball, which are all conditions favorable to an escape of the intestinal matters into the peritoneum. 3. Maintaining in cases of abdominal wounds terminating by cure that there did not exist any intestinal wound, cure in these conditions is, however, frequent enough. He could collect more than one hundred such cases where the perforation had been recognized by the usual symptoms: fecal matter coming out of the wound, immediate hematemesis, melæna, or early expulsion of the ball by the anus.

Three principal causes bring on death in abdominal gunshot wounds: hemorrhage from a large vessel, shock, and peritonitis from effusion of intestinal matter. Against the first two very little can be done; against the third, much more frequent, intervention is not always necessary. Nature will prevent, in several ways, the intestinal contents from being effused in the peritoneum: 1. By the formation of a mucous obturator which closes the perforation. He has verified this fact in his experiments on dogs. 2. By a peculiar way, the simple contraction of the muscular coat, which will close the opening. 3. The most common, by the rapid formation of adhesions with a neighboring intestine or with the parietal peritoneum. In these abdominal wounds he acts according to the following rules.

1. Strong compression of the abdomen, as after laparotomy, to prevent an effusion of intestinal matter or blood into the peritoneum.

3. Opium, and absolute fasting, giving only every quarter of an hour a little iced milk to allay thirst.

3. It is only then, when these precautions have failed, that laparotomy should be resorted to.

Dr. Trelat, of Paris, was absolutely opposed to the two doctrines, 1st, the absolute operative abstention, which is condemned by six or seven examples of certain cures due to intervention; 2d, the expectation, until sure signs of peritonitis have set in. He thinks laparotomy necessary as soon as there are signs of stercoraceous effusion. These phenomena may be immediate or only appear later, but as soon as there is the least sign of peritonitis, he would not hesitate to operate. The medical treatment recommended by M. Reclus is advantageous, but must not be entirely relied upon.

Dr. Labbé, of Paris, recorded a case of a man, of twenty-nine years, alcoholic and addicted to morphia, who shot himself in the abdomen with a revolver-ball, size ⅓ of an inch, directed from above downward. He saw him two hours later, with hardly any pulse, cold, having had already several fainting-spells, and appeared lost. A few injections of ether restored him, however, somewhat, and he having shot himself in the country it was necessary to take him to Paris, about three miles, where he arrived about six hours after the accident, his temperature 96° F., no immediate intervention could be thought of. During the night he had violent pains, green vomiting, temperature raised. In the morning slight tympanites indicated peritonitis. He operated upon him fourteen hours after the accident. On incising the abdominal wall about three pints of blood escaped; and on examining the small intestine he found about the middle of the ileum four double perforations very near to each other, and above them a fifth one; in addition the mesentery was perforated, and was the source of the hemorrhage. The intestines were closed by Lembert sutures, the peritoneum washed out with sponges and great quantities of boiled water, and the abdomen closed. Operation lasted one hour and ten minutes. After the operation the patient became warmer, but died in twenty hours. This indicates in such cases immediate intervention, for in fourteen hours the peritoneum had had time to become red and have exudations on its surface.

Dr. Nimier, of Paris, said that from the study of gunshot wounds of the cranial cavity, during the Tonkin War, he found that most of the deaths were caused by the irritation of the cerebrum by the ball, the blood, bony splinters, etc., or by infection of the wound. Cure had especially been obtained in those cases where an early intervention had suppressed these inflammatory causes. He recommended in cases of gunshot wounds of the cranium: To shave and clean the cranium; to cut away the bruised lips of the wound; to enlarge it, if necessary,

to elevate the bone or take away the bony splinters; take away the foreign bodies, or the apparent missiles; work with an antiseptic solution, then dress with an occlusive antiseptic dressing. If there exists a hernia of the cerebrum, as in one of our wounded who was cured, the surgeon must apply a slightly compressive bandage. If the ball is lost in the cranial cavity, some symptom may indicate its location; intervention becomes then a matter of diagnostic science or pluck. In case of meningo-encephalitis the surgeons who have an opportunity might try the opening of the serous cavity, and the antiseptic irrigation of the same.

SPONTANEOUS HEMATOMA OF THE ORBIT.

Dr. Panas, of Paris, last January examined a boy, four years old, habitually healthy, except that he suffered from repeated epistaxis, and presented in the left orbicular region, upper and external part, a lobulated tumor, which had pushed the eye out, downward and inward. Ophthalmoscopic examination showed that the optic papilla was white and diffuse, while the luminous perception was nil. The orbital tumor presented a certain fluctuation, and punctures brought out black and clotted blood; it was a pure hematoma. It was only after four months that the superior region of the orbit began to disappear gradually, but one of the important symptoms exhibited was very serious dyspeptic troubles, real indigestion, accompanied every time by epistaxis; and this dyspeptic phenomenon even went as far as vomiting. Considering the general condition of the patient, we find him too stout for his age, that he is a dyspeptic, and a fatty dyspeptic. He thinks that this orbital hematoma is connected with the dilatation of the stomach; it is well known that congestion or hemorrhage is very common in stout dyspeptics. Is there here a phenomenon of reflex hemorrhage of the order of vaso-paralytic manifestations?

ON CHOLECYSTECTOMIES.

Dr. Thiriar, of Brussels, said that at the first session of this Congress he presented three cases of ablation of the biliary vesicles; his three patients are still well today, and have had no return of hepatic colic. In July, 1887, in a lady aged thirty, he extirpated the biliary vesicle. She had suffered for six years from terrible hepatic colics, which nothing could relieve. The vesicle contained no calculi, was enclosed by the liver and duodenum, to which it adhered firmly. The dissection was a difficult one, as in certain parts the duodenum was deprived of its serous tissue. Finally, the vesicle was extirpated. The cure was rapid, and the patient has had no return of the trouble.

Out of 6 cases of cholecystotomies by Spencer Wells's methods, there have been 3 deaths, 50 per cent., and one return of the trouble; out of 72 cases of ordinary cholecystotomies—that is, with suture of the biliary vesicles on the abdominal walls—13 deaths, or 18.05 per cent.; 59 operated upon have survived. There has been one return, and it had a persistent fistula. We had, then, 53 radical cures, which gave 48.6 per cent. of complete cures.

We know of 22 cases of cystectomies with 3 deaths after the operation, which makes 13.65 per cent. Of these 3 failures, one is attributed to a cerebral tumor; the second was a perforation of the cystic canal by a calculus. In the third case there were two calculi in the ductus communis choledochus, one was pushed back, the other crushed, according to Lawson Tait's method.

Cholecystectomy gives us, then, leaving the first case out, a mortality of 9.98 per cent., and all the operated patients were cured. In accordance with these results he thinks we must interfere without hesitation. The biliary vesicle is of no use in the economy, it can be extirpated without inconvenience, and if we could demonstrate the existence of a painful cholecystitis, or irritable vesicle, as we have painful cystitis and irritable cystitis, the indications of cholecystectomies could be very much extended, one would have to resort to it in all painful crises having for their origin an irritable biliary vesicle.

OBITUARY.

CORNELIUS REA AGNEW, M.D., LL.D.

The profession in New York was very much startled on Monday, April 8th, to learn that Dr. Agnew had gone home from a consultation with serious abdominal symptoms. These soon developed into what appeared and proved to be general septic peritonitis.

Dr. Agnew had generally been in excellent health; he had always taken wise and good care of his physical system. He came of a long-lived family; he was not fifty-eight years old when he died, his birthday being August 8, 1830. His appearance of excellent bodily and mental preservation had given his friends reason to think that he would live out his days, and fill to the full the measure of his useful and distinguished life. But he succumbed, after an illness of eight days, to a disease that probably originated in the appendix vermiformis, for while no foreign body was found, impacted feces and perforation and peritonitis started from this point.

Dr. Agnew was born in New York City, and was graduated in the arts from a New York college, in medicine from the College of Physicians and Surgeons, after which he served the full terms of assistant and resident in the New York Hospital. His educational lineage was of the best type. He began practice as a general practitioner, with a strong leaning to surgery. At one time he was talked of as attending surgeon to the hospital where he was educated. He soon, however, devoted his entire professional energies to the care of diseases of the eye and ear, for which he had especially fitted himself by study in Paris under Sichel and Desmarres, in London under Bowman, and in Dublin with Sir William Wilde. He never became a narrow specialist, and to the end of his days he would have been a competent general practitioner, so wide were his experience and his studies.

His special work in diseases of the eye was begun in the New York Eye and Ear Infirmary in 1855. He resigned this position in 1864. His services in connection with Van Buren, Gibbs, and Bellows, in establishing and carrying on the Sanitary Commission during the Civil War, are a part of our national history. He was one of the founders of the Union League Club of New York, and an honorary member of it at the time of his death. He was chiefly instrumental in establishing the Brooklyn Eye and Ear Hospital in 1869. By his influence such citizens as S. B. Chittenden and H. B. Claflin were induced to found and finally to endow this charity.

In 1869, in connection with Drs. Loring and Roosa, he engaged the interest of prominent and wealthy citizens

of New York, so that the Manhattan Eye and Ear Hospital was established in a dwelling-house hired for the purpose. Through Dr. Agnew's untiring and skilful efforts this institution was also permanently settled in a large and handsome building erected for it. Among the chief of the leading New Yorkers who contributed the quarter of a million of dollars finally necessary to this end, was the Honorable Edwin D. Morgan, on whose staff Dr. Agnew acted as Surgeon-General in 1859 and 1860.

Dr. Agnew did a large share of the surgical work at the Brooklyn Eye and Ear Hospital for a number of years, and in the Manhattan up to the moment of his fatal illness. He was easily among the first as an operator, and he also possessed great skill in the general management of cases, and ability in the executive care of hospitals.

He was a devout member of the Presbyterian Church with strong dogmatic convictions, but he was extremely catholic and liberal in his judgments of those whose theories of life and its duties were different from his. He was preëminently a peacemaker in the profession, in all the little difficulties and misunderstandings that arise among bodies of men with the same interests.

His contributions to medical literature are by no means the least part of his work. They are to be found in our medical journals and in the Transactions of the American Ophthalmological and Otological Societies. They were of such a nature as to be generally quoted and often translated into the German and French languages. His reputation as an ophthalmologist and otologist is as wide in Great Britain and Ireland and on the Continent of Europe as in our own country.

Dr. Agnew was a man of rather below medium height, but of most dignified presence, a graceful and interesting speaker, and a capital presiding officer. In no part of his life was there any failure. He died in the midst of the active performance of duty. He preserved to the last conscious moment the equanimity and faith that had characterized his life. He gave the most careful directions in preparation for the operation that was performed upon him, in the hope of finding an obstructed bowel. He departed this life, surrounded by his family, in the most intrepid and cheerful spirit, without fear and without reproach.

At a meeting of the New York Academy of Medicine held April 19, 1888, the following preamble and resolutions were unanimously adopted, and, as a further mark of respect to the memory of Dr. Agnew, the Academy thereupon adjourned.

The New York Academy of Medicine has been informed of the death on Wednesday, April 18, 1888, of Dr. Cornelius Rea Agnew, who, both as an officer and a member of the Academy, has been most assiduous and successful in his efforts for its welfare.

The Academy hereby records its appreciation of his untiring zeal, of his eminent ability, of his executive capacity, and of his fidelity; of the largeness of his views for its development, of his generosity both in his gifts and in personal labors for its good.

He was alert to make the best of its methods of work, as well as to improve their efficiency. He sought to develop its scientific discussions and proceedings by judicious classification of subjects; he was warmly interested in the enlargement of the library; he was exacting in attention to economy in the expenditure of its funds; he was deeply earnest in the plan for procuring a new building. In his loss the Academy has sustained a heavy blow, and the removal of his friendly and energetic personality is a great bereavement, while we shall miss his wise counsels, his discriminating judgment, his courtesy and vigor in debate, and his promptness in forwarding every scheme for the scientific and practical advantage of the Academy.

We have lost a true friend and an efficient worker. Beyond what he has done for the Academy, we are proud of his achievements in what makes the medical profession an honor and a power for good.

He founded two eye and ear hospitals and placed them on a successful basis. He aided in the organization and was for many years one of the managers of an asylum for the insane. He was active in many medical societies. While practising a specialty, his outlook and concern were for the whole profession.

He had no professional narrowness, and his judgments were always inclined to be charitable to those who differed with him. His services as a patriot are part of the history of our country; he was zealous for the civic weal, and a leader in movements for reform.

Sanitary and social improvements were among the causes to which he earnestly devoted himself. He took an active part in helping on education, both in its popular cultivation and in its higher and technical developments.

Probity, uprightness, unselfishness, and courage were typified in him, while his character was imbued and moved by deep religious conviction. His life is, to us, a glory and a stimulus.

Resolved, That we respectfully tender to his family, the assurances of our deep sympathy and with the tribute of our affection, our high admiration for the many noble qualities which were embodied in Dr. Agnew.

NEWS ITEMS.

Preliminary Programme of the Congress of American Physicians and Surgeons, to be held in Washington, September 18, 19, and 20, 1888. The *American Surgical Association* announces the following papers to be read:

Excision in Articular Disease. By Dr. John Ashhurst, Jr., of Philadelphia.

Microörganisms: their Relation to Surgical Disease. By Dr. Nicholas Senn, of Milwaukee.

Cerebral Localization: Its Relation to Operative Surgery. By Dr. Stephen Smith, of New York.

Intracranial Tumor Successfully Removed. By Dr. W. W. Keen, of Philadelphia.

Experimental Researches on Gastric Fistula, and its Bearing on Gastrostomy. By Dr. J. Collins Warren, of Boston.

Forty Years of Chloroform and Ether. By Dr. D. W. Yandell, of Louisville.

The Surgical Management of Typhlitis and Perityphlitis. By Dr. W. T. Bull, of New York.

The Choice of Operation for Vesical Calculus. By Dr. Hunter McGuire, of Richmond, Va.

Hernia: Its Treatment, etc. By Dr. C. H. Mastin, of Mobile, Ala.

The Radical Cure of Hernia. By Dr. George W. Gay, of Boston.

Certain Indications for Trephining, and their Comparative Value. By Dr. J. Wm. White, of Philadelphia.

Nerve Stretching. By Dr. N. P. Dandridge, of Cincinnati.

Nephrectomy for Gunshot Wound of the Kidney. By Dr. DeForest Willard, of Philadelphia.

The *American Association of Genito-Urinary Surgeons* announces the following papers to be read:

Clinical Observations on Diseases of the Testicles. By Dr. L. B. Bangs, of New York.

Clinical Observations on Chronic Gonorrhœa, and Two Cases of Cancer of the Seminal Vesicles, with pathological specimens. By Dr. J. P. Bryson, of St. Louis.

Operative Treatment of Hypertrophy of the Prostate; and Case of Bowel Ending in the Urethra of a Child Four Weeks Old; Relief by Operation. By Dr. A. T. Cabot, of Boston.

On the Effects of Rapid Changes of Altitude in an Advanced Case of Interstitial Nephritis. By Dr. George Chismore, of San Francisco.

The Connection between Masturbation and Stricture. By S. W. Gross, of Philadelphia.

Operations on the Kidney. By Dr. W. H. Hingston, of Montreal.

Syphiloma of the Vulva. By Dr. J. N. Hyde, of Chicago.

The Curability of Urethral Stricture by Electricity, and Investigations; and The Comparative Value of Suprapubic and Perineal Drainage in Curable and Incurable Bladder Disease. By Dr. E. L. Keys, of New York.

The Filaria Sanguinis Hominis in the United States, Especially in its Relationship to Chylocele of the Tunica Vaginalis Testis; and A Case of Perineal Section for Traumatic Retention; Unusual Condition of the Bladder. By Dr. J. E. Michael, of Baltimore.

The Prophylaxis of Syphilis. By Dr. P. A. Morrow, of New York.

Unusual Case of Urethral Calculus. By Dr. H G. Mudd, of S. Louis.

On the Radical Cure of Stricture by Dilating Urethrotomy; and Demonstration of a Perfected Evacuator, and an Improvement in the Method of Removal of Débris from the Bladder. By Dr. F. N. Otis, of New York.

Pyæmia as a Direct Sequel of Gonorrhœa. By Dr. R. Park, of Buffalo.

Retrojections in Gonorrhœa. By Dr. E. R. Palmer, of Louisville.

Prostatotomy for Enlarged Prostate at the Age of Forty-two. By Dr. Abner Post, of Boston.

A Case of Removal of Both Testicles for Recurrent Carcinoma; and A Case of Nephrolithiasis Complicated with Hydronephrosis in which Lumbar Nephrotomy was Performed. By Dr. F. W. Rockwell, of Brooklyn.

Some Points on the Differential Diagnosis of Bladder and Kidney Affections with Demonstrations of the Cystoscope and other Instruments; and On the Physiology of the Bladder. By Dr. Alexander W. Stein, of New York.

Local Treatment of Chronic Urethral Discharges. By Dr. F. R. Sturgis, of New York.

Some Points on the Etiology of Stricture of the Urethra. By Dr. R. W. Taylor, of New York.

Operative Treatment of Hypertrophy of the Prostate; and Spontaneous Fracture of Stone in the Bladder. By Dr. F. S. Watson, of Boston.

The Relation of the Prostate to Chronic Urethral Discharges; The Value of the Tolerance of the Iodides as a Diagnostic Test of Syphilis; and Urethral Stricture and Enlarged Prostate in their Relation to Vesical Calculus and Calculous Pyelitis, with Cases. By Dr. J. William White, of Philadelphia.

The Prognosis of Stricture, based on Thirty Years Death Record of Stricture at the London Hospital and the Practice at St. Peter's Hospital. By Dr. E. Hurry Fenwick, of London.

The Congenital Anomalies of the External Urethral Orifice. By Dr. C. Kaufmann, of Zurich.

Death of Dr. Edward G. Loring.—We regret to record the sudden death of Dr. Loring in New York City on the evening of the 23d inst., presumably from heart disease. Dr. Loring started out in his usual health, and when returning late in the afternoon dropped in the street and died almost instantly.

Dr. Loring graduated from the Harvard Medical School in 1864, and subsequently entered upon the active practice of ophthalmology. He was a member of the American Ophthalmological Society, a frequent contributor to the literature of his specialty, and the author of a textbook on Ophthalmoscopy.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM APRIL 17 TO APRIL 23, 1888.

STERNBERG, GEORGE M., *Major and Surgeon.*—Having been instructed by the President to proceed to the Island of Cuba, for the purpose of continuing his investigations of the methods of preventing the spread of epidemic diseases, will in connection with his present duties, report to the Secretary of the Treasury for further instructions.—*S. O 89, A. G. O.*, April 18, 1888.

The operation of par. 17, S. O. 79, c. s., A. G. O. (so much thereof as relates to GEO C. BUSHNELL, *Captain and Assistant Surgeon*, U. S. Army) is suspended until May 1, 1888.—*S. O. 90, A. G. O.*, April 19, 1888.

ARTHUR, WM H., *Captain and Assistant Surgeon.*—Ordered from Fort Niagara, N. Y., to Fort Bowie, Arizona, to take effect on the expiration of his present leave of absence.—*S. O. 86, A. G O*, April 14, 1888.

BLACK, CHARLES S., *First Lieutenant and Assistant Surgeon.*—Ordered from Fort Davis, Texas, to Fort Sidney, Nebraska.—*S O. 86, A G. O.*, April 14, 1888.

CROSBY, WILLIAM D., *First Lieutenant and Assistant Surgeon.*—Ordered for duty at Jefferson Barracks, Mo., after being relieved by Assistant Surgeon William H. Arthur, and upon expiration of the leave of absence granted him in S. O 60, A. G. O., March 14, 1888.—*S O 86, A. G. O.*, April 14, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING APRIL 21, 1888.

HUTTON, W. H. H., *Surgeon.*—To proceed to Biloxi, Miss., on special duty, April 21, 1888.

LONG, W. H., *Surgeon.*—Granted leave of absence for fourteen days, April 21, 1888

SAWTELLE, H. W., *Surgeon.*—Granted leave of absence for seven days, April 21, 1888.

URQUHART, F. M., *Passed Assistant Surgeon.*—Granted leave of absence for seven days, April 10, 1888. To assume temporary charge of Cape Charles Quarantine Station, April 17, 1888.

WHITE, J. H., *Passed Assistant Surgeon.*—Relieved from quarantine duties at Sapelo Station, April 21, 1888.

WILLIAMS, L. L., *Passed Assistant Surgeon.*—Relieved from duty at Marine-Hospital, Boston, Mass.; to assume charge of Cape Charles Quarantine Station, April 17, 1888.

BRATTON, W. D., *Passed Assistant Surgeon.*—Relieved from duty at Marine-Hospital, San Francisco, California; detailed as medical officer Revenue Steamer "Bear," during summer cruise, April 19, 1888.

ORIGINAL LECTURES.

THE MIDDLETON GOLDSMITH LECTURE.

ON THE RELATION OF THE DISEASES OF THE KIDNEY, ESPECIALLY THE BRIGHT'S DISEASES, TO DISEASES OF THE HEART.

Delivered before the New York Pathological Society, April 18, 1888.

BY J. M. DA COSTA, M.D., LL.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE AT THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA; PHYSICIAN TO THE PENNSYLVANIA HOSPITAL.

WHEN, by your kind thought, I was asked to deliver the Middleton Goldsmith lecture before your learned body, several subjects occurred to me which, from their great pathological interest, seemed worthy of the occasion, and which I believe the generous founder of these lectures would have approved of, could his cheery presence be here to animate us. From among these I choose, partly because it has been with me one alike of pathological and clinical investigation, the relation of diseases of the kidney, especially the Bright's diseases, to diseases of the heart. Much has been done of late years to examine this subject; but it is far from being clear or complete, and I must claim your indulgence if, in the endeavor to add a little to our knowledge of it, I allude to some facts which to you must be trite.

We all know that there is a close connection between diseases of the kidneys and diseases of the heart. But how intimate is this connection, and what determines it? Is there anything in an affection of the heart which would lead to a kidney affection? Or is the kidney disorder the starting-point of the undoubted combination observed? Again, are the lesions, when found together, both due to a common cause which determines them, and not the direct consequence of each other?

Allow me to detain you with a brief discussion of these weighty questions, before I call your attention to some of the finer points of pathological research which I shall attempt to demonstrate to you.

One of the first questions to solve is, Whether disease of the heart in itself leads to disease of the kidneys? The general impression is that it often, indeed generally, does. But on analyzing a large number of cases I find that this belief is incorrect. I will here give some of the results of my investigations into the matter, and will take the records of the Pennsylvania Hospital for a period of ten years, extending from the beginning of 1877 to the beginning of 1887, and similar records from the Clinical Department of the Jefferson Medical College for a period from June, 1875, to January 1, 1888, selecting merely the cases of which it was reasonably certain that the cardiac affection was the primary lesion.

At the Pennsylvania Hospital were noted of such cases of *valvular heart affections*, 76; at the Jefferson Medical College Clinic, of valvular heart affections, 51. Of these 127 cases, in all of which the urine was examined, for the most part repeatedly and at different times, and in many of which, especially in the cases at the Pennsylvania Hospital, autopsies are recorded, there were in 92, it is specifically stated, no evidence of any kidney affection, as shown by the absence of casts, of albumen, and, in a number of instances, by the notes of the post-mortem changes. The 76 valvular heart cases at the Pennsylvania Hospital furnished 28 cases in which some concurrent kidney affection was observed; the 50 cases at the Jefferson Medical College Clinic showed but 7. Of these 7, in 1 (Case III. of series), happening in a child with a mitral regurgitation, there had been scarlet fever three years, and an attack of rheumatism two years prior to the record of the case; there was hypertrophy with dilatation in connection with the valvular disease, and chronic parenchymatous nephritis. In another case (Case XIII.), that of a man fifty-two years of age, the mitral lesion, following rheumatism, was associated with urine one-fourth albuminous and of character usual in parenchymatous nephritis. The dropsy began in the abdomen, the swelling there preceding that of the feet and legs for nearly a year. In the third case (Case XXV.), a presystolic mitral murmur was found with hypertrophy of moderate degree, but with considerable dilatation. The heart's action was irregular, the urine was full of albumen, and attacks of cardiac asthma and occasional uræmic convulsions occurred. In the fourth case (Case XX.), a married woman, twenty years of age, there was some abdominal dropsy and a puffy face. The valvular lesion consisted in aortic regurgitation with a slight mitral regurgitation; considerable hypertrophy of the heart existed. The pulse was 128. The urine was free from sugar, of specific gravity 1.018, and contained small amounts of albumen. The kidney was considered to be in a state of parenchymatous inflammation.

Of these four cases, in all of which, probably, the kidneys were in a state of chronic parenchymatous nephritis, the first ought really to be excluded, since the kidney affection much more likely had its origin in scarlet fever, leaving thus only three undoubted cases.

In 3 more of the series albumen is mentioned as occurring in very small quantities. In one (Case XVI.), it was present without tube casts; in another (Case XXXI.), where a mitral presystolic murmur as well as an adherent pericardium existed, a few hyaline tube casts were discerned in a feebly acid urine, free from bile and sugar, but containing a small amount of albumen and crystals of oxalate of lime. In a third, in which mitral regurgitation with considerable hypertrophy and dilatation was noted, albumen in small and varying amounts was detected, but nothing else. In all three instances it was due to congestion of the kidneys, and not an evidence of Bright's disease. We have then but 3 cases in 51 in which a kidney affection really existed.

I will now examine the 28 cases out of the 76 recorded at the Pennsylvania Hospital, in which the urine examinations indicated coexisting disorder of the kidneys. In 16 of the 28 the record speaks specifically of but small amounts or of traces of albumen and of the absence of casts. In one of these (Case I.), the autopsy tells of kidneys showing no marked alteration of structure except that, weighing respectively six and seven ounces, the capsules were thickened, and the right kidney contained two small cysts. The highest amount of albumen recorded in these 16 cases is one-sixth of the test-tube, sometimes one-tenth, and often the merest trace.

In 6 cases (Cases II., XVI., LV., LXIII., LXIX., LXXVI.) tube casts are described in addition to the albumen. They were hyaline or slightly granular casts. In 2 of these 6 cases we have autopsies; and this is a summary of the record. In one (Case LXIII.), the hypertrophied heart weighed thirty-six ounces, there was marked insufficiency from contraction of the aortic leaflets, slight thickening of the mitral; the kidneys were congested, cyanotic, otherwise normal. In the other (Case LXIX.), the heart weighed fifteen ounces, the mitral and aortic valves were both thickened. The kidneys were congested, but not altered in structure.

In 6 cases the clinical record is that of much more serious disease. But one of these (Case LXV.) we must at once exclude, as the albumen, the pus, the epithelium, which existed in connection with the mitral disease were clearly of vesical origin, and any renal implication was most doubtful. Five cases of marked renal affection, with highly albuminous urine, we still have to account for. Of these, in one (Case LXI.) there were also pus cells and bladder epithelium; but distinct renal casts were detected, and the case was looked upon as one of parenchymatous nephritis complicating mitral insufficiency. In two (Cases XLII. and LIV.), the same view was taken of the renal complications, associated in Case XLII. with mitral narrowing; in Case LIV. with both mitral and aortic insufficiency. But in this case, in which highly granular and hyaline casts abounded, and in which the albumen was in bulk two-thirds of the test-tube, the conclusion is vitiated by the patient having been a great drunkard, and all his tissues having been profoundly altered. Case XLVII. is very instructive on account of its clear history. It happened in a man who had rheumatism thirteen years prior to admission into the hospital, but in whom dropsy and puffiness of the face only appeared two months before. The urine contained albumen, granules, and fatty casts. The greatly enlarged heart weighed, with clots, thirty-six ounces, without clots thirty-two ounces. The mitral orifice readily admitted four fingers, so did the tricuspid orifice; the aorta was fully twice as thick as normal, but the aortic valves were competent. The walls of the right auricle were double the natural thickness; the left ventricle, its cavity enlarged about one-half, had walls measuring near the base one inch. The kidneys were engorged, and appeared in the early stages of parenchymatous nephritis. The left kidney, weighing twenty-four ounces, contained a few cysts on the surface, its bloodvessels were prominent, but not thickened. The right kidney was about the same in size and structure.

In Case LXX. we also have an autopsy. The aortic and mitral leaflets were thickened and contracted. The kidneys were large, firm, harder than normal and evidently diseased, but showed no adherent capsules or signs of contraction.

Summing up the whole inquiry, we find in 127 cases of valvular disease of the heart, but 8 in which any true affection of the kidney existed—anything more than mere congestion. And among these eight, there is not one instance of the contracted or cirrhotic kidney. In truth, the kidney disorder that results from a valvular disease of the heart is simply a congested kidney of full size, redder, a little more glistening, and in elderly people, or where the congestion has been of long standing, firmer than normal, showing even slight increase of fibroid texture, and, perhaps, a rather more adherent capsule. Persistent engorgement of the renal veins gives the well-known livid, cyanotic appearance to the somewhat indurated organ. The epithelium of the tubes is swollen, and finally undergoes granular degeneration.

I have, by the analysis of the cases, endeavored to give you a proof how rarely valvular disease of the heart leads to chronic disease of the kidneys, other than congestion. When it does, the form of affection is that of a chronic congestion, which, in its turn, passes into a parenchymatous nephritis. The granular contracted kidney does not, I believe, result from the process of congestion just alluded to; though, as I have already said, occasionally, especially in elderly people, the kidneys from long-standing congestion may appear hard, and exhibit a slight amount of fibroid change. These statements seem at variance with those of one of the most eminent of your members, Dr. Delafield,[1] who, in 137 cases of death from heart disease, reports 27 large white kidneys, 29 atrophied kidneys, and 28 of chronic nephritis which could not be classed as either large white, or atrophied organs. Perhaps the apparent discrepancy is to be explained by the cases being heart disease, of which it was not specifically known whether it preceded the renal affection or followed it.

During life it may be very difficult in individual cases to determine whether we have, as the result of the heart malady, simply a congestive condition of the kidneys, or real Bright's disease; in truth, as in both states dropsy is a prominent symptom, we obtain but little aid from the general symptoms, having to base our opinion largely on an accurate cardiac investigation. It may be thought that the urine would afford us much assistance; but this it does not always do. A good many of my observations in purely cardiac cases, speak of urine of low specific gravity, scanty, containing traces of albumen, and here and there casts. The character of these casts is, for the most part, epithelial and not highly granular, though this, too, must not be taken as an absolute rule. On the whole, the most important diagnostic sign, with reference to the urine, is found in the slight and varying amounts of albumen and in the infrequency of the casts. Moreover, though it has been stated that the urine in even these heart cases with renal complication which is not Bright's disease, may have a low specific gravity—in one of my cases it was only 1.006—as a rule, the specific gravity of the scanty urine is high, ranging from 1.020 to 1.024; in one instance of mitral disease my record speaks of 1.030. Sugar was examined for, but found only once (Case XXII. of the Jefferson Medical

[1] System of Medicine by American authors, vol. iv.

College series); here there was aortic regurgitation. Urates, my notes say, are often abundant, biliary coloring matter is not infrequent.

The character of the pulse, the absence of marked arterial tension, and the precise physical signs of the cardiac disease, give us more valuable diagnostic evidence, taken as a whole, than the state of the urine. We may also lay stress on the want of uræmic symptoms, and avail ourselves of the ophthalmoscope as a means of diagnosis. It has, in fact, happened to me several times to determine, by finding albuminuric retinitis, the true meaning of the renal change and the secondary nature of the valvular affection. In one of these instances, indeed, albumen was at several examinations absent, tube casts were but few, the specific gravity was, as a rule, low; but the whole progress of the case, the uræmic symptoms which arose, the absence of dropsy, showed, irrespective of the eye appearances, that the renal malady was the preponderating and original affection.

Before proceeding it may not be without interest to point out that the most common form of valvular disease, associated with renal disorder of the kinds we have found to exist, is mitral narrowing. In 8 of the cases at the Pennsylvania Hospital it is noted only in 2 that the urine is free from albumen. In the cases in which a real structural affection, a parenchymatous nephritis, is developed, mitral stenosis has a preponderating influence. Next stands—for tricuspid disease is so rare that I have not data sufficient to judge by—mitral regurgitation. In uncomplicated aortic disease albumen and casts are very seldom detected in the urine, so seldom that it is always a question whether a mitral complication is present when kidney engorgement is found.

Pure *hypertrophy* and pure *dilatation*, instances, therefore, of enlargement without valve affection, give us the same form of kidney derangement we have been studying. But with reference to hypertrophy, unless the cavities are at the same time decidedly stretched we do not find albuminous urine. Thus this existed in only 1 out of 10 cases noted at the Jefferson Clinic. In pure dilatation, urine albuminous in traces, indicative of congestion of the kidney, is more common. Still, it does not exist in the majority of cases; and I have known it not to appear until the last week of life, even though that life had been a burden for months, owing to the enormous dropsical swelling and the turgid lungs.

We have been studying diseases of the heart and the kind of kidney affections they induce, selecting for analysis cases where, from the history, or the post-mortem results, or from both, the record of the antecedent malady was clear. We now turn to diseases of the kidney and their combination with diseases of the heart. It is well known that this combination is a frequent one. We find diseases of the kidney associated with valvular disease of the heart; with hypertrophy; with dilatation; and with pericardial affections. In studying the subject I mean to draw conclusions only from instances in which from the history, as well as from the concomitant features of the case, we may fairly judge that the kidneys were the first or at least simultaneously diseased.

Let us examine the *valvular diseases of the heart* as they are found associated with affections of the kidney. I find, looking at the records of the Pennsylvania Hospital for ten years, from the beginning of 1877 to the beginning of 1887, that in 101 cases of renal disease in which the state of the heart is particularly mentioned, 41 cases have a concurrent valvular heart affection, and in 60 there is no such lesion. Of the total 101 cases, 57 are acute Bright's disease, and 44 chronic. Of the 41 renal cases with valvular lesion of the heart, 29 are Bright's cases of the chronic type and 12 are of the acute type. Of the 29 cases of chronic Bright's disease with associated valvular heart lesion, it is noticed that 13 have a preceding history of rheumatism. In 5 there is a positive statement of no preceding rheumatic history. In the other 11 cases, nothing is remarked about rheumatism.

Of the 12 acute cases with concurrent valvular lesion, 3 cases have the record that rheumatism did not precede. In the other 9 cases nothing is said with reference to a rheumatic history.

Out of 29 cases of chronic Bright's disease with valvular disease, the age of the youngest was thirty-three years; 14 of the 29 were beyond the age of forty-five years; the oldest was sixty-five years of age.

Of the 44 chronic renal cases, 8 were examples of the large white kidney. The ages of these 8 were from forty-eight to sixty years. 1 case had double mitral and aortic murmurs, and was preceded by several attacks of acute rheumatism. Of the other 7, nothing is stated about either the heart or a rheumatic history.

Of the 57 acute renal cases, in none are mentioned signs of cardiac hypertrophy without a valvular affection, nor, indeed, do the notes show that even with this complication was the heart enlarged.

In the notes of the Clinic of the Jefferson Medical College, in 21 acute cases of Bright's disease, 20 of which had marked dropsical symptoms, the heart was found to be normal in all but 4, 2 of which had had a previous history of acute rheumatism. In these 4 cases there were evidences of valvular disease without hypertrophy.

From an analysis of these observations, it becomes evident that the character of the kidney affection, in combination with the valvular lesion in the heart, is in the vast majority of instances the contracted kidney. Next stands acute Bright's disease, where also we find valvular affections, but here without the hypertrophy so common in the first group. In the acute, the strong influence rheumatism exerts is very evident; nor is that influence lost in the chronic, where an unusually large proportion are associated with rheumatism, too large a proportion for us to assume that it is a mere coincidence.

Let us inquire what the state of the valve lesion is. It is chiefly an affection of the mitral valve, consisting in a thickening of the mitral, with here and there rough deposits. Next in frequency, but with similar pathological changes, we observe a lesion of the aortic valves, occasioning either aortic narrowing or aortic regurgitation. A further cause of the valve affection is seen in some of these cases to be due, I believe, to the hypertrophy of the heart forming part of the Bright's disease preceding some general thickening of the valve, though even this may be wanting. A stretching of the valve subsequently takes place, but insufficient to close the orifice in the enlarging heart. Thus the hypertrophy and the dilated condition of the cavities give rise to the valvular imperfection rather than this to the enlargement of the heart. It is in this way that I explain some very striking and interesting cases of hypertrophy occurring in advance of the valvular lesion, which I have observed, and in

which the autopsies showed simply this imperfect closure of the orifice with a slightly thickened mitral valve, and at times with shortened and more rigid papillary muscles.

I have known, but far less often, a similar state at the aortic orifice. The aortic disease that existed was due to the stretching of the valve, which, having reached a certain point, could go no further. This stretching, with the simultaneous thickening, produced an opening through which the blood flowed back. It is thus that we may have a valvular disease following hypertrophy with dilatation, rather as the result of this process, than the hypertrophy and dilatation the result of it. If you ask me whether this is a common cause of valvular lesion in Bright's disease, I say it is distinctly not; it is very much less common than marked valvular thickening with degenerative change.

You see, then, that the valvular disease of the heart which occurs in diseases of the kidney, may be of varying origin; chronic thickening, deposits, degenerative changes, coexisting rheumatic alterations, which have led to these changes, and, lastly, mere hypertrophy and dilatation, which, associated, perhaps, with slight valve thickening, or with rigid papillary muscles, in its turn leads to valvular imperfection. Omitting the last-named group, the ordinary valvular affections in the Bright's diseases, are the result of the altered tissue nutrition of the valves and the degenerative changes which take place there, as they take place in both the large and small vessels of the body. They are favored to a greater or less degree by the morbid products, which, from want of proper elimination on the part of the kidneys, circulate in the blood. It may also be a question whether, in part at least, the altered nutrition of the valve may not be due to affection of their nervous supply. The changes, the degenerative ones certainly, are favored by age. Yet we cannot assume that age is the important factor it appears at first sight; for the acute Bright's affections show also, as has been proved, a strong tendency to the implication of the valvular apparatus, and the acute affections are much more common in the young, or, at least, in younger people, than are the chronic affections. Let me further notice, once more, a point brought out in the analysis of the cases submitted to you, namely, the frequent existence of rheumatism. This may well produce the valve injuries at the same time that it leads to other changes in the body; and thus be a general cause, both for the valvular affection and for the disease of the kidney and of other textures.

Before ceasing to examine this aspect of the subject, I will call your attention to some purely clinical facts which must make us receive with caution many of the statements of coexisting valvular disease of the heart and of Bright's disease. It is often recorded that there was present a soft murmur, variously heard; in some instances at the apex, in others at the right base. Now these murmurs in Bright's disease are not the result of valvular affection. They come from the state of the blood; or they are simply murmurs from temporary perversion of valve action, what we might call functional murmurs. They are inconstant, they are soft, and they are not signs of valvular disease of the heart. You will easily see that the error is all the more readily committed because we have hypertrophy, with or without dilatation, as such a common attendant upon Bright's malady. Thus, the mere hearing of a murmur in the heart is not a sign of valve affection in Bright's disease, not even when there is coexisting hypertrophy. We have to take into account its persistence, its character, generally rough, the state of the second sound of the heart, and the fact that it may be heard in the axilla, and posteriorly near the angle of the scapula, to make clear that it is of organic type, and not of the temporary character just referred to. Bearing this in mind, we shall have to reject a great many of the cases of so-called valvular disease of the heart often loosely reported, in which the only evidence of the valvular affection is based upon a murmur, the particular character of which is not stated; or its softness or temporary nature is alluded to, but an erroneous conclusion is drawn from its existence.

The difficulty does not exist with reference to diastolic murmurs, which, in my experience, are always organic. But it is not lessened by a study of the pulse, which is in itself altered by the arterial lesions of the Bright's malady and by the thickened left ventricle; nor can we place, for similar reasons, much dependence on sphygmographic tracings.

I think, then, that the number of cases of valvular disease of the heart, existing as a complication of Bright's disease, is more often over-stated than under-stated. Indeed, with the greatest care, unless the case have been for a long time under observation, it may be almost impossible to detect the true relation between the maladies. Much of the difficulty will be, however, solved, if we accustom ourselves to look upon them as not dependant upon each other, but due to a common cause, working almost simultaneously, or even at different periods, mischief in kidney, heart, and other textures. To the frequent starting of this common cause in rheumatism, attention has been called.

Let us pass to an examination of the *hypertrophy of the heart* which exists in combination with Bright's disease of the kidneys; I mean where the hypertrophy, with or without some dilatation, is a pure process, and not complicated with valvular disease. With reference to the acute cases of Bright's disease, I have already mentioned that we do not find hypertrophy. In the 22 cases of this character at the Jefferson Clinic, and in the 57 cases at the Pennsylvania Hospital, therefore in 79 cases, in most of which there was marked dropsy, in not one were the signs those of hypertrophy, not even in the instances with valvular lesion. A few doubtful exceptions are observed in the notes where strength of impulse is mentioned; but in these it is probable that the valvular affection which coexisted had its origin in a previous attack of rheumatism.

Thus then we may assume as positive that hypertrophy of the heart does not occur in acute Bright's disease. This is vastly different in the chronic form of the malady. Here, as is well known, hypertrophy is the rule. This subject is a matter of such common observation that it scarcely needs reinforcement by figures; but I will quote, since they are based solely upon post-mortem records on a most extensive scale, the recent researches of Goodheart in *Guy's Hospital Reports* for 1886.

In the ten years from 1873 to 1882 inclusive, there were autopsies of 344 cases of granular kidney, and of 196 of chronic parenchymatous nephritis. The weight of the heart in the cases in which the kidneys were described as granular, was in only 103 under 12 ounces, which was, therefore, within the limits of average weight. In

226 it was above this weight. Making allowance for all possible exceptions, as old age and wasting disease, and adding 36 which were hypertrophied hearts, though of average weight, there are 262 cases of marked hypertrophy in 329 undoubtedly granular kidneys.

After making all deductions for the cases of chronic parenchymatous nephritis, there were in 25 only a heart of average weight; in 119 there was hypertrophy of the left ventricle, a proportion of over 1 to 4. In lardaceous disease of the kidney, hypertrophic changes in the heart and arteries were not observed, which agrees well with the general observation on the subject.

Dilatation of the heart becomes associated in a more or less marked degree with the growing muscle. It affects preëminently the left side of the heart. In Goodhart's paper, just quoted, I find 51 cases of notable dilatation of the left ventricle associated with hypertrophy in the 344 cases of granular kidney, and 33 cases in the 196 cases of chronic parenchymatous nephritis. It would, therefore, appear that the dilatation predominates in chronic parenchymatous nephritis; while pure hypertrophy does so in granular kidney.

In cases of hypertrophy such as I have described, the heart attains very great size; the muscles are firm; for the most part it is a pure hypertrophy, only here and there there takes place some increase of the fibrous texture as well as of the muscular. The muscular fibres are a little more opaque, and sometimes more granular than normal. As the disease advances, secondary degeneration, granular and fatty, may occur; but they do not happen unless there be decided coexisting disease of the vessels.

The state of the vessels in these instances of hypertrophy is very interesting to note. They show the same condition which has been found in the kidneys, in the brain, in the spinal marrow, in the lungs, and in many other parts of the body.

The inner coat is thickened, the muscular coat hypertrophied, the outer coat in a state of fibroid change, and the whole lumen of the vessel greatly lessened by these encroaching lesions. This lessening of the calibre is the same, as are the changes the same, that we find in the renal vessels, and it may take place to a very great degree. My colleague at the Pennsylvania Hospital, Dr. Arthur V. Meigs, has recently shown me a section of a heart obtained from a man under his care who died of granular kidney, with aortic valve disease, and left ventricle from three-fourths of an inch to an inch thick, exhibiting besides increased muscle beginning interstitial change. Microscopically examined, the first ascending branch of the left coronary artery was so much thickened, chiefly by the increase of the intima, that the lumen of the vessel was a mere chink, the thickening being irregular, about four times more on one side than the other.

You will readily see how such a state of things might lead to secondary degeneration by cutting off the blood supply from the hypertrophied muscle; and it is most likely that these degenerations which we have in the hypertrophied hearts of Bright's disease, which, however, I believe are not the rule, come on as an after-result of the altered vascular supply.

As a few minutes ago, I called your attention to some points of diagnosis with reference to valvular disease in Bright's affection, I may now call your attention to some points with reference to hypertrophy. It is not always easy to make this out clinically. We have to consider not only the size of the percussion dulness, but the extent of the impulse as well as its force and position; the lowered apex beat, which is often felt on a line with or beyond the nipple; and the heavy character of the first sound. Nor must we fail to take into account the character of the second sound, its accentuation at the base, which commonly happens in these hypertrophies in connection with renal change. Strong, extended impulse, displaced apex, altered sounds, and increased percussion dulness are the phenomena by which we judge; but not by any one of these alone, certainly not by the impulse, which may be temporarily increased by other causes than cardiac hypertrophy. On the whole, I lay most stress on the altered character of the sounds of the heart, both at the apex and the base, and the changed position of the impulse.

The enlargement of the heart which takes place in Bright's disease of the kidney may be made use of in prognosis. We are often greatly at a loss to form an opinion as to the probable length of the case and to the way in which it is progressing. Up to a certain point, the occurrence of dropsy and of eye changes will assist us, as well as the evidences of marked arterial tension. But dropsy, while common in chronic parenchymatous nephritis, is very generally absent, or but slight in cirrhotic kidney. The urinary examination does not always afford us much light, for some of the worst cases are those in which—I allude especially to the cirrhotic kidney—the amount of albumen is small, or often temporarily absent, and in which the tube-casts are few; nor can we lay too much stress on the character of these casts. It is under these circumstances that I think the heart condition becomes an especially valuable means of prognosis. Where the heart is but slightly affected, there will be reason to believe that the case will continue for some time, provided we do not observe signs of uræmic poisoning. Where, on the other hand, the hypertrophy is marked, there is ground for the fear that the disease is more general, is advancing, and that the case will not belong to those long cases of the affection which we sometimes encounter. Thus the study of the heart may be made use of as a means of estimating the amount of general change and the likelihood of shorter or longer life.

Let me reiterate the view that, according to my experience, the hypertrophy in the majority of instances is a pure hypertrophy, unconnected with degenerative changes. It is certainly so in the earlier stages of the affection. In instances of long-standing disease and in elderly people, these degenerative changes may be found in the progress of the case; but my observations do not at all agree with those of Buhl, who has stated that fibrous and chronic interstitial myocarditis is very frequently found in connection with the hypertrophy. To its occasional occurrence, I have already alluded.

Dilatation of the heart, unconnected with hypertrophy, or at least predominating over the increase of the muscular walls, is extremely rare. When it happens, it is the latter kind of cases, namely, beginning as hypertrophy, but the rate of increase of the muscular structure not remaining in proportion to the dilatation of the cavities that is met with. Among the cases at the Jefferson Clinic, I have collected some instances of what might be fairly called dilatation unaccompanied by hypertrophy, or attended only by a slight degree of hypertrophy; and

I have seen a small number in private practice. Goodhart points out that in the young the risk of dilatation of the heart is much greater than in older persons.

Another lesion of the heart which we observe in connection with Bright's disease, both acute and chronic, is *pericarditis*. But inflammation of the outer membrane of the heart forms only part of that general tendency to serous inflammation which we find in Bright's disease. It is probably due to the contaminated state of the blood, and neither its occurrence nor its explanation need here detain us.

Of all the heart affections passed in review, hypertrophy is the most common. Let us look at its cause. I leave out of consideration those cases where clearly existing valvular disease may have led to the hypertrophy; though even here it is always questionable whether some of the increased growth be not due to other causes than the valvular affection, and may not have preceded it. I will take the pure instances of hypertrophy and ask, How are we to explain them? It will serve our purpose best if, in considering this much mooted and most intricate subject, we give a short summary of the different views held as to the cause of the hypertrophy, rather than attempt an historical review of how and by whom these views have been brought forward.

One of the main views entertained is, that the hypertrophy of the heart is due to the blood contaminated by renal excrementitious matter, exerting a stimulating effect upon the action of the heart, thus leading to hypertrophy of the ventricle; and, further, that the impure blood requires greater force of ventricular contraction to propel it through the unwilling vessels. This view has the great authority of Bright, and is to this day advocated by some eminent teachers.

A second view, while taking note of the influence of the impure blood, holds that the altered blood tension produced by the disease of the kidney, and the difficulty of the blood circulating through it, give rise not only to the well-known feature of heightened arterial tension, but to increased size of the heart to overcome the resistance of the renal organs. This is largely the view of Traube and some of the German investigators, and has been recently reaffirmed by Cornil.[1]

A third view is that the left ventricle beats with augmented force because the arterioles refuse to receive the altered blood, and in consequence of the resistance these vessels hypertrophy, especially in the arterial coat. To overcome this muscular resistance, the heart has to act with greater force, and its muscles increase. This is, in the main, the view of George Johnson, and is largely based on that change in the muscular coat of the arteries which he has so well described.

A fourth view is that a fibroid degeneration, a fibroid overgrowth of the outer coats of the arteries, takes place over a large portion of the vascular system. In consequence of this, the heart has to struggle to overcome the resistance of the permanently narrowed vessels, narrowed by these hyaline, fibroid changes; and the enhanced blood-pressure shows not only in the raised arterial tension but the increased resistance leads also to cardiac hypertrophy. This is mainly the view of arterio-capillary changes, of a vascular fibrosis as the cause of hypertrophy of the heart, which has been strongly and ably advocated by Gull and Sutton.

The last two views have much in common, at least as regards the production of the hypertrophy in consequence of the altered condition of the vessels.

I will mention a fifth view, which for the present I shall simply indicate, namely, that the hypertrophy, as well as to a great extent the vascular changes, are the result of a common process which takes its origin in the ganglionic nervous system. This is the view which in its main features flows out of some researches made by Dr. Longstreth and myself, and which here I simply state, intending presently to call your attention to the particular facts bearing on it.

Now, analyzing these different views, let us first take notice of the assumed influence of impure blood, and it is for practical purposes possible at the same time to examine into the supposed alteration of the blood-pressure due to the resisting kidneys. These views which I thus group together seem to me untenable. If true, why should we not have hypertrophy of the heart, and especially the form of hypertrophy far the most common, of the left ventricle, in other diseases of the kidneys than Bright's disease? Why should not, too, in the acute form of this malady, the heart be increased? It might be objected to this argument that, in the acute affection, the disease does not last long enough to produce muscular increase; but the objection will not hold good with reference to the other diseases of the kidney, in which serious, we might even say destructive kidney lesions take place, in which uræmic symptoms happen, yet in which there is no cardiac hypertrophy. I will take the instances, a number of which have come under my observation, of persons dying from extensive cystic degeneration of the kidneys in whom the heart was found absolutely normal.

Here is one. In a gentleman whom I attended with a very large tumor in the abdomen, and who passed bloody and albuminous urine, there were for three weeks before death most marked uræmic symptoms. At the autopsy both kidneys were enormously enlarged, measured each about fourteen inches in length, were filled with cysts, and no trace of renal structure could be detected. It was, indeed, difficult to understand how life could have lasted so long with such extreme disorganization; yet the heart was absolutely healthy.

In a second case, the kidneys measured six inches in length, nearly four in width, and three and a half in thickness. The tissue was almost wholly converted into cysts, from the size of an egg to that of a pin's head. There was no disease of the heart. This specimen is now in the Museum of the Pennsylvania Hospital.

In a third case the two kidneys were greatly enlarged, irregular in outline, the capsule was roughened by shreds of inflammatory adhesions; the organs, measuring each about seven inches in length and four in width, were filled with cysts. The thoracic viscera were in an absolutely normal condition. The liver was found to be highly fatty. The kidneys are also in the Museum of the Pennsylvania Hospital.

I shall cite two more cases, partly to sustain my view, and partly on account of the evident uræmia which preceded death. A man, under forty years of age, by profession a gambler, was admitted into the Pennsylvania Hospital in a comatose condition. He had been struck

[1] Compte-Rendu du Congres International, tome i., Copenhagen, 1886.

at by a companion, while drinking in a saloon, but was not hit. Immediately afterward, to the astonishment of those around him, he fell to the ground unconscious, and remained in this condition until death, a day or two later. No history of his previous state of health was obtainable, further than that he had seemed well, and was nightly occupied at his business as a dealer in gambling games. The urine was found to contain some albumen, and a large amount of sediment, mostly of a cellular character. Death occurred in the hospital with all the signs of marked uræmia. The urinary secretion was extremely scanty, and the unconsciousness profound.

The circumstances connected with the death led to the arrest of the companion who aimed the blow; but the investigation of the coroner showed that death was due to natural causes, and not to violence. At the autopsy, the kidneys were found to be in an advanced state of cystic degeneration. They were greatly enlarged in all directions, and the tissue was almost entirely converted into cysts. The disease had evidently been of long duration. The lungs were normal, so was the heart.

Yet another case. A young servant woman, who had been in good health so far as known, fell on the floor while engaged at the wash-tub, and was found lying in an unconscious condition. She partly regained consciousness, but, on her admission into the hospital, could give no satisfactory history. She died a few days later in a comatose state, with every evidence of uræmia. The kidneys showed advanced cystic degeneration. The heart was normal, and no lesions were presented in the other organs, save congestion of the lungs.

I have thus presented to you five cases leading to death with the most advanced cystic degeneration of the kidneys existing, with the blood evidently impure, and, finally, occasioning, in the majority, marked uræmic symptoms, yet with actually normal condition of the heart.

I might go further in this line of argument, and call your attention to the enormous kidneys with calculi imbedded in them, kidneys which produce abdominal tumors large enough to be mistaken for gastric and omental cancers, also leading to death, and in which no disease of the heart was found; so, too, in instances of cancer of the organ; though, in this condition certainly, and even in cystic degeneration at times, the argument is somewhat vitiated by the fact that, while one kidney undergoes extreme change and disorganization, the other may remain normal, or, at least, be still capable of performing its function fairly well.

The next views, those of arterial changes, whether in the muscular coat producing muscular hypertrophy, or from fibroid growth in the outer coats, I shall not discuss, further than to say that I believe the anatomical researches on which they are founded to be correct, having often seen the conditions referred to. Nor is it necessary to go into the question which is the most common of these changes; for I think that both may be found in different cases, and even in the same case at different stages. While thus concurring in the correctness of these observations, I will point out how insufficient they are to interpret the cardiac hypertrophy; how impossible it is to prove that blood is resisted by the altered vessels on account of its character; how difficult it is to explain the enlarged heart simply as the result of vascular changes, when we have striking alterations in the vessels, both large and small, in old age, and from syphilis, and in and beyond aneurisms, where we do not find cardiac hypertrophy happening as rapidly, or to anything like the extent that it does in Bright's disease, if, indeed, it happen at all.

Let me now, before taking up the fifth view, which I told you had grown out of observations by Dr. Longstreth and myself on the nervous ganglia, call your attention briefly to these observations, and supplement them by some which have not hitherto been published. Let me add, and here acknowledge, that in the researches about to be brought forward, which were most difficult and laborious to carry out, it is to the care and attention of Dr. Longstreth that they owe their merit, rather than to anything I have myself been able to do. Let me also recall that in the investigations we made on Bright's disease[1] we found marked changes in the renal ganglia, of a character showing increased fibrous tissue and atrophy of the ganglion cells. These were associated with decided alterations in the renal vessels, as exhibited to you in these micro-photographs, which will make the matter clearer to you than I can from description. This condition in the renal ganglia has been confirmed by Saundby,[2] who, however he differs with our conclusions, has seen exactly the same pathological lesions.

I shall proceed to present to you the statement based upon eleven cases accurately observed, in which the cervical ganglia from which the cardiac nerves arise were minutely examined; and five of these cases, which tell the tale of all, I will give you in some detail. The records relate particularly to the inferior cervical ganglia, giving off mainly the inferior cardiac nerve. All of the cases were interstitial nephritis; 9 were chronic contracting kidneys, and 2 contracting kidneys of more acute form.

CASE I.—Emma H., æt. sixty-five, admitted into the Pennsylvania Hospital May 18, 1885; died May 18, 1885; admitted for cerebral hemorrhage; had vomited; was unconscious, and completely relaxed or paralyzed; had a few irregular convulsive movements; two quarts of highly albuminous urine were drawn by catheter; she died in three hours. Post-mortem examination showed an extravasation of blood in the external part of the left hemisphere, but it had not extended to the ventricles. Death resulted in this case apparently from uræmia, rather than from the cerebral clot directly. The kidneys were very much reduced in size, with thickened capsules and granular surfaces, dotted with small cysts. The left ventricular wall was much thickened, measuring over one inch. The minute structures of the inferior cervical ganglion showed many marked changes; the ganglion cells were deeply pigmented, appeared shrivelled or compressed; equally to be noticed was the tissue around the ganglion cells, composed of a delicate fibrillar tissue in which appeared very numerous round and spindle nuclei. Some of these nuclei were doubtless those of the nerve structures, but the majority were a new growth of connective and fibrillar elements; in places they were so numerous as to obscure the ganglion cells. In the greater part the vesicular nucleus of the ganglion cells could be seen, but the nucleus was generally visible faintly stained with carmine. A very striking feature was the appearance of the vascular structures; in the first place, the capillaries seemed in some parts to pervade nearly the whole area, some with a narrow calibre carrying but a single red blood corpuscle, and from this width upward to those with six corpuscles abreast, and many of these vascular tubes presented ampullar dilatations; some of

[1] American Journal of the Medical Sciences, July, 1880.

[2] British Medical Journal, Jan. 13, 1883.

this condition can be accounted for by the mode of death, but the most was due to permanent changes. The walls of the arterioles showed the thickening so often found and described in the arterial walls in these cases of renal disease.

CASE II.—Hannah G., æt. seventy, admitted September 4, 1884. No. 920. Died November 13, 1884. Had been gradually failing in health, and lately had chest symptoms and œdema; the secretion of urine had slowly diminished. On admission there was orthopnœa, the lungs were full of coarse râles, and were emphysematous, rendering any accurate determination of the size and condition of the heart impossible. The apex of the heart was far to the left of the normal. There was ascites and also diarrhœa.

The heart showed hypertrophy of the left ventricle, its tissue was undergoing fatty changes and atrophy; the kidneys although much altered did not exhibit the marked changes of the other cases. The minute structure of the inferior cervical ganglion cells indicated atrophic conditions; the cells were pale with less than the normal amount of pigment (as usually seen in the ganglia of adults dying of disease), the nucleus was plainly visible, but the nucleolus stained with carmine very faintly. Between the ganglion cells the tissue was of firmer character than normal, and appeared to encircle these cells with stiff fibres. There were no round nuclei, but only flattened spindles in this space. The capillaries were not conspicuous, but the walls of the arterioles were altered, though to a less marked degree.

CASE III.—Mary McG., æt. fifty-two, admitted Nov. 3, 1884. No. 1288. Died Jan. 30, 1885. Her history tells of a severe cold followed by swelling of the legs; urine of dark color and much reduced in amount; later, nausea and vomiting. On admission, the urine was smoky and contained fifty per cent. of albumen; the microscope showed blood-, hyaline-, and granular-casts, and also some epithelial casts. Only twelve ounces of urine were passed in twenty-four hours. Dyspnœa and diarrhœa existed. Later came uræmic convulsions and strongly urinous odor of the breath and body. Post-mortem examination: Heart weighed sixteen ounces; right distended, left contracted and much hypertrophied. Liver small, pale, and granular. Kidneys reduced in size, firm, capsule adherent and the surface granular. The case was an acute attack of nephritis in a contracting kidney.

The microscopic examination of sections of the kidney of this case was very interesting, showing the majority of the Malpighian bodies converted into firm fibrous nodules, and only in a few places were the convoluted tubes to be seen. Here and there a Malpighian body presented somewhat of a normal aspect, with a few tubes around it in which the epithelium could be distinguished. The chief feature was the fresh outpouring of small indifferent cells, as seen in acute interstitial nephritis. The ganglion cells were in an advanced state of degeneration, full of granules, shrivelled, and the nucleus and nucleolus scarcely to be distinguished. Between these cells the tissue presented a fibrous aspect.

CASE IV.—Rose B., æt. thirty-seven, admitted Dec. 13, 1884. No. 1517. Died Jan. 12, 1885. The attack followed gradually after pregnancy, with greatly diminished urine secretion—one-half teacupful in twenty-four hours. Diarrhœa and swelling of abdomen were noted. The lungs were full of râles, and the pleural cavities contained effusion. The heart action was rapid, the pulse "corded," the artery hard. The urine was albuminous and contained granular casts. Post-mortem examination: Pleural and abdominal effusions; old pericarditis; hypertrophy of the left ventricle, the wall measuring one and a half inches; liver showed cicatrices, possibly syphilitic; kidneys very small, the capsule thickened, the surface highly granular, the cortex had almost disappeared, while the cones were much distorted.

The inferior cervical ganglion presented even more highly altered conditions than in the previous case. In not a few instances the cells seemed to have nearly vanished, or a few grains of pigment evidenced their site. Other cells while showing some pigment looked blurred, shrivelled, and irregular in outline. The nucleus was misshapen, and the nucleolus was like a fragment of poorly stained matter pushed over to one side of the nucleus and attached to its wall. Around the cells the fibrous tissue formed circles, closely resembling the thickening of Bowman's capsules in a contracting kidney. Even the spindle nuclei in the tissue between the cells had lost their distinctness, and the fibres looked less firm and rigid, but coarser.

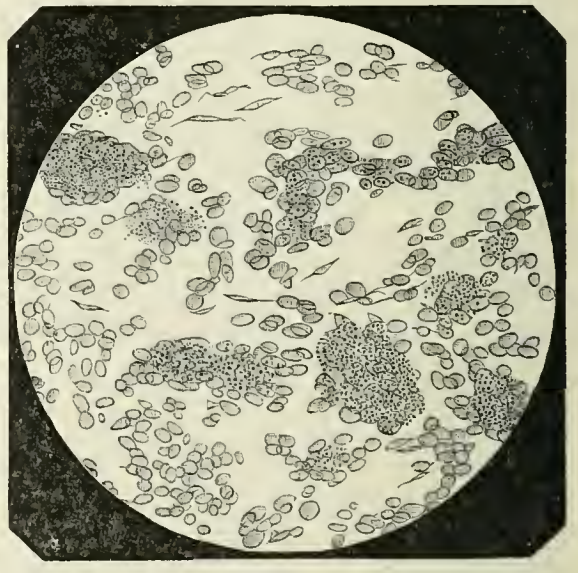
CASE V.—Mary H., æt. thirty-four. Admitted January 4, 1885. No. 1647. Died January 8, 1885.

For four months had had œdema, and for two days orthopnœa. The urine contained one-sixth albumen, and hyaline and granular casts. Death was sudden. Post-mortem examination showed old pericardial thickenings; weight twenty ounces, the left ventricle measured one and one-half inches. The kidneys weighed each one and one-half ounces, capsule thickened, and tightly adherent, the surface was very granular. On section, the cortex had almost disappeared, and the pyramids were much distorted.

This specimen was less well prepared for examination than the others, owing to the delay in obtaining the autopsy; but, however much the ganglion cells changed through the delay, this factor cannot account for the alterations of the tissue of the cardiac ganglion. The general conditions were the same very nearly as in the previous specimen.

I will not present to you any more details of cases, but will rather exhibit to you some microscopical drawings, taken directly from sections. Fig. 1 shows the ganglion

FIG. 1.



cells treated with the ordinary carmine staining, highly granular and pigmented; their outlines indistinct; the nucleated nucleus scarcely visible. The texture between the ganglion cells is crowded with small, rounded or spindle-shaped nuclei. These nuclei are specially numerous around and overlying the ganglion cells. The specimen is from a case in a moderately advanced stage of degeneration. Fig. 2 shows the lesion in a later stage. The whole tissue is firm and hard looking. The gang-

lion cells are surrounded by rings of coarse fibres, in which are a few remaining spindle nuclei. The ganglion cell itself has greatly shrivelled; the nucleus is pressed to one side, the nucleolus showing indistinctly. In some places the ganglion cells have wholly disappeared.

FIG. 2.

These, then, are the pathological minute lesions in Bright's disease in the ganglia regulating the heart movements. Before entering into the question of the bearing of the abnormal appearances, it may be well to answer the question, How does death come in the hypertrophied heart of Bright's disease? It comes with contraction of the left ventricle and dilatation of the right; in other words, it is a death of apnœa rather than one of asthenia. The diseased ganglia do not produce paralysis of the heart. As an instance of how even acute destruction of the ganglia will cause death, similar as regards the heart to that in Bright's disease, I cite the following case of injury and of hemorrhage into the cervical ganglia, the autopsy of which was most carefully made by Dr. Longstreth.

Thomas McC., aged fifty. Admitted into the Pennsylvania Hospital, February 1, 1882.

The patient fell on shipboard, fractured the third, fourth, and fifth cervical vertebræ, and became immediately paralyzed, both as to motion and sensation from the level of the second rib and deltoids downward; breathing was diaphragmatic; the pupils were contracted. There was priapism and retention of urine; the heart's action was frequent and feeble. Post-mortem examination showed large clots pressing on the cervical ganglia; at the third vertebra the cord was compressed and softened. The lungs were congested; the right heart was distended, the left ventricle firmly contracted. The microscopic examination of the ganglia, especially the inferior cervical ganglion, exhibited in many places the presence of extravasated blood around the ganglion cells; some of these cells showed already changes, especially pigmentation, although but a few hours had elapsed between the accident and death; in other respects the cells and tissue of the ganglion appeared normal. The kidneys were normal.

But to return to the examination of hypertrophy of the heart in Bright's disease. I have, I trust, made clear to you that there exist associated with the enlarged heart, marked changes in the ganglia of the sympathetic nerve from which the cardiac nerves are derived. Is it going too far to assume that these changes are an integral part of the disease; that they may determine the hypertrophy? How, I cannot explain to you exactly. It would not be difficult to bring forward a theory of loss of controlling influence on the heart, produced by the altered condition of the nervous apparatus; but our knowledge of the physiology of the nerve supply of the heart is not accurate enough to admit of absolute reasoning from cause to effect. Still, that disturbed nerve power produces changes in structure by affecting its nutrition, we know in every tissue of the body. Why should not the same be true for the heart? Again, if we adopt this view of the derangement of nerve condition and of the vasomotor influence being the starting-point, we can readily explain the well-known lesions in the vessels, both large and small. Indeed, when we look at the wide-spread changes which occur in them in Bright's disease, especially in its chronic form; when we see everywhere accumulating the evidence that these changes happen in all the vessels of the body, in those of the spinal cord, the brain, the lungs, the liver, in veins as well as arteries—we are driven to the conclusion that there must be some general cause at work which determines so great, so universal an alteration. That general cause, from the nature of things, can only be in the blood, in the vascular system itself, or come from the nervous offices which give life to the vascular system. The change is too extensive to be a mere self-determined local growth of the coats of the vessels. We cannot, indeed, ignore the agency of the waste-laden blood in its full development. But what starts the change? What is the cause of the degeneration? Is it not fair to look beside the blood, to a cause so predominant as the nervous influence, which is everywhere?

I would thus locate as most likely the original starting-point of the alteration, alike of the vessels and of the heart muscle, in the nervous ganglia and in the parts of the nervous system controlling the nutrition of these textures. What the ultimate cause of the lesion is cannot be stated, nor need we assume that one cause alone will determine it. It may be gout, it may be lithæmia, it may be rheumatism, it may be alcohol, it may be lead, it may be purely perverted nervous function from worry, from strain, from anxiety. Any one of these causes may start that alteration in the ganglionic nervous system which leads to degeneration and to the formation of increased fibrous tissue and subsequent atrophy; and with it also to derangement in the heart and in the vascular textures supplied by the affected ganglia and nerve filaments.

These are, of course, not matters that can be at once proved or adopted. You must take them as lines of thought which have come naturally from the investigations pursued, and which promise as rich a return as any that we have had from following out views hitherto brought forward. Whether the suggestions based on these researches prove to be correct or not, I think that the observations themselves furnish one more proof of the general character of what we call Bright's disease, especially in the cirrhotic form. They show us that the primary changes are to be looked for away from the kidneys, not in them, and that there is a general disease, based on a general widespread cause, underlying the vascular alteration, heart hypertrophy, and kidney disease.

But to return from these reflections to the state of the heart in Bright's disease. Looking now at the result of all the observations and the process of reasoning by which I have endeavored to collate them; looking at the general pathological facts which have been cited, I draw this conclusion: that the cardiac hypertrophy which is found in Bright's disease is not in any sense the consequence of that disease. It is an integral part of the same general morbid process, of which the kidney lesion is only the most obvious expression. You may believe, with me, that it is in the nervous system that we are to search for the ultimate, or, it may be more correct to say, the original source of the malady. You may hold that this is not proven, that the changes there are only part of the general texture alteration, and are not the first; that they are result, not cause. But I trust you will see how disseminated an alteration they indicate; how everything points to a general rather than to a local malady; and not think me too venturesome in stating that chronic Bright's disease ought not to be looked upon as an affection of the kidney at all, though it is there that, to the naked eye, its most pronounced lesions occur. In adopting this conclusion, the cases that die of apoplexy from disease of the vessels of the brain before the kidney disease shows any signs; the cases with general vascular tension in which there is as yet no albumen or other signs of renal malady; the cases with marked, the cases without as marked, cardiac lesion receive their ready explanation. They cease to be objects of wonder; the mischief wrought by the general malady has been wrought more elsewhere than in the kidneys. It may exist to a greater, it may exist to a less degree in any structure; it may be diversified in a very varying degree; and be present in parts in very alterable proportions.

These conclusions I draw more particularly from a study of the pathology of the contracted kidney. Perhaps it would be better to limit them to this condition, and to call this general malady Bright's disease of the kidney only so long until some one with a genius for names gives it one we can all adopt. There may, in fact, be some of the forms of the so-called Bright's disease which are really affections of the kidney; there may be deposits or degenerative processes in the kidney simply superadded to the textural changes in the contracted organ. These intricate questions cannot be here discussed; they are, indeed, with present knowledge, beyond our solution. But examined in the light of the view which we have inquired into to-night; with each group of cases looked at by itself; with the structural alterations in other organs and parts than the kidneys, minutely inspected; with the condition of the bloodvessels everywhere, and of the nervous ganglia noted; with the antecedent changes as far as possible considered; it may be then that other groups will stand forth separately as showing diverse general states as their basis.

No pathological research in these days of keen induction stands long by itself. No view can be even approximately proved that we do not at once begin to search how, as practical physicians, we can make it available for the prevention or cure of disease. That the treatment of Bright's disease, and of what are regarded as its complications, is not what we wish for, is everywhere felt. If lines of investigation and of thought should lead to the recognition of the malady being a general rather than a local one, and discern its starting-point, lines of practice which are in accordance will be pursued; and it is by following these lines that helpful and hopeful results will, I believe, come. As yet, even with the wish to work in that direction, we may not have the exact agents for the purpose. But science now is too resolute to halt helplessly before obstacles when once the path beyond is clearly recognized.

ORIGINAL ARTICLES.

HYDROFLUORIC ACID AS A DESTRUCTIVE AGENT TO THE TUBERCLE BACILLUS.

By E. L. TRUDEAU, M.D.,
of Saranac Lake, N. Y.

The treatment of pulmonary tuberculosis by inhalations of the vapor of hydrofluoric acid is essentially of French origin, and was first introduced in 1862, by Bastien, and made use of in 1886 by Charcot and Bouchard, but without attracting much attention. Later Seiler, in a communication to the French Academy of Medicine, July 21, 1885, and also Eugene Chevy, in a thesis written in the same year, reported good results from this treatment; while more recently Garcin, in a paper read before the same body, in September, 1887, warmly advocates the method as curative. In an exhaustive report, Professor Herard and his committee appointed by the French Academy, have recently confirmed Garcin's claims, and pronounced inhalations of the acid vapors capable of curing pulmonary tuberculosis "if not too far advanced." At Dr. Herard's request, H. Martin has made some experiments which indicate that this acid possesses valuable antiputrefactive and germicidal properties. In England, William Thompson, on September 12, 1887, at Manchester, drew the attention of the British Medical Association to the "intense antiseptic properties" of the fluosilicate of sodium.

Hydrofluoric acid was discovered by M. Fremy. The anhydrous acid is gaseous at ordinary temperatures, but is easily condensed into a fluid, which gives off large quantities of whitish fumes; it boils at 19.04° C., has a density of 0.988 at 13°, and does not freeze at a temperature of —40° C. It is more commonly obtained by the calcination of the hydrofluorate or the fluoride of potassium, but may be economically prepared by the decomposition of calcium fluoride (fluorspar) under the influence of concentrated sulphuric acid in excess. The undiluted vapors are highly corrosive and caustic.

The treatment of phthisis by this chemical compound was suggested to Bastien by the fact that at the glass factories of Baccarat and St. Louis, the vapors of hydrofluoric acid, constantly used in etching, far from injuring the phthisical workmen exposed to them, seemed beneficial to their malady. Garcin places his patients for an hour daily in a small room or cabinet into which he forces air pre-

viously passed through a solution composed of one part of acid to three parts of water, held in a gutta-percha bottle; this acidulated air is mixed with the atmosphere of the cabinet in varying proportions according to the patient's susceptibility, from 20 to 30 litres to each cubic metre being considered sufficient. Perhaps the most convenient method, and the one which I have employed, is as follows: Having made a small room, in which the patient sits, as air-tight as possible, a lead crucible containing from one to two teaspoonfuls of the acid is placed in a tin vessel holding hot water, under which an alcohol lamp is kept burning; the amount of vapor evolved will depend on the amount of heat applied, which can be regulated according to the patient's tolerance.

The inhalations, when properly diluted, have produced no bad effects in any case, and are not contraindicated even when a tendency to hæmoptysis exists. It is probable that little systemic absorption occurs, as workmen in glass factories often pass many years breathing the fumes without any ill effect on their health. Garcin subjected 100 phthisical patients in all stages, for one hour daily, to this treatment, with the following results: 35 cures, 41 ameliorations, 10 deaths, and 14 with no effect. Under their use it is claimed all the symptoms undergo rapid amelioration the tubercle bacillus itself disappearing from the expectoration.

The hydrofluoric acid treatment is a natural outcome of the recent advances in the etiology of tuberculosis, and its avowed aim is the direct destruction of the tubercle bacillus in the air-passages. An agent capable of accomplishing this has long been the desideratum of many recent investigators, who have thought its discovery might materially advance the therapeutics of this disease. Leaving, therefore, the clinical and therapeutical aspects of the question to future investigation, the present research has been directed solely toward determining what destructive power, if any, hydrofluoric acid possesses over the tubercle bacillus, and the evidence obtained is herewith submitted. In the first experiments liquid solutions were employed, while in the others dilutions of the vapors with atmospheric air were tested.

Liquid Solutions.

Experiment I.—Into five sterilized watch-glasses 5 c.c. of the following solutions of hydrofluoric acid are poured: 1 : 100, 1 : 200, 1 : 400, 1 : 800, 1 : 1600. From the surface of four blood-serum tubes covered with a rich growth of the tubercle bacillus some cultures are scraped, and with these three fresh tubes are planted, and two rabbits inoculated in the right lung and kept as controls. The remaining bacilli are then equally divided, added to the five solutions of acid in the watch-glasses, and well stirred. They are allowed to remain thus immersed for one hour, when larger bits of the culture are picked out with a platinum needle, and plants from each watch-glass are made on two blood-serum tubes. the remaining bacilli are allowed to settle to the bottom of the vessels, the excess of acid solution drawn off with a pipette, and sterilized water added in its place, the whole again stirred and 2 c.c. taken from each solution in Koch's syringe and injected into the right lung of two healthy rabbits. All the tubes are labelled and placed in the thermostat, while the inoculated rabbits, together with the controls, are put in a large pen and well cared for.

February 23. The three control tubes are covered with growth. All the other tubes remain sterile, except those subjected to the 1 : 1600 solution, which show a perceptible growth.

The two control rabbits died February 21st and March 2d, and both present the usual lesions of advanced pulmonary tuberculosis. Cover-glass preparations, stained with fuchsin, show bacilli, and a pure culture of the tubercle bacillus is obtained by planting serum tubes with scrapings from the lesions.

25th. Two of the animals injected respectively with the germs exposed to the 1 : 100 and 1 : 200 solutions were found dead. The autopsies show in both extensive fibrinous exudation in the right pleura and gangrene of the lung. The diseased tissues were friable, of a uniform gray color, and present nowhere either tubercles or caseous spots. Several cover-glass preparations, made from scrapings of the cut surfaces of these lesions, show no bacilli; a number of tubes planted from the same source, at the end of three weeks, show no growth of tubercle bacilli; several of them are putrid.

In inoculating the rabbits on February 8th, in two of them the solutions of acid containing the bacilli were injected without first drawing off the excess of acid and replacing it with water. This precaution was only taken when the violent reaction at once caused in these animals by the injection was noticed. The above facts, when taken in connection with the autopsies, leave little doubt that these two deaths were due solely to the corrosive action of the acid.

The ten remaining animals were apparently in good health two months after inoculation, when they were killed. In all but three of them a small fibrous scar in the middle lobe of the right lung marks the point of inoculation, but the lungs, as well as all the other organs, are perfectly free from any disease. Both the animals inoculated with germs soaked in the 1 : 1600 solutions showed slight tubercular lesions as well as one of the rabbits injected with the 1 : 800 mixture containing bacilli; the limit of efficacy for watery solutions may, therefore, be fixed at between 1 : 400 and 1 : 800.

Acidulated Air.

Experiment II.—*December 28, 1887.* A small bit of linen cloth attached to a platinum wire is first sterilized, then dipped on the condensation water of a tube containing a culture of the tubercle bacillus, and rubbed over the germs growing on the surface of the serum. It is then withdrawn, and from it

two tubes are planted in the usual way, and kept as controls. The wire with its rag is then inserted into a small round glass cylinder, corked at both ends with cotton wadding. Through this cylinder a current of atmospheric air, previously allowed to bubble through a 1 : 3 solution of hydrofluoric acid and water, held in a gutta-percha bottle is steadily passed for one hour, the necessary pressure being obtained from a compressed air apparatus attached to the gutta-percha bottle. At the end of an hour the wire and rag are withdrawn and rubbed on the surface of four solidified serum tubes. These, together with the controls, are put in the thermostat.

January 18. The controls are covered with growth, while the other tubes have remained sterile.

20th. The surface of the sterile tubes is scraped, and replants made from all of them.

February 14. No growth has appeared in any of the replants.

This experiments was repeated a month later, with the same results.

Experiment III.—*December 28, 1887.* Tubercle bacilli are mixed with sterilized water, and from this liquid two control tubes are planted, and two control rabbits inoculated in the right lung. The remainder of the liquid containing the germs is then subjected to a stream of air previously passed through a 1 : 3 mixture of hydrofluoric acid and water, the acidulated air being allowed to bubble up for an hour through the water in which the bacilli are floating. At the expiration of that time several tubes are planted with the cultures thus treated, and into the right lung of three rabbits two centimetres of the liquid which holds them are injected.

January 18. Controls show growth, while no change has taken place in the other tubes.

February 10. Control rabbits are killed, and show the usual lesions of moderately advanced pulmonary tuberculosis.

15th. Two of the rabbits are killed, and their lungs, as well as the other organs, found free from disease.

March 15. The third rabbit is killed, and all the organs are found normal.

Experiment IV.—Planted four serum tubes as nearly as possible with the same quantity of a culture of the tubercle bacillus. Two of these are subjected every other day, for ten days (five applications), to a current of air laden with the hydrofluoric acid vapors, as follows, while the two others act as controls. All the tubes are kept in the thermostat together; every other day the ones to be experimented on are quickly removed to another oven, heated at 38° C., and while there a current of air previously passed through a 1 : 5 solution of hydrofluoric acid in water is directed through a glass pipette into each tube for half an hour. At the expiration of this time they are removed to the thermostat and kept with the controls.

March 24. Controls show growth, and other tubes appear sterile.

The albumen in the serum, when exposed to the acid vapor, becomes firmly coagulated, as shown by its whitish color and loss of transparency, beside the acid reaction produced in the culture medium of itself may inhibit the growth of the microbe on its surface without destroying it. To avoid as much as possible this source of error, on March 24 the surface of the sterile tubes is scraped, and replants from each made on freshly stiffened serum.

April 16. Replants show no growth.

This experiment was repeated several times, the solutions of acid and water being diluted each time, and three applications in all being made, with a day intervening. The dilutions used were 1 : 7, 1 : 9, 1 : 16, 1 : 30, 1 : 50. The limit of efficiency was reached at 1 : 50, luxuriant growths taking place after one application only of air passed through a solution of this strength, while a hardly perceptible growth occurred if the process was repeated three times. The other tubes remained sterile, as well as replants made from them.

As septic and putrefactive processes play so important a part in the progress of pulmonary phthisis, the following test of the influence of hydrofluoric acid vapors over the bacteria of putrefaction is made.

Experiment V.—*March 13.* A rag attached to a platinum wire is dipped into some putrid blood, and from this two control tubes, containing liquid serum, are planted. The rag is then placed under a bell-jar of a capacity of 1500 cubic centimetres, and to the centre of the glass, on which it rests, a bit of sheet lead, holding 0.20 of hydrofluoric acid, is pushed. The acid is vaporized by gentle heat, and the rag with its bacteria is left, exposed to the vapors for one hour. At the expiration of this time it is withdrawn, dipped successively in three liquid serum tubes, and these, together with the controls, are put in the thermostat.

18th. Controls putrid, other tubes unchanged; a drop of blood taken from each control stained with fuchsin, and examined under the microscope, shows innumerable bacteria; a drop from each of the other tubes, similarly treated, shows no bacteria.

The same experiment was repeated March 20, except that 0.15 of the acid was vaporized under the bell-jar instead of 0.20, all the conditions remaining the same.

24th. Controls putrid, and other tubes unchanged.

26th. All the tubes are putrid, and drops from each, placed under the microscope, show bacteria. Thus one part of acid, vaporized in 7500 of air, is the smallest quantity that will effectually destroy putrefactive bacteria after an hour's exposure.

Experiment VI.—*March 3.* Four rabbits are inoculated in the right lung, and under antiseptic precautions, in the anterior chamber of the right eye with a pure culture of the tubercle bacillus. Two are daily subjected to inhalations of hydrofluoric acid vapors as follows, while two are kept as controls; the purpose of the eye inoculations being to note in the living animals, by comparison with the controls, any influence that might be exercised on a distant lesion by the systemic absorption of the acid inhaled, while the lungs at the autopsies are to demonstrate any effect produced by the more direct contact of the vapors. The rabbits to be experimented on are placed daily for three hours in a large, nearly air-tight box, into which acidulated air is conveyed by

means of a rubber tube tightly fitting a hole cut in the middle of the box. This rubber tube is directly connected with the gutta-percha bottle holding the acid solution, through which a condensed air apparatus forces a current of air. All the animals are kept together under the same conditions, except when those to be subjected to the treatment are placed for three hours daily in the box described above. The strength of the solution by which the air is charged varied somewhat, but most of the time was above 1 : 5. The rabbits appeared to experience no ill effects from their sojourn in those strong vapors. The ocular disease progressed so uniformly, and with such slight variations in all the animals, that the following record, taken from the notes made at the time, will answer for both the controls and the subjects of the experiment.

6th. The operation has been successful in every case, the cornea remaining quite clear ; a few whitish specks of lymph are seen in front of, and around the edge of the pupil.

12th. Small tubercles visible on the iris.

18th. Cornea beginning to grow cloudy.

20th. Many small white dots (tubercles) are apparent in the substance of the cornea. Iris tubercles growing cheesy, diffuse inflammation of the iris is noted.

27th. Cornea becoming vascular.

31st. Slight bulging of corneal wound, which is becoming cheesy.

In one of the rabbits subjected to the inhalations no tubercles were made out on the iris, but they are plainly visible on the cornea. The character and extent of the lesions varied no more in the other animals than could easily be accounted for by the slight but unavoidable differences in the amount of virus introduced. Thus no appreciable effect was produced by the treatment on distant lesions. On the disease in the lungs with which the vapors were brought in close contact the results were as follows :

April 9 The controls are killed and both show besides the ocular tuberculosis, described above, the usual appearances of advanced pulmonary tuberculosis. Tubercles are found scattered everywhere over the pleura and invade the parenchyma of the right lung in many places ; the middle lobe of this organ, which has been pierced by the needle, being almost completely solidified. Many cheesy spots are to be seen both on the pleura and on the cut surfaces of the pulmonary tissue. Frozen sections in the microtome, stained with hæmatoxylin, show tubercular deposits in the middle and lower lobes of the lung.

One of the rabbits subjected to the inhalations was noticed to suffer from diarrhœal symptoms on March 27th and died March 28th. The abdomen was retracted, the intestines congested and empty, but no tubercle was found in the abdominal cavity. On opening the chest, tubercles are seen freely scattered over the surface of the visceral and parietal pleura, a few of which are becoming cheesy. The left lung is sound with the exception of a small eruption of minute tubercles at one spot on the pleura. Sections made through the right lung show no solidification nor cheesy spots or any tubercle anywhere, except in the immediate vicinity of the point of inoculation in the middle lobe, around which some solidification is present. At the distance of a few millimetres from this point, however, the pulmonary tissue appears normal. Fresh sections made on the freezing microtome through the pulmonary parenchyma at various distances, and stained with hæmatoxylon show under the microscope no tubercle, except in the immediate vicinity of the needle thrust in the middle lobe.

The other rabbit remained in excellent condition and was killed April 5th. The autopsy gave about the same results as that of his mate, the same pleuritic lesions are present, but more of the pulmonary parenchyma is involved. Frozen sections stained with hæmatoxylon show under the microscope some tubercle at a greater distance from the point of inoculation than in the preceding animal, but still nowhere as extensive as in both controls, and none in the lower lobe. Bacilli are present in the existing lesions of both these animals.

In comparing the autopsies all that can be said is that whereas no difference exists in the extent and character of the pleural disease, less tubercle has invaded the lung tissue proper in the animals subjected to the inhalations. The direction taken by the disease might in so small a number of cases be purely accidental, and no satisfactory conclusion can be arrived at from the result of this experiment, the proof being insufficient and of a somewhat uncertain character.

The evidence obtained by the first four experiments warrants the assumption that hydrofluoric acid, even when quite freely diluted with both water and air, is capable of destroying the tubercle bacillus, and indicates that even weaker dilutions than were employed might prove efficient to this end if oftener applied. The influence exercised by this chemical compound over putrefaction is demonstrated by Experiment V., while its therapeutic value is left undetermined by Experiment VI.

To what extent the above facts can be utilized in the therapeutics of the disease, future observation must determine. Dilute solutions of the acid, or, if these prove too caustic, of its sodium and ammonium compounds, which have been found by H. Martin much less irritating, might be tested in surgical tuberculosis with advantage. In the treatment of the existing lesions of pulmonary phthisis the hydrofluoric inhalations would at least possess over the antiseptic sprays, already in use, the advantages of tested efficiency and greater penetrability. It is evident, however, that even if the acidulated air could be breathed without injurious effects in dilutions which have been found to be efficient, but a small proportion of the bacilli, namely, those lying directly in contact with the atmospheric air, could thereby be destroyed while no antagonistic effect on those imbedded in solidified areas of lung, tubercular nodules, or diseased glands could be hoped for.

An excellent illustration of the inefficiency of antiseptics beyond their point of actual contact is given by the autopsies in Experiment VI., which showed the course of the tubercular pleurisy to have been entirely uninfluenced by the daily inhalations to which the animals were subjected.

It should be kept in view that so long as the tissues present a favorable nidus for the development of the bacilli, the destruction of a portion of them, if this should be found feasible, would not necessarily eradicate the disease. It is not likely that hydrofluoric acid can alter those chemical and vital changes in the organism which allow of the growth of this microbe, and to this end thus far those conditions which promote bodily vigor have alone been found effectual. The recommendations of the method however are, that its application is easy and does not interfere with the employment of hygienic and climatic treatment, and that by it we may hope to diminish the amount of virus against which the organism has to contend. Whether this hope will be realized, an extended clinical application of the treatment alone can determine.

A SUPPLEMENTAL ACCOUNT OF THE CASE OF A BEARDED WOMAN IN WHOSE BEHALF ELECTROLYSIS WAS FIRST EMPLOYED FOR THE DESTRUCTION OF THE HAIR PAPILLÆ.

By W. A. HARDAWAY, M.D.,
PROFESSOR OF SKIN DISEASES IN THE MISSOURI MEDICAL COLLEGE, AND IN THE ST. LOUIS POST-GRADUATE SCHOOL OF MEDICINE.

The case to which I wish to recall attention was published some years ago, and possesses considerable interest in two respects. In the first place, the young woman who is the subject of this communication, was the unfortunate owner of a beard that for strength and luxuriance rivalled the hirsute appendages of any man, and, secondly, she is the first woman ever operated on by electrolysis for the removal of "superfluous hair."

Under the title of "Case of a Bearded Woman," published in the *St. Louis Medical and Surgical Journal* for November, 1877, I gave a tolerably full account of the development and peculiarities of the abnormal growth of hair in this patient, but, to add further interest to the subsequent history, I shall take the liberty of making some brief quotations from the original article:

Miss X., twenty-two years of age; her general, mental, and physical characteristics are essentially feminine, and up to the age of eighteen there had appeared nothing to indicate her subsequent deformity. But about this time downy hairs began to be observed, and before a great while all the ordinary sites of the beard were occupied by this growth, which was of light color and silky texture. At this period she consulted a medical man, who advised a depilatory powder, stating that it would permanently remove the obnoxious hairs. As a matter of course, the result was disastrous. From the repeated stimulation thus obtained the hairs soon became stiff and strong, the color deepened to a dark brown—almost black—and her beard became thicker and more profuse than is usual even with men.

For the further features of the case, and the references to the method of treatment adopted, I shall quote literally from my original paper, merely omitting unimportant details:

"The beard grows thickly and evenly on the lip, chin, cheeks, and in the submaxillary regions. The growth extends over the malar bones as true beard, and not, as is ordinarily seen, in the form of lanugo. There is no other abnormal growth of hair on the body or limbs. . . . The hair of the head is black, of fine texture, in ordinary amount, and quite long. There is nothing peculiar about it. . . . Miss X. has never shaved, but for the last three years has used a dipilatory powder. To give an idea of the heaviness of the young lady's beard, I have often noticed, that after it had been closely taken off, the skin retained that blue-black color frequently seen in men with very dense beards after shaving. The beard is never allowed to grow more than a quarter of an inch in length, so that I am unable to state how long it would become if unmolested, but I presume, from all the indications, that it would be patriarchal in its proportions."

After having given some few other details in regard to the family history of the patient, etc., I introduced the subject of treatment in the following words:

"The radical cure of hirsuties by electrolysis is brilliant in its results, as it is only in this way the hair papillæ can be destroyed, thereby absolutely preventing a regrowth of the hairs."

In concluding the article, I called attention to the fact that my friend, Dr. Michel, had been using this method for four or five years in trichiasis and distichiasis, and I promised to give a detailed description of this process in its application to dermatological work at an early day.

At the time I made my report I had removed 248 hairs from Miss X.'s face by the electrolytic method, and subsequently, at irregular intervals, I took a considerable number more. In 1882, being pressed with a great deal of business of the same sort, I was fortunate in securing the assistance of Dr. Nelson, who has kindly furnished me with the following account of his observations in her case:

"I have no record of the number of hairs removed from her face, but I commenced the treatment August 10, 1882, and ended it in February, 1885. During the first part of this period I saw her once, twice, or three times each week. During the latter months she came four to nine times a week, and each séance lasted from one to two hours. There were about three hundred and fifty séances, and the number of hairs removed at each séance would vary from thirty to one hundred and fifty. After terminating the regular treatments in February, 1885, Miss X. returned in April and had eleven treatments, in July

she had seven, in September five, and in July, 1886, she had three, since which time I have not seen her.

"I think the result of the treatment conclusively demonstrated the efficacy of electrolysis in the relief of hirsuties. I should say that this patient's beard, if allowed to grow, would have been a full, strong beard for a man. It was very dark, almost black in color, and constituted a very serious deformity.

"I believe the final result to have been thoroughly satisfactory to Miss X., inasmuch as her face was considerably marked by variola: of course, the complexion was not smooth, but she was free from the annoyance of the hair when I last saw her, some eighteen months ago."

I think the result in this case may be very justly regarded as exceedingly happy and satisfactory, and it is a source of much gratification to me to know that similar successes are now being obtained every day by dermatologists all over the world.

In 1878, at the second annual meeting of the American Dermatological Association, having in the meantime had considerable further experience in the electrolytic procedure, I wrote a formal paper on the subject, since which time I, and many other dermatologists, have contributed a number of special articles on this method to the medical press of this country and Europe.

Since I first began work on Miss X., I and my assistants have destroyed many thousands of hair papillæ, and although I have seen women with very formidable growths of facial hairs, it has not been my fortune to encounter a similar case, and I sincerely trust that I never shall.

While no one now disputes the feasibility of the operation, I can remember very distinctly that when I began this work the general statement of the text-books was that the radical treatment of such cases was unavailing, and that the pincers, the razor, or the depilatory were the only palliatives.

I may be excused, in this connection, a brief, practical digression. I have heard it occasionally stated that the hairs will return after the operation. Long since to test this matter I operated in marked limited areas, such as in hairy moles, etc., and when the work has been *expertly* done, I have failed to see the hairs reappear, and it certainly must be confessed that in the case recorded above we have obtained a result as remarkable as it is gratifying.

Poor operators do not get as fair results as good operators, and in regions thickly set with hairs the best operators must expect a certain proportion of failures on the first going over; and, furthermore, with some patients the hairs come away readily, while in others great difficulty is experienced.

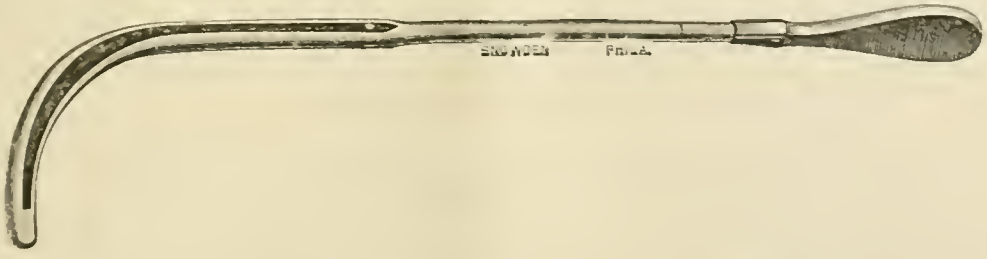
Then, again, in a large number of instances an active state of hair production is going on when the patient comes for treatment, and often continues for an indefinite period, so that a case is seen time and again for years. On the other hand, when this tendency has exhausted itself the removal, when once accomplished, is accomplished for good. Such is evidently the case with Miss X. It is possibly true that the fine downy hairs interspersed between the operable ones are stimulated to a lustier growth by the electrolytic depilation, but of this I am not quite convinced: but even if this does occur, it makes very little difference, as in time they would assume larger proportions, even if left alone, and would have to suffer ultimate removal.

A MODIFIED STAFF FOR THE OPERATION OF LATERAL LITHOTOMY.

By JOHN H. BRINTON, M.D.,
PROFESSOR OF THE PRACTICE OF SURGERY AND OF CLINICAL SURGERY IN THE JEFFERSON MEDICAL COLLEGE.

In the operation of lateral lithotomy, a failure to enter the bladder properly has often happened. Such a mischance not only causes painful embarrassment and mortification to the surgeon, but may lead to urinary infiltration, pelvic cellulitis, and not infrequently to the death of the patient. This accident is not an imaginary one: it is frequently mentioned in the books, and I have seen it take place more than once at the hands of prominent surgeons.

The error in the operation may be regarded as twofold: *First*, the incision in the urethra may be insufficient; and, *second*, the recto-vesical space may be divided and opened up. The operator believes that he has entered the bladder, and with his forceps searches for the stone. In reality, he is groping behind the bladder, and becomes more bewildered every moment, perhaps vaguely feeling through the vesical wall a stone which he cannot grasp.



I am satisfied that this failure to reach the bladder may be accounted for in two ways: *First*, from an uncertain holding or direction of the staff, on the part of the staff-holder, by which the end of the staff

is tilted out of the bladder, and the point of the knife is thus misdirected backward. *Secondly*, it may happen that when the knife is thrust along the staff, it may fail to take the curve, but may leave the groove at a tangent, slip downward and backward, and thus open up the post-vesical space. This slipping of the knife is favored by the construction of the lateral groove, which is usually such that the knife must hold its position by the pressure of its point against the staff. To obviate this difficulty, and to support the knife blade in its traject, I some years ago modified my left staff, by widening and bringing up the inferior lip of the groove in a spiral manner, so that this may form a shelf upon which the end of the knife may rest, and along which it may be thrust unerringly and safely into the bladder. An actual experience in many lithotomies has satisfied me of the advantages of the staff thus slightly modified, and I believe that by its use a high degree of certainty in the operation, and of confidence to the operator may be insured.

In the accompanying cut a representation of the modified staff is given.

MEDICAL PROGRESS.

The Technique of Intestinal Injections.—QUINCKE is quoted by the *Deutsche medicinische Wochenschrift* of April 5, 1888, in his description of methods of intestinal injections which he has recently found useful. In place of the hard tip which is ordinarily used on enema syringes, he substitutes a soft flexible nozzle about eight to eleven inches long, and of convenient calibre. The tip is slightly harder than the rest, and has two lateral openings; the external end is dilated somewhat, the whole resembling an œsophageal tube. It must be perfectly smooth, and of the best rubber. The insertion of such a tube is far less painful than the use of the ordinary tip. It may be ordinarily inserted two or three inches, but when necessary may be passed four or six inches without injury. This tube may be very easily cleansed, soap and water and carbolic acid sufficing to disinfect it thoroughly. An injection of oil may be readily given by filling the dilated external extremity with oil, and then attaching the irrigator tube; the water from the irrigator will force the oil before it into the bowel. In obstinate tympanites the tube may be allowed to lie in the bowel for an hour or more, securing the free exit of gas. Quincke secures the retention of a considerable quantity of water high in the bowel by a very ingenious device which consists in attaching to any convenient portion of the tube a collapsed rubber balloon two inches in diameter when inflated. This balloon may be filled with water by its own small separate tube. When introduced to the desired height, the nozzle aperture is free above it. The balloon is then filled with water, occluding the bowel; the desired injection is then introduced beyond it, and as much fluid as desired is thrown in at the desired level.

The Treatment of Ingrowing Nails.—PATIN is quoted by the *Centralblatt für Chirurgie* of April 7, 1888, as advising the following method of treatment:

After carefully cleansing the affected foot, he paints the granulations beneath the ingrowing nail with a solution of gutta-percha, 10 parts; in chloroform, 80 parts. This application is repeated as often as possible, and results in gradually raising the nail from the flesh, which heals under the protection of the film of gutta-percha.

Aconitine and Digitaline.—The *Revue Gén. de Clin. et de Thér.* of March 22, 1888, gives the following formula for the use of these alkaloids:

Digitalin.	gr. ⅙.
Sacchar. lact.	ʒ i.
Gummi Arab.	gr. 15.
Glycerin. et aq.	q. s.

To be made into 100 granules.

The Use of Antipyrin during Labor.—At a recent meeting of the Academy of Medicine of Paris QUEIREL reported that he had used antipyrin as an analgesic during labor in 15 or 20 cases, with excellent results. A hypodermatic injection of four grains was often given, and repeated without inconvenience. During the period of dilatation of the cervix the effect of antipyrin was especially good; the progress of labor was not retarded, but accelerated. Labor pains occasioned much less suffering, while the contractions of the uterus were rendered more vigorous. —*L'Abeille Médicale*, March 19, 1888.

Milk Jelly and Milk Powder.—The *American Druggist* for April, 1888, gives the following directions for preparing these milk foods:

As a variation in milk diet, the following is recommended by Professor Liebreich:

Heat one quart of milk with one pound of sugar, and when the sugar is dissolved continue the heat, at a boiling temperature, for about ten minutes. Now cool it well, and then add, *slowly* stirring, a solution of one ounce of gelatine in a cupful of water. Next add the juice of three or four lemons and three wineglassfuls of wine, brandy, or other liquor. Set the glasses containing the mixture in a cold place, so that the contents may gelatinize. It is necessary to have the milk quite cold before the other ingredients are added, as it would otherwise curdle.

Dried milk, in the form of powder, may be prepared by evaporating skimmed milk in a suitable apparatus, preferably in vacuo and under continued stirring, at a temperature of 60° to 70° C. (140° to 158° F.) to a syrupy consistence, then mixing it with 30 to 50 per cent. of its weight of finely powdered sugar, and continuing the heat, with constant stirring, between 30° and 55° C. (86° and 131° F.) until the product has assumed a dry, granular condition.

The Disinfection of Vessels Containing Tuberculous Sputum.—GRAUCHER, at a recent meeting of the Society of Hygiene and Public Medicine of Paris, reported experiments which he had made upon the best methods of disinfecting vessels containing tuberculous sputum. He employed carbolic acid, 1 to 20; caustic potash solution, 1 to 20; sulphate of copper, 1 to 20; chloride of zinc, 1 to 20; and bichloride of mercury, 1 to 100. Of these bichloride of mercury only was efficient. In disinfecting sputa, water at a temperature of 212° F. was found efficient in destroying the tubercle bacilli.—*Le Progrès Medical*, March 31, 1888.

Cold Baths in Typhoid Fever.—The Paris correspondent of the *Medical Press* of April 11, 1888 writes that at the last meeting of the Société des Hôpitaux M. Richard brought forward the subject of treatment of typhoid, in which were included cold baths. He had recently seventy-six cases under his care, of which thirty-eight were treated after Brand's method and the remainder in the ordinary way. Of the first category only two died, while he lost four in the second. The cold baths, he found, were always very agreeable to the patient; the delirium, stupor, and sleeplessness disappeared almost completely. Bronchitis need not be considered as a counter-indication to the treatment, as several times he did not hesitate to order the baths with every symptoms of the lung affection, and he never had any evil result. The temperature of the baths varies from 65° to 68° F., and they are administered between six in the morning and eleven in the evening. Each patient was bathed every three hours if his axillary temperature exceeded 99.5° F., and in grave cases every two hours. The average number given daily was five, of a quarter of an hour each. Cold affusions were practised on the head during the bath, and a glass of cold water was given him to drink. Two or three spoonfuls of good wine were drunk by the patient after each *séance*. M. Barth said that the danger of the Brand method consisted in the pneumonia which he frequently witnessed as a consequence of the immersion, but such was not the opinion of M. Renoy, who declared that statistics, on the contrary, proved that pneumonia is much less frequent in patients treated by cold baths than in those treated by other methods.

Papayotin in Diphtheria.—The *American Druggist* for April, 1888, gives the following formula:

Papayotin.	75 grains.
Distilled water	90 minims.
Glycerin.	½ fluidounce.

For local application to diphtheritic membranes by means of a camel's-hair pencil.

Tannin in the Treatment of Tubercular Diseases.—At the fifth meeting of the Societâ Italiana di Chirurgia, recently held at Naples, PROFESSOR ANDREA CECCHERELLI, of Parma, drew attention to the value of tannin in the treatment of local affections of tubercular origin. From experiments which he had made on animals, and from clinical experience, he believed it to be a powerful antiseptic, with a specific power of destroying the tubercular virus. He found that the addition of tannin prevented the putrefaction of animal tissues and fluids, and that decomposition was very considerably delayed in the bodies of animals which, while alive, had undergone a course of treatment with tannin. He had also found that whilst he could produce tuberculosis in certain animals by the injection of phthisical sputa, or of tubercle bacilli, the injections produced no bad effect when tannin was injected simultaneously, or was given internally every day for some time. He had treated twenty patients suffering from tubercular diseases with tannin, both externally and internally, with very satisfactory results. He, therefore, looks upon tannin as an excellent remedy in tubercular affections of the bones and joints; under its influence ulcers heal kindly, any tubercular formations that may already exist are destroyed, and generalization of the disease is prevented. Dr. Ceccherelli considers that tannin is much superior to iodoform in the treatment of tubercular disease, besides having the further advantage of being perfectly harmless.—*British Medical Journal*, April 7, 1888.

Hydrosalpinx Treated by Apostoli's Electrical Method.—APOSTOLI, of Paris, in a recent clinical lecture, exhibited a case of salpingitis which he had treated by galvano-puncture, on two occasions, with a diminution of the hydrosalpinx present and an improvement in the patient's general condition. He considers the method of treatment by the galvano-cautery a most valuable procedure in non-suppurating inflammation of the uterine appendages, and regards penetration of exudates in the vaginal cul-de-sac through the vaginal wall a proper procedure, with antiseptic precautions and rest for the patient.—*Revue de Thérapeutique*, March 15, 1888.

The Treatment of Bronchitis.—The *Therapeutic Gazette* of April 16, 1888, in an editorial on this subject, gives the following formulæ:

For the acute stage:

R.—Potass. citrat.	℥j.
Suc. limonis	f℥iss.
Syr. ipecac.	f℥ss.
Tr. opii camph.	f℥iij.
Syrupi . . . . q. s. ad	f℥iij.

S.—Dessertspoonful every two hours.

After the acute stage:

R.—Ammonii chloridi,	
Ext. glycyrrhizæ . . .	āā ℥iss.
Glycerini	f℥ss.
Mucil. acaciæ	f℥ij.
Syrupi,	
Aquæ . . . . āā q. s. ad	f℥iij.

S.—Dessertspoonful every two hours.

Dermepenthesis, or Animal Skin-grafting.—CARDOGAN-MASTERMAN, in the *Provincial Medical Journal* of April 2, 1888, reports the following case of successful grafting with rabbit's skin:

A middle-aged tradesman, who had been drinking to slight excess for some years, came to me with a recent traumatic orchitis. The pain and swelling were excessive, so morphia was given, three leeches applied, and an ice-bag. In the night acute *delirium tremens* developed, and when violently struggling to escape from the grasp of two neighbors, who were trying to put him in bed, the swollen scrotum was severely bruised—I think knelt upon—by one of the men. The next morning it was black and cold. Poultices were applied, and so on, but in a day or two the whole of the integument sloughed away from the root of the penis to the perineum, leaving the pouch of the testicles exposed, and covered only by the pale pink lattice of the *cremaster* muscle. When the wound had been cleaned, there was a border of but half an inch wide of the scrotum left in a healthy condition, and the case was complicated by the extremely bad condition of the patient's health generally, and extensive bedsores. I found, however, that a circular piece of skin, two inches in diameter, would just cover the testicles; and, with little

hope of success, again tried the rabbit as its source. A young one was procured, the area marked out with ink on its previously clipped abdomen, the animal killed by a blow on its neck, and the piece of skin rapidly dissected off and applied on the clean wound surface, pressed closely down, covered with a piece of lint dipped in hot water, and then with a fair-sized linseed-meal poultice. The latter was, in turn, kept hot without removal by an India-rubber hot-water bag, which was frequently emptied and refitted. At the end of forty-eight hours the transferred skin was cautiously examined, and found to be adherent. A fresh poultice was applied and reinforced as before for three days longer, when the outer layer came away with the fur, leaving a firm, smooth integument, looking more like the mucous lining of the lips than ordinary skin, and when I last saw it so it remained.

Cancer Treated by Erysipelas Inoculation.—The *Lancet* of April 8, 1888, writes as follows on this subject: That an attack of erysipelas will often profoundly modify, or even cure, another disease which may be present in the subject at the time has long been known; but it remained for Busch and Fehleisen deliberately to expose patients suffering from malignant growths to the action of the virus in the hope of curing the graver malady; Fehleisen's were the first cases in which the virus was inoculated, and his cases served as subsidiary confirmation of the pathogenic character of the streptococcus which he had isolated, and cultures of which were employed in his inoculations. The method, he remarks, is naturally only to be thought of when the malignant growth is beyond the reach of operative removal. (See "Memoir on Erysipelas," in the selected essays published by the New Sydenham Society, 1886.) The most recent adoption of this measure is that recorded by Dr. Axel Holst, of Christiania, in the current number of the *Centralblatt für Bakteriologie* (No. 13).

The patient was a woman, aged forty, who had a recurrent carcinoma of the left breast, for which she declined further operation. In a few months the cancer had infiltrated the greater part of the surface of the right half of the chest, forming a red brawny mass, with a raw surface, nodulated on the margins, whilst the axillary and clavicular glands were much enlarged, and the upper limb œdematous. In spite of the unfavorable aspect of the case, it was decided to try the effect of erysipelas inoculation. Accordingly, on August 10th last, the inoculation was performed by scarification of the raw surface, the cultures used being the fifteenth generation (in peptone agar-agar) from a case of erysipelas nineteen months and a half previously. Beyond a slight rigor next day, no effect followed; and it was further found that the material gave no result when inoculated in a rabbit's ear.

Dr. Fehleisen was applied to, and on the 22d the material he sent was inoculated in several parts of the diseased surface, and this time with success. After twenty-one hours the patient had a series of rigors followed by the appearance of an erysipelatous blush, which, within thirty hours, extended over the whole right arm, and later spread to the left side of the chest, back, and even to the left arm. In a few days the erysipelatous area was confined to a margin from one and one-quarter to three inches in width; and on the seventh day the fever, which throughout had not been high, fell by crisis. At the end of four months and a half the erysipelas still persisted on the right arm, but the patient had manifestly lost ground.

During the first two months and a half the progress of the cancer appeared to be arrested, and for some distance the wound had healed over, whilst the induration had become less marked. But the right arm still remained œdematous, and after the period named the ulceration broke out afresh, the supraclavicular glands again increased in size, and fresh nodules appeared, one in the left breast. The inoculation had, then, probably prolonged life, for the arrest in the progress of the cancer was marked; but it may well be that the patient's loss of strength and of appetite (which prior to the inoculation had been remarkably good) were due to the erysipelas, which persisted on the right arm to the end. To us it seems that the case was hardly a suitable one for this treatment, which, at any time must, to say the least, require some courage to adopt.

The Treatment of Aphthæ.—Hirtz prescribes the following:

Aquæ destill.	parts 8.
Tinct. coca	parts 2.
Sodii salicylat.	parts 2.

The mouth should be cleansed with this mixture, on soft cotton, five or six times daily.—*Revue de Thérapeutique*, March 15, 1888.

Surgical Morality.—The *Medical Press* of April 4, 1888, writes very appropriately on this subject as follows:

A pernicious practice obtains among surgeons of publishing only their successful cases. Not only is the practice not strictly honest, but it inflicts positive harm, seeing that the result may be to mislead their readers as to the value of this or that procedure. This is particularly striking in the matter of wiring fractured patellæ. The medical journals are continually publishing cases which certify to the satisfactory results obtained, but we do not remember to have seen one for a long time in which the risks and disadvantages of this somewhat heroic treatment are set forth. Yet it has occurred to our knowledge that in the practice of one surgeon at least two cases recently developed very severe inflammatory symptoms as a sequel to the operation, which, in one of them, proved fatal. Now the inconvenience caused by an imperfectly united patella is, after all, but small, and a mortality of even one per cent. would suffice to render the operation unjustifiable; at any rate, without placing the patient in full possession of the arguments for and against surgical interference. Too many men are blind to the fact that often the greatest amount of information is to be learned from the unsuccessful cases. To ignore non-successes is, moreover, to act in an unscientific and reprehensible spirit, for no true surgeon could, or ought to wish to perpetuate a method which can only be made popular by "cooking" the statistics.

Salol Collodion for Fissured Nipples.—The *Gazette de Gynécologie* of March 1, 1888, gives the following formula:

Salol,	
Ether	āā ʒ 1.
Dissolve and add	
Collodion. flex.	ʒ 7½.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MAY 5, 1888.

THE RELATION OF HEART AND KIDNEY AFFECTIONS.

EVER since Bright's memorable observations, the connection between heart and kidney affections has been the subject of much speculation and study, and with an increasing knowledge of the anatomical facts the interest in the question has rather heightened than waned. In the Middleton-Goldsmith lecture for this year, which we present to our readers in this number, DR. DA COSTA discusses certain important aspects of the problem.

Two main questions are offered. Does disease of the heart lead to disease of the kidneys, and what is the relation of renal affections to cardiac disease? On the first point Dr. Da Costa has a large amount of valuable material to offer, and deals with this side of the problem with a fulness which its importance merits. The results of a careful analysis of 127 cases of valvular disease show that in only 8 there was actual renal disease, amounting to more than congestion, and in not one was the kidney contracted. These clinical results contrast strongly with the post-mortem records of Delafield, quoted by Dr. Da Costa, in which of 137 cases of death from heart disease there were 27 large white kidneys, 29 atrophied kidneys, and 28 of chronic nephritis, which could not be classed as either large white or atrophied organs. The conclusion reached is, that heart disease rarely leads to chronic renal disease, but to the well-known large, firm, congested organs.

Of valvular affections of the heart, associated with disease of the kidney, there were 41 cases in 101 instances of Bright's disease (57 acute and 44 chronic). Of these 41 cases of valvular lesion 29 were Bright's cases of the chronic type, and 12 were of the acute type. In 13 of the 29 chronic cases and in 3 of the acute cases, rheumatism was an antecedent. One of the most interesting points in this connection is Dr. Da Costa's experience in 79 cases of acute Bright's disease. In only 16 of these there was valvular disease, but neither in these nor in any of the other cases could hypertrophy be determined. No support is here found for the statement of Traube, which has been very generally accepted, that even in acute nephritis hypertrophy of the left ventricle can be determined within a month or six weeks from the date of the onset. Observations on the arterial tension in these cases would have been of value.

Naturally the chief interest in this subject centres in the hypertrophy without valve lesion, which is so commonly associated with the contracted kidneys of chronic Bright's disease; and, as a rule, with extensive change in the arterial coats.

The various theories which have been advanced to explain this condition are reviewed and fonnd inadequate, and the suggestion is made that the hypertrophy as well as, to a great extent, the vascular changes are the result of a common process which takes its origin in the ganglionic system. In eleven cases changes were found in the inferior cervical ganglia, indicating atrophy and fibrosis. Dr. Da Costa believes that in a deranged nerve influence, depending upon widespread changes in the ganglionic system, a solution of the question will be found. To this general cause may be reasonably attributed the great and universal alteration found in heart, vessels, and kidneys in chronic Bright's disease. There is no inherent improbability in this view, for we know how powerfully nutrition is influenced by changes in the nerve centres, but the anatomical question cannot yet be considered as finally settled. The investigations of Hale White would indicate that the very changes here described are extremely common in many diseases, and the tendency of late has been against attributing any special importance to these alterations. The suggestion of the lecturer, however, adds interest to the whole question, and brings into prominence a hitherto neglected aspect, from the further consideration of which new light may be thrown on many of the obscure problems in the etiology of chronic Bright's disease.

CEREBRAL ACCIDENTS IN EMPYEMA.

THE reflex accidents which occur in the course of the surgical treatment of purulent pleurisy deserve more exact investigation than has been accorded them. Striking as clinical phenomena in their mildest form, they become invested with peculiar interest when we recognize in them the mechanism of that appalling sudden death which has occasionally occurred during the act of washing out the pleural cavity.

The free use of the bistoury in effecting the freest drainage of the pleura, which the antiseptic methods of modern surgery permit, has done away with the necessity for irrigating these cavities, and it is probable that cerebral accidents will become much less common in the future. The fact that grave reflex accidents may be provoked, under circumstances not to be foreseen, by injecting the pleural cavity, and even by the introduction of a sound, must lead to the eventual abandonment of these procedures. Meanwhile, the intelligent study of the subject will serve to hasten this desirable result.

The investigations of Aubouin, in 1878, of Landouzy, 1880, and of Martin, 1881, have recently been extended by DE CÉRENVILLE (*Revue Médicale de la Suisse Romande*, January 20, 1888), who has added to the list of cases six occurring under his personal observation. These he describes under the designation *Epilepsie Pleurétique*. The attack begins without warning, and presents the characteristics of an ordinary epileptic seizure. Its duration is extremely variable. It may last five minutes, an hour or two, or, with intermissions, several days. It may terminate in death as sudden as that of aortic disease, or in prompt recovery without repetition of convulsions. Fugacious palsies are noted; less commonly persistent monoplegias or hemiplegia. These reflexes are caused by mechanical irritation of the pleural surface, usually by injection of various fluids, exceptionally, as in a case of Leudet's, by the sound, while in one case reported by Billroth the nervous manifestations followed the insufflation of iodoform. Hemorrhage from the pleura has been coincidently noted in a large proportion of the cases, but it is clear from a study of the reports that, while more force than usual has been employed in administering the injections in a few instances, undue violence plays no necessary part in the causation of these accidents. It is a singular fact, moreover, that they occur late in the course of treatment—in thirteen cases once only within ten days, in nine instances between the twentieth and seventieth day, three times after the seventieth day, and once after the lapse of twenty months. They cannot, therefore, be ascribed to the shock of the primary operation, nor to the contact of irritating liquids with the pleural surface at the moment that it ceases to be bathed with accustomed pus. De Cérenville conjectures that the cerebral reflexes of empyema are in some unknown way causally related to new anatomical conditions developed in the process of cicatrization.

The author concludes his paper with the suggestion that injection of the pleural cavity should not be intrusted to a subordinate, who is not *un homme de l'art*, but should be practised by the physician himself, or by a capable assistant. We venture to go further, and emphasize the rule that such injections should not be practised at all, and to this rule there will be found few if any exceptions.

THE ACTION OF STROPHANTHUS.

IN late numbers of THE MEDICAL NEWS we have called attention to the action of strophanthus upon the circulation, and now take pleasure in calling attention to a valuable series of researches by FRAENKEL on the use of this drug in heart disease. Administered in a dose of five to fifteen drops three times a day Fraenkel finds (*Deutsche med. Wochen.* of February 23 and March 1, 1888) the drug quite useful in those cases of heart trouble dependent either upon valvular disease or upon inefficiency of the cardiac muscle. In excessive dilatation, or in circulatory lesions resulting from chronic contracted kidney, he believes it to be useful, but that it can in any way replace digitalis in his hands is apparently impossible. In some cases of valvular diseases he used it with negative results. In cases of arterial sclerosis of all varieties and causes Fraenkel found strophanthus of some value, although he found it necessary to give as much as fifteen drops of the tincture three times a day; a dose somewhat larger than that commonly employed in this country.

In conclusion, Fraenkel summarizes his remarks to the following effect: That strophanthus is an efficient heart tonic which can in no sense approach to digitalis, save in some individual cases, where it seems to act more favorably, owing to the presence of some peculiar condition. As a result of this he states that, sometimes when nothing but disappointment has followed the use of the older remedy, the greatest success has followed the employment of strophanthus.

The best results reached with the use of strophanthus were in functional disorders, however, such as those commonly brought about by alcohol and tobacco, and also in the removal of ascites dependent upon portal engorgement.

A SAD tragedy has recently occurred in a New England town, which will call public attention to the perils that attend the new school of quackery which pretends to heal all manner of disease by prayer alone. In this case, the lives of a young mother and her newborn infant were sacrificed to this new school of "Christian science," so-called. The responsible attendant was the dead woman's mother, who, having become a convert to the new fad, was content to experiment with it upon her own family; another "scientist" was also present. No physician was called in until after both the victims were lifeless. The woman died by hemorrhage, and for the child nothing was done. An autopsy upon both bodies was made in the presence of the medical examiner of the district, and it was conclusively shown that the mother and child were healthy before death, and that they might have been saved if they had had such attention as an ordinary nurse could have rendered. A prosecution of the two deluded women for criminal neglect will presently be begun. This is not the first time that the heresy of curing disease by prayer has been responsible for loss of life, but this is the first instance within our knowledge where there has been a double casualty. If by this sad event the eyes of the public shall be opened to the dangerous tendencies of this do-nothing treatment, the sacrifice may not have been in vain.

The rapid spread throughout the country of this heresy has been remarkable, and its success as a money-getting scheme is without parallel in the history of modern quackery. It has very little to do with the poor, but makes all its appeal to a "fine class of people," many of whom have heretofore been addicted to homœopathy. The presumption is that its career, though brilliant, will be short-lived.

THE Medical and Chirurgical Faculty of Maryland have elected the following officers for the ensuing year:

President.—John Morris, M.D.

Vice-Presidents.—J. E. Michael, M.D., Thomas B. Evans, M.D.

Recording Secretary.—G. Lane Taneyhill, M.D.

Assistant Secretary.—Robert T. Wilson, M.D.

Treasurer.—W. F. A. Kemp, M.D.

Executive Council.—I. E. Atkinson, M.D.; P. C. Williams, M.D.; S. W. Miltenberger, M.D.; George H. Rohé, M.D.; Thomas S. Lattimer, M.D.

THE Association of Medical Superintendents of American Institutions for the Insane will hold its forty-second annual session at Old Point Comfort, Va., May 15, 1888.

THE Academy of Medicine of Belgium offers, through an anonymous donor, a prize of 8000 francs ($1600) for the best essay on the Clinical History, Pathogenesis, and Therapeutics of Epilepsy; the offer closes December 31, 1888. For essays worthy of mention, from 300 to 1000 francs will be given. For the discovery of an agent which shall be of genuine value in the permanent cure of epilepsy, 25,000 francs are offered. Further information may be obtained from the secretary of the Academy.

THE fifth meeting of the Society of Italian Surgeons convened in Naples, on March 26, 1888, under the presidency of Prof. d'Antona, of Naples.

THE Marshall Hall prize, for the best original work, in English, on the physiology and pathology of the nervous system, during a period of five years, has been awarded to Dr. Gaskell, Lecturer at Cambridge.

THE death of Professor de Chaumont, Professor of Military Hygiene at Netley, is announced. In association with Professor Parkes he made valuable studies in hygiene, under the direction of the British Government.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, April 2, 1888.

THE PRESIDENT, D. HAYES AGNEW, M.D., IN THE CHAIR.

DR. W. W. KEEN reported the following

CASE OF EXTIRPATION OF ENLARGED CERVICAL GLANDS UNDER COCAINE.

Miss S., aged twenty-two years, medical student, consulted me in December, 1886, in reference to a number of enlarged glands in the neck; she was of a tubercular family, and was afflicted with a curvature of the spine. In July, 1885, Dr. Henry B. Sands, of New York, removed thirteen glands by making an incision in the left side of the neck, reaching from just below the mastoid process nearly to the clavicle. A keloid appeared in the scar

shortly after the operation, beginning at the lower end and invading the whole scar, in which the stitches then disappeared from below upward until one inch from the upper end was the only part that was normal. This keloid invasion and decline changed the scar from nearly a linear cicatrix to one about an inch wide.

November 24, 1885, Dr. Sands removed from the right axilla a number of enlarged glands, certainly a dozen.

December 22, 1886, I removed one quite large gland from above the clavicle on the left side, my incision being at the line of the old scar. I injected a four per cent. solution of cocaine under the skin, and the only pain she felt (although the tumor was deeply placed) was when I divided a small cutaneous nerve. She recovered without any trouble.

May 27, 1887, a large number of glands had rapidly increased in size. I made an incision in the line of the old scar throughout its entire length, and after dissecting through the dense cicatrized tissue and cutting the sterno-cleido-mastoid muscle entirely loose from the parts beneath, except at its two ends, I removed eighteen glands, from the size of a large pea to a good-sized hickory nut, which lay, some of them under the occiput, most of them under the sterno-cleido, and in connection with the great vessels, and three of them just above the clavicle. These last had to be reached by an incision at an angle with the first one, forming an inverted V.

Ether was given, and strict antisepsis was used, with bichloride of mercury and carbolic acid and bichloride dressings. A rubber drainage tube and a bundle of horsehairs were used for combined tubular and capillary drainage. The dressings were changed at the end of twenty-four hours, the drainage tube removed, leaving the horsehair *in situ*. On the third day, the temperature having risen to 102° F., I redressed the wound, but found everything in good condition. On the fifth day I again dressed the wound and found it entirely well. The horsehair stitches were removed.

The temperature had risen still higher, but this was explained by a severe pain in the knee which ushered in an attack of rheumatism. This proved to be a prolonged and severe attack, but she recovered from it ultimately without any heart trouble, and resumed her studies in the fall of 1887.

March 9, 1888, a number of glands had enlarged, most of them farther back in the neck, along the posterior border of the sterno-cleido-mastoid, and one as large as a filbert under the occiput. Ether caused her so much discomfort that she decided again to try the effect of cocaine. I injected fifteen minims of a four per cent. solution at the site of the suboccipital gland and thirty minims along the old scar, in which I proposed making my chief incision. I then dissected out six glands in all.

The dissection was difficult, on account of the cicatricial tissue, and occupied one hour. I poured into the wound a few drops of the solution of cocaine three times, less than two drachms being used in all, including that injected under the skin. The patient declared, both then and subsequently, that she felt no pain, and as a medical student being interested in the operation, part of the time she held a hand-glass in her hand, and watched the different steps of the operation, and made comments on them.

The wound was approximated with Chinese silk sutures (sublimated), and a sublimated dressing applied.

For the suboccipital wound horsehair alone was employed; for the larger wound, combined tubular and capillary drainage. I was particular to make my incision in the line of the old scar, as after the previous operation some moderately marked keloid changes took place in the new scar, while the incision and stitch wounds in the old scar were free from any such trouble.

The following is a record of the state of the pulse and of the temperature:

March 9, 12 M., pulse 78, temp. 99.2°. 2 to 3 P.M., operation. 4 P.M., pulse 94, temp. 102.4°. 7 P.M., pulse 86, temp. 99.3°.

10th, 7.30 A.M., pulse 86, temp. 98.4°. 5 P.M., pulse 98, temp. 98.4°.

After this date the pulse varied very little from 74, and the temperature kept at 98.4°.

I dressed the wound on the 10th and removed the rubber drainage-tube, and again on the 14th, when I removed all the horsehair and all the stitches. The wound was well, excepting the small sinus left by the horsehair, which healed quickly.

Remarks. There are four points which seem to me interesting in connection with this case. The patient has had five operations and over fifty glands removed. The glands were a great mental annoyance to her, and, as they were undergoing cheesy degeneration and would have resulted in abscesses, the operation was very satisfactory both to the patient and to myself. Whether it has saved her any further constitutional infection is open to doubt, but, at least, the operation has not done any harm in that direction; in my opinion it has done *good*. It is a very *good* illustration of the ease with which such glands may be even repeatedly operated on with speedy recovery and no ill effects. I have now repeatedly removed such enlarged scrofulous glands, and in no case have I seen occasion to regret it.

Secondly, the effect of cocaine.

The first operation which I did upon her with cocaine was very successful, and the patient's discomfort after ether was so very great that she was willing to undergo a considerable amount of pain to avoid it. The amount of cocaine used at the last operation was not large, and in its effects was a perfect success.

I think the patient was under a certain amount of mental exaltation, which was shown by a slight rise in the temperature before the operation, although in perfect health; and this may account, to some extent, for her not feeling any pain.

She has declared to me repeatedly since the operation, that in spite of the small amount used, the entire operation, which lasted one hour, was painless.

It was very curious to me to see her holding a hand-glass in her hand to watch the operation, and to hear her make comments upon it. It is a thing quite new in my personal experience during any serious operation. Her conduct in this respect seems certainly to bear out the supposition that she did not feel any pain.

Third. The rise in temperature. This was too sudden to be caused by inflammation for only one hour had elapsed since the operation, and the rise of temperature had entirely disappeared in three hours.

For this rise in temperature three possible causes may be suggested. First. Its origin might be psychical. The patient certainly was not a little excited by the operation. I myself, have never seen a rise in temperature that I

could attribute to emotion. My friend, Dr. Osler, tells me that it is not uncommon in children to see a rise of from one to two degrees caused by emotion, such as crying spells. In this case, however, the rise was three degrees.

Secondly. It is possible that it was due to the constitutional action of the cocaine. Dr. H. C. Wood informs me that this is undoubtedly a symptom of cocaine action, and that some persons are excessively susceptible to small amounts of cocaine. In this case, during the entire hour which the operation lasted, the total amount used was fifteen minims, hypodermatically, of the four per cent. solution, and about forty-five minims were poured into the wound, but most of this visibly ran off on the surface.

Dr. Wood suggests a third possibility: that cocaine may paralyze the afferent sensory nerve, and not paralyze the afferent nerves connected with the heat centres. These points I must leave to physiologists and pharmacologists.

Fourthly. The unusual course of keloid, which invaded the scar from below, travelled upward and disappeared in the same manner from below upward.

Dr. Thomas G. Morton exhibited the

SPECIMENS FROM TWO CASES OF REMOVAL OF THE APPENDIX VERMIFORMIS BY ABDOMINAL SECTION.

The speaker stated that he had already reported two cases of removal of the appendix vermiformis to the Academy. One of these cases had died and one had recovered. Of the two cases reported in the present communication, one had died and the other recovered. In the fatal cases, the result might have been different if the operation had been performed earlier.

The first case was that of a child ten years of age. When seen the patient was in a condition bordering on collapse. The appendix presented a large perforation, and three foreign bodies were found. There was inflammation of the general peritoneal cavity, and the patient died of exhaustion eight or ten hours after the operation.

The second case was that of a lady, twenty-eight years of age. Two years ago what appeared to be a simple abscess in the right iliac region was opened. She recovered and remained in good health until three weeks ago, when symptoms of rapid inflammation in the region of the appendix appeared. The abdomen was opened by a lateral incision on the third day; a large perforation in the appendix was found, but no foreign body. The appendix was removed and the abdominal cavity was washed out with hot water. Two drainage tubes were introduced—one of rubber, the other glass—and the wound was kept open to permit of the escape of probable sloughs.

Special stress was laid on the advisability in cases of extensive inflammation where sloughing of cellular tissue is likely to occur, of leaving a very free opening for the escape of the results of destructive inflammation.

Dr. J. Ewing Mears said that with reference to the incision to be employed in these cases, he thought the experience of operators has led to the conclusion that up to a certain time the lateral incision is the one to be selected. Dr. Weir fixes the time at five days. After the abscess has been evacuated, it is to be treated as any other abscess cavity. When, however, perforation of the abscess has occurred and the general peritoneal cavity is involved, median laparotomy should be chosen, and the case treated as we should treat any other case of suppurative peritonitis.

THIRD FRENCH CONGRESS OF SURGERY.

Held in Paris from March 12 to 17, 1888.

(Specially reported for The Medical News.)

(Continued from page 474.)

ON DERMOID CYSTS OF THE ANTERIOR FONTANELLE.

Dr. Lannelongue, of Paris, said that in none of the ten cases published in the past, had the diagnosis been made beforehand; it had always been done by punctures or incisions. These cysts are very rare; he had found only twelve cases, two being his own. In these two cases he established a correct diagnosis. The tumor occupies the large fontanelle in young children, and later the neighboring bony parts of the bregma. Of spherical form, widely applied to the surface of the cranium, it is very fluctuating. In three cases it was found transparent, without murmur or beating; certain tumors, however, soon after birth, have presented beating. The tumor is irreducible, and is not modified by change of position. On its surface the skin is normal and movable. Deeper it is adherent to the cranial parietes, which encircle it in a bony projection. These cysts have only been observed a few days after birth; they have been seen in old people, but their presence is recognized in the first two or three years. At first the size of a hazelnut, they may acquire the size of an egg or fist. Diagnosis is difficult, especially when the tumor is transparent. The idea of a meningocele can be disregarded, for a dermoid cyst is irreducible, and a meningocele does not exist in the region of the anterior fontanelle, outside of teratological cases. Tapping is not absolutely necessary for diagnosis; sometimes even it is of no use, the liquid might be like the cephalospinal fluid. Dissection of the tumor will present at its base the cranial wall, and the fontanelle, which is never completely obliterated. Its structure is that of a dermoid cyst; the liquid is clear, devoid of albumen, and rich in sodium chloride.

These cysts, like those of other regions, have for their origin the surrounding of an ectodermic island in the thickness of the vascular layer at the time of embryonic development. These cysts are median as regards position. There is a circumstance favorable to this surrounding of the ectoderm, in the suture of the dorsal embryonal groove, at the bottom of which develops the central nervous system.

Trying to explain why dermoid cysts of the cranium are situated more often at the lambdoid portion of the bregma than at any other point of the median line, he thought that the surrounded ectodermic islets can be displaced and pushed aside by an ossification of the cranial bones; they are in this manner pushed to the fontanelle spaces. The only treatment is the complete extirpation of the tumor; the operation, done with care, presents no danger, even for children of eight or ten months; the fontanelle is not always ossified, but this is no contraindication against intervention.

Dr. Ollier, of Lyons, had seen three cases of dermoid cysts, one of which is particularly interesting: it was a

cyst, the base of which was adherent to the cranial wall for about two to three inches. He was obliged to leave, without extirpating it, the circular bottom of the cyst, and he was surprised, some time after, to find that cure had taken place, and that the bottom of the cystic sac replaced the hairy scalp.

USEFULNESS OF LARGE INCISIONS IN THE ŒDEMAS OF MALIGNANT CARBUNCLES.

Dr. M. Pollosson, of Lyons, reported the following case: A man, aged forty-three, working in leather, was taken with a malignant pustule of the left cheek. In a few hours the œdema extended to the cheek, neck, and chest, with danger of asphyxia. He immediately extirpated the pustule with Paquelin's thermo-cautery, and made twenty-five large incisions and numerous punctures with the same instrument on the cheek, neck, and chest. The total length of incision must have been about an inch and a half; the asphyxia disappeared, the œdema subsided, and general symptoms were better. He thought these large incisions are invaluable in grave cases. They allow the running out of the serum, and permit the application of antiseptics.

RESECTION OF BONES TO REMEDY LOSS OF SUBSTANCE OF SOFT TISSUES.

Dr. E. Cirmisson, of Paris, has practised this operation twice. His first case was a woman, aged thirty-five years, epileptic, who had two severe wounds of both forearms. The result was on the left side, a flexion at right angles of the hand on the forearm, making the hand useless. In May, 1887, he excised, as completely as possible, the cicatricial tissue of the antero-inferior region of the forearm; he tried to straighten the hand, but in making this movement there remained at the antero-inferior part of the forearm a large loss of cutaneous substance, which could not have filled up without reproducing the forearm deformity. He then excised 1¼ inches of both radius and ulna, at a short distance above the carpus. The bony consolidation did not take place, and in October, 1887, he sutured the two ends of the radius; cure took place by first intention, and toward the end of December consolidation was complete. The silver suture remains encysted in the tissues.

His second case was a man, forty years of age, in whom a severe burn of the right leg had determined an equino-varus club-foot, and a permanent ulceration in front of the external malleolus. On the 5th of September, 1887, he practised the tibio-tarsal excision, preserving the external malleolus. Cure took place after slight suppuration. Now the patient is beginning to walk on his leg, the ulcer is cicatrized, the shortening measures 1½ inches.

ON THE SURGICAL TREATMENT OF TUBERCULOSIS OF THE BLADDER.

Dr. Guyon, of Paris, had tried the radical cure of vesical tuberculosis on the same ground that external local tuberculosis is treated. In two cases he has found the tubercle well situated for interference.

The first case was a man, aged twenty years, no gonorrhœa, who presented a very painful tuberculous cystitis; the urine contained a great many bacilli. He opened the bladder by abdominal section, then dilated the neck, and painted the parts with iodoformed oil. After seventeen days drainage, the patient was completely cured.

His second patient, a man aged forty years, who had never had gonorrhœa, presented a tuberculosis limited to the bladder; the urine contained tubercle bacilli. The bladder was opened, the diseased parts curetted and cauterized with the hot iron. The patient was cured of his local tuberculosis, for no more bacilli appeared in his urine; a certain amount of cystitis remained, however. He preferred in these interventions the hypogastric method.

THE USE OF FORCEPS IN VAGINAL HYSTERECTOMY.

Dr. Demons, of Bordeaux, thought that in post-operative hemorrhage the use of pressure forceps to stop the bleeding an excellent method, when the uterus cannot be drawn down; but when this organ can be pulled down, he preferred ligature. The danger of forceps lies in the fact that we may seize the ureter, which fact has happened on several occasions; even the anterior wall of the rectum may be caught. Moreover, the formation of a slough, the result of the use of these forceps, will postpone healing, whilst the ligature has not these objections.

As to the excision of the vagina, which is recommended by M. Richelot, it is a good precaution, but we must not make it too extensive, or we may wound the ureters; recurrence, of course, takes place more often in the broad ligaments.

Dr. Péan, of Paris, drew attention to the fact that he had been the first to use pressure forceps in vaginal hysterectomies, having presented, in 1882, his observations before the Academy of Medicine. He said that no reference had been made to the important service rendered by temporary pressure; which, with two or more long forceps, straight and curved, permits the rapid detachment of the uterus without loss of blood. This allows us also, when the organ has been extracted, to pull down the broad ligaments, and when it is thought necessary to ligate them in halves, without difficulty or fear of hemorrhage. It will also permit us to omit the ligature, when we leave these forceps in place. Contrary to M. Demons, he thought that the forceps ought to be used especially in cases where the uterus can be easily drawn down.

Dr. Terrier, of Paris, had thought vaginal hysterectomy very difficult when he used ligatures, and now finds it very easy since the forceps have been used. He has made this operation 19 times, with 15 good results and 4 deaths, 1 being from hemorrhage in a case treated with ligatures. It gives, then, a mortality of 22 per cent. To appreciate the further results, we must not only separate the 4 cases of deaths, but also 4 cases in which the intervention was to have been temporary and palliative, but in which hysterectomy became necessary on account of opening the peritoneum; out of these incomplete cases, he had only 1 death; out of the other 11 cases, he had in 7 rapid return of the trouble; 3 other patients where tumors had been recognized microscopically as cancers, have remained cured for two years and nine months, one year and nine months, and one year; finally, in 1 case, he had to deal with an intra-cervical œdema, which did not return. These results represent 70 per cent. of rapid relapse, and 30 per cent. of cures which appear permanent. He concludes:

1st. That vaginal hysterectomy for cancer is a very serious operation, as it gives 22 per cent. of operative deaths.

2d. The operation appears more rational than partial amputations, although those are more easy and less dangerous primitively.

3d. Incomplete hysterectomy is not more grave, but is insufficient in all incomplete operations.

4th. Relapse occurs in 70 per cent. of cases; it is usually rapid.

5th. Cure is possible. He had found it in 30 per cent. of his observations where the diagnosis had been histologically verified.

DR. RICHELOT, of Paris, said that when the uterus can be drawn down, the only way to prevent hemorrhage is to use the forceps; moreover, cure is not retarded by the use of these forceps; for having made an autopsy three days after an operation, he found a well-advanced cicatrization. As regards the ureter, the accident of seizing these canals has occurred with ligatures.

As to the supra-vaginal irregular amputation, he considers it as a very successful operation, as much so as curetting. As to the use of the pressure forceps, he thinks that it is to their use that we owe the increase in the number of vaginal hysterectomies.

INDICATIONS AND TECHNIQUE OF VAGINAL HYSTERECTOMIES FOR CANCER.

DR. POZZI, of Paris, said that vaginal hysterectomy can be applied to all cases in which supra- and infra-vaginal amputations of the neck of the uterus were performed. This operation is contraindicated in the following conditions:

1. Extension of the disease to the broad ligaments, shown by immobility of the organ and difficulty in lowering it after anæsthesia.

2. Primary and secondary extension to the vagina even when very limited.

3. Considerable volume of the cancerous uterus, rendering impossible or difficult its extirpation without tearing.

Palliative hysterectomy with or without excision of the vaginal cul-de-sac in all cases of this kind, must be disregarded. The dangers are out of proportion to the advantages it will procure. In all cases where a radical cure must not be attempted the palliative surgical treatment is of great service against hemorrhage, ichorous oozing, and pain. The operation consists in the methodical curetting of the diseased tissues followed by cauterizing with the red-hot iron.

The cutting curette is to be preferred, when well handled, to the knife. The red-hot iron will effectually complete the action of the curette. It can be carried without danger to the bottom of the uterus.

In cases of cancer of the neck and body, without extension, but too voluminous to be extracted per vaginam, the precedent palliative treatment (curetting with cauterization) should be preferred to total extirpation by abdominal section (Freund's operation).

4. The use of pressure forceps permanently does not give sufficient security against hemorrhage, especially primary. It exposes one to the compression and wounding of the neighboring organs and renders antiseptic precautions more difficult and the dressing more painful.

Pressure forceps are only to be used as a necessity and not as a method of choice, which is to be reserved for the ligature. These must be applied successively to the divided vaginal walls and on the broad ligaments, after inversion of the uterus. In cases where the uterus alone is taken, and the organ is movable and easily depressed, ligatures offer no real difficulties. One could say that pressure forceps permanently applied are only necessary in a hysterectomy which ought not to have been undertaken.

ABDOMINAL HYSTERECTOMY FOR VOLUMINOUS FIBROMAS.

DR. TERRILLON, of Paris, said that during five years he had treated 76 women suffering from voluminous fibromata which could not be extirpated per vaginam; 16 have been operated on by abdominal hysterectomy, the section was made above the vagina. 6 were treated by Battey's operation for grave hemorrhages due to the presence of fibromas of a medium size. 6 died on account of the presence of a fibroid body in the uterus which gave rise to variable accidents. Finally, 48 have been treated by medical methods. Abdominal hysterectomies have been nearly all treated by a method which consists in fixing the pedicle outside. Two only have been treated by returning the pedicle in the abdomen. Out of the 14 cases treated by the external method, 6 pedicles were ligatured with iron wire, with a rubber tube. This last method cuts the pedicle more easily. These 16 hysterectomies gave him 5 deaths and 11 successes. Death was produced in 2 cases by shock, no traces of peritonitis or septicæmia; 1 peritonitis, 1 from grave hemorrhage during the operation, 1 from pyæmia on the seventeenth day. Out of the 6 cases of extirpation of the ovaries and Fallopian tubes 5 were absolutely cured, the hemorrhages having stopped; 1 died sixty days after the operation from intestinal obstruction, the hemorrhages had ceased. The 6 deaths due to the fibrous body are: 2 by hemorrhage, 2 by phlebitis, 2 by septicæmia. In the other 48 cases he has used ergotin, which gave good results in hemorrhages, but often failed, even increased hemorrhages when the uterine cavity was enlarged. Cannabis Indica stopped the pains and hemorrhages. Finally, salt baths have been useful in anæmia due to repeated hemorrhages.

CAVERNOUS LYMPHANGIOMA.

DR. CH. MONOD, of Paris, saw a girl, eight months old, who presented on one shoulder a tumor the size of a hen's egg, the clinical characters being those of a cyst with thickened walls. On extirpation it was found to be a circumscribed cavernous lymphangioma, that is, a tumor with multiple divisions lined by an endothelium similar to those lining lymphatic vessels and filled with a serous liquid. This example led him to think that we have probably often confused *lymphangiectomies* with *lymphangiomas*.

The usually accepted definition for sanguine angioma is that it is a tumor constituted in great part by vessels of new formation (Cornil and Ranvier). Applying this definition to lymphangioma, he thinks we ought to reserve this last designation for tumors of lymphatic origin, in which one can admit and demonstrate the new formation of vessels and lymphatic laminæ.

To apply the name of lymphangioma to simple lymphatic dilatation would be exactly similar to giving the name of angioma to dilatations of the veins (varicose veins) or arteries (aneurism), which no one would accept. The lymphangioma, so accepted, is a very rare

tumor, he had only found two cases in medical literature which are like his, one by Reichel and the other by Middeldorpf. The only treatment for these tumors is extirpation and it is without danger.

URETHRECTOMY IN CERTAIN STRICTURES.

Dr. Poncet, of Lyons, said that the excision of a portion of the urethra, followed by the union of the two divided ends, is a good operation which finds its indication in peri-urethral fibrous induration encircling the urethra with an indurated perineal mass. Out of nine patients on whom he operated he had no death nor grave accidents; in three cases he obtained union by first intention.

After several months the result was perfect; a No. 20 bougie could be easily passed. In the six remaining cases the union took place more slowly, and the patients remained a few weeks in the hospital. The final result of this operation is superior to that of external urethrotomy, especially when union takes place by first intention. The calibre of the canal remains normal, and a few months after the operation it is difficult to find the former seat of the stricture. If union by first intention does not take place on account of the extent of the stricture, or for any other cause, a new canal will be formed by granulation. The cure, however, will necessitate several weeks, and if one wants to maintain a sufficient calibre to the urethral portion of new formation, daily catheterization must be practised, which the patient must do himself.

Micturition and coitus take place without interference; such has been the case in five of his patients whom he had seen several months after the operation.

SURGICAL TREATMENT OF HEPATIC CYSTS.

Dr. Segond, of Paris, said that there are two ways to reach infra-diaphragmatic hepatic cysts: the abdominal method; the pleural one. The abdominal method necessitates a tilting forward of the entire liver, and fixing it by approximate sutures in this new position. The pleural method, more direct, necessitates the successive incision of the thoracic wall, the pleural cul-de-sac, and finally the diaphragm. He has had satisfactory results in two cases on which he operated by the pleural method, incision of the thoracic wall, with or without costal excision. The first one was complicated by vomica and pulmonary suppuration, the other, more simple, and without connection with the lung. He concludes that transpleural incision, with costal excision, is the method of choice for posterior infra-diaphragmatic cysts. The dangers are less, he thinks, than when the anterior incision is performed and traction on the liver is made.

OPENING HYDATID CYSTS OF THE LIVER BY THE PLEURAL METHOD.

Dr. Maunoury, of Chartres, reported the case of a man of twenty-nine, who had an hydatid suppurating cyst of the upper surface of the liver, giving rise to very severe symptoms; being unable to reach this part by the anterior abdominal section, he opened it at the eighth intercostal space, which was the most projecting; on this level there existed, in the pleura and peritoneum, adhesions which appeared very solid. Two days later the pleural adhesions were destroyed, the contents of the cyst entered the pleura, and the patient died.

A few months ago, having to treat a woman, aged thirty-four years, presenting a similar cyst, he operated differently. He opened, at the most projecting point, the tenth intercostal space, and incised the parietal pleura through the diaphragmatic pleura. He sutured them together, so as to produce a complete canal through the serous membrane, then finished by incising the diaphragm, exposed the cyst, punctured it, and finally brought it to the exterior, fixing it on each side to the skin. No accidents occurred, and the patient is now perfectly well.

SUTURE OF THE INTESTINE FOR A CÆCAL FISTULA.

Dr. Horteloup, of Paris, reported the case of a woman who had had a perityphlitis; an abscess followed, which terminated in the formation of a large cæcal fistula, being four inches long and two broad. He tried on two occasions to remedy the trouble by sutures, but failed; he then resorted to the following operation: he made a circular incision between the mucous membrane and the cicatricial tissue; detached completely the intestine from the abdominal walls, and applied nine isolated sutures of carbolized silk, to close the abnormal opening; then, before uniting the abdominal wound, he washed the intestinal wound and the peritoneal cavity with boiled water, then finally applied isolated sutures to the abdominal parietes. The *next* day he gave his patient a purgative enema and the patient had regular evacuations, the sutures held firmly. Thirty-six hours later he gave him castor oil. He insists on two points of this operation:

1. The sutures he employed he prefers to Lembert's suture, as they require much less tissue than the latter.

2. The early administration of laxatives.

This last fact is contrary to accepted rules, but he claims that by keeping the intestines quiet with opium, the formation of gases is favored, which often brings on a condition of meteorism which tears the sutures and gives bad results; while laxatives prevent intestinal inertia which is due to a reflex state, and the intestine is much more easily restored to a normal and physiological condition.

NEWS ITEMS.

Mortality among Physicians.—The Illinois State Board of Health, in its *Report* of April 20, 1888, publishes the following conclusions from tabulated reports of death and disease among physicians:

The obvious inference is that physicians on entering practice form a class of selected lives, since they have an advantage of nearly 3 per cent. as compared with all males at the same ages—that is from twenty-four to forty; and of over 50 per cent. as compared with the total population, both sexes, at the same ages, this latter great disparity being no doubt largely due to the casualties among women during the childbearing period.

As the wear and tear of practice begins to tell, this advantage is soon lost, so that during the period from thirty to seventy the death-rate of physicians is 8 per cent. greater than that of all males, and during the period from forty to seventy it is more than 11 per cent. greater than that of both sexes.

The Pollution of Ice.—The Massachusetts State Board of Health has been investigating the purity of the ice supply of Boston and vicinity. A recent number of the *Boston Herald*, in publishing a report of the work done

by the Board, describes the following example of the dangers of impure ice, occurring at a hotel at Rye Beach:

The Rye Beach trouble was ably reported upon by Dr. A. H. Nichols. He was engaged by the proprietors of the hotel, who were, of course, suffering pecuniarily from the trouble, to investigate it thoroughly. The disorder in question may be comprehended under the general term disturbance of the digestive system, characterized by a sensation of giddiness and nausea, vomiting, diarrhœa, severe abdominal pains, all of which was accompanied by fever, loss of appetite, continued indigestion, and mental depression. The epidemic, though confined to so limited boundaries, baffled for a considerable time all efforts to trace the trouble to any specific cause. At first the drinking water was suspected, but that was drawn from wells at a safe distance from all drains and contaminations. It was also ascertained that some of the persons affected, having apprehended trouble from some such source, had used some other beverage. They had not hesitated, however, to use ice, either melted or otherwise. Suspicion at length rested upon the supply of ice furnished the house. A large portion of the ice furnished the town was found to be gathered from shallow ponds, formed during the winter by the flooding of meadows, and it, therefore, contained, as a rule, more or less grass and old vegetable matter, being, consequently, far less transparent than the ice supplied in Boston.

The ice in this case was found to contain numerous foreign substances, varying in size, and apparently of vegetable origin, and the blocks were opaque. By questioning residents of the place, it was found that, during the winter, one had taken home some of the ice for the purpose of testing it, to find out whether it was fit to use, and, having eaten some of it, was made violently ill. Others had noticed a disagreeable odor arising from it. Two gentlemen who had taken some of it on a fishing excursion were made ill by using it, and in the room in which the ice was stored for the hotel there was a very bad smell. When the water from the melted ice was poured into a glass in the sunlight there was seen to be a discoloration, and it was charged with suspended matter. The pond itself was then examined, and was found to be stagnant, while down at one end of it there was a homogeneous mass of putrescent matter, composed of marsh mud and decomposing sawdust. When stirred the water near this place emitted an intolerably offensive odor. At houses near by it was found that in the summer time the windows had to be closed when the water was in any way disturbed, on account of the smell it gave off. Prof. W. R. Nichols was asked to examine samples of the water, and reported that it contained in suspension a considerable quantity of vegetable matter more or less decayed, and possessed a slightly disagreeable odor which became more noticeable as the water was warmed. Of the organic matter, some was so heavy as to settle down at once into the bottom of the vessel into which it was poured, but the lighter material remained for an indefinite time diffused through the water and would be drunk by anyone using the ice in the ordinary way. Prof. Nichols thought that it was quite reasonable to suppose that the ice had been the cause of the sickness.

Coincident with the disuse of ice at the hotel the guests began to get well, and there was no further sickness.

Ice taken from a cart of the Boston Ice Company was analyzed beside that taken from Rye Beach, and the result showed that, while the organic and volatile matter was 0.31 in the Boston ice, it was 5.72 in the Rye Beach ice; and, while the chlorine was 0.02 in the Boston ice, it was 3 23 in that from Rye Beach. Dr. Nichols is constrained to say that great responsibility devolves upon those who undertake to provide food and drink for large numbers of individuals, and to such this experience inculcates the importance of giving special attention to the purity of drinking water, and guarding against every possible source of contamination. The notion that ice purifies itself by the process of freezing is not based upon trustworthy scientific observation. On the contrary, it is utterly wrong in principle to take ice for consumption from any pond, the water of which is so fouled that it is unfit for drinking purposes.

The Dangers of Carpet Beating.—The Paris correspondent of the *Popular Science News* writes that the Conseil de Salubrité of Paris has recently discovered the inconvenience of allowing carpets to be brushed and beaten in the open air in the vicinity of inhabited houses, on account of the dust which is so raised, and especially on account of the bacteria which may be set free when the carpets come from houses where zymotic diseases have existed. The Conseil de Salubrité has decided that this operation will be allowed only under the following conditions: The carpets must be brushed and beaten in entirely shut-up rooms, and the dust deposited on the floor will be washed with water containing some disinfectant of potent action; strips of wool, etc., will be burnt immediately. This measure is a good one, and will certainly prove useful. Sources of contamination are much too numerous to be allowed to remain, when we possess means of destroying them.

Typhoid Contagion by Clothing.—The Berlin correspondent of the *Medical Press* of March 28, 1888, writes that many striking illustrations of the origin and spread of typhoid fever epidemics are on record, but not many are more instructive than the history of a persistent epidemic that played havoc in a German artillery barracks during more than a decennium, from 1873 to 1885. Two neighboring barracks were occupied by the 1st Division of the 2d Hanoverian Field Artillery Regiment, No. 26, and in the year 1873 a case of typhoid was imported, probably, as is supposed, on the return from France of the army of occupation, and from that date to the close of the epidemic 146 cases of fever occurred. Almost the whole of the cases occurred in one of the barracks, in which 238 men found accommodation, although the drinking water of both was from a common source. Every attention was paid, every inquiry was made into possible sources of disease, the latrines, water, buildings, everything was put and kept in the best possible condition, but the disease still baffled all inquiry. At last, the question of the propriety of closing the barracks came up for consideration, when, in 1883, the observation was made that about one-half of the cases were furnished by the men of one battery alone, and suspicion fell upon the bed linen and clothing. It was then ascertained that three of the recent cases had used the clothing and bedding of men that had been attacked. This led to closer examination of the clothing, and it was then discovered that the linings of the trousers were almost, without exception, soiled by

dried fecal matter, of which a part probably had its origin in typhoid patients. The clothing had previously gone through a routine of disinfection by sulphur vapor, but as the result showed the disinfection had been nil. It was now submitted to more careful treatment and thorough cleansing, twelve hours saturation with chlorine gas, and lastly, dry heat for several hours more. From this time, November 18, 1885, no more cases of disease occurred.

Benzine an Adulteration of Antipyrin.—Dujardin-Beaumetz calls attention to recent analyses of antipyrin as commonly sold, which showed benzine to be present not rarely as an adulteration. Some of the ill effects reported may be thus accounted for.

Lipanine, a Substitute for Cod-liver Oil.—The *Revue Scientifique* writes that cod-liver oil is in certain cases so wonderful a medicine, that we must regret that we do not know its active constituents with exactness, so as to be able to administer them in a form less repugnant than that of the oil itself. M. Mering has performed an experiment in this line that should be noted.

Starting from the theory, adopted by most doctors and pharmacologists, that cod-liver oil owes its superiority over other fatty oils to its richness in oleic acid—white oil contains from 0.18 per cent. to 0.71 per cent., and brown oil 2.54 per cent. to 5.07 per cent.—the author has tried experiments with a mixture of olive oil (100 parts) and oleic acid (6 parts), to which he has given the name of lipanine, and to which he attributes the following advantages:

Lipanine would have no disagreeable taste and would be perfectly digestible, because of its high emulsive power, oleic acid saponifying with the alkalies of the bile and pancreatic juice. For this reason it could be administered for long periods in large doses without injury to the digestive faculties. In fact, M. Mering reports that for a period of six months he administered this remedy to forty patients, of whom thirty were children, and that all took it without repugnance and without subsequent ill effects. The dose varied from one to four teaspoonfuls, according to the patient's age, and this was continued from six weeks to three months. Most of the patients were scrofulous or rickety, some consumptives or diabetics. All of them under this treatment increased in weight, their general condition improved, their strength returned, and these good results were obtained also among a great number of children in charge of Professor Kohts. In a word, these effects would appear absolutely comparable with those obtained with cod-liver oil, but the advantages of lipanine in its freedom from taste, easy toleration by the stomach, and capability of administration in the hottest summer weather are equally obvious.

A Tribute to the Late Dr. Cornelius R. Agnew.—The following communication to the *New York Evening Post* of recent date evidences his work among the soldiers during the War of the Rebellion:

To the Editor of the Evening Post,

SIR: Permit me to place one flower on the grave of Dr. C. R. Agnew, in grateful remembrance of his kindness to soldiers during the late war.

I was severely injured in the eye while fencing with a brother officer at the headquarters of the Army of the Potomac. Gen. Meade's Surgeon-General advised that I should at once be sent to Dr. Agnew in New York, and this was done. For thirty days Dr. Agnew's care was bestowed upon me with marvellous skill and the tenderness of a loving parent. At the end of that time I was able to return to duty, when, upon asking the doctor for his bill, he laid his hand on my shoulder and looked into my eyes and said: "Captain, what I have done for you is only an expression of what I feel is due to every man who wears your uniform. You do not owe me anything."

On my way back to the army I met a captain of artillery whose hearing had been injured by the bursting of a shell near his head. We had met often at Dr. Agnew's office, and, on comparing notes, each learned of the doctor's generous kindness to the other.

Only a few people *know* of Dr. Agnew's devotion to the men of the army. To me, "The world seems lonely without him." Respectfully yours,

AN EX-OFFICER OF THE U. S. ARMY.

CORRIGENDUM.

THE interesting article entitled, "A Case of Symmetrical Gangrene," which appeared in our issue of last week, page 461, should have been credited to Dr. M. A. Veeder, *not* "Beader" as printed.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING APRIL 28, 1888.

RHOADES, A. C., *Medical Inspector.*—Detached from special duty, New York, and waiting orders.

HENNEBERGER, L. G., *Passed Assistant Surgeon.*—Detached from Naval Hospital, New York, and to special duty attending officers and families New York.

OBERLY, A. S., *Medical Inspector.*—Granted six months leave with permission to visit Europe.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM APRIL 24 TO APRIL 30, 1888.

BAILY, JOSEPH C., *Lieutenant-Colonel and Assistant Medical Purveyor.*—Granted leave of absence for twenty days on surgeon's certificate of disability, with permission to apply for an extension.—*S. O. 92, A. G. O.*, April 21, 1888.

BAILY, JOSEPH C., *Lieutenant-Colonel and Assistant Medical Purveyor.*—Will transfer the public funds, for which he is responsible, and the charge of the Medical Purveying Depot in New York City, temporarily, to Captain Henry Johnson, Medical Storekeeper.—*S. O. 92, A. G. O.*, April 21, 1888.

Par. 13, S. O. 89, A. G. O., April 18, is revoked by par. 1, S. O. 93, A. G. O., April 23, and STERNBERG, GEORGE M., *Major and Surgeon, U. S. Army*, is directed to proceed to the Island of Cuba for the purpose named in the letter of the President addressed to the Secretary of War on the 17th inst. Upon the completion of this duty will return to his proper station, and submit his report to the President on or before June 25, 1888.

VICKERY, R. S., *Major and Surgeon.*—Granted leave of absence for four months, with permission to apply for an extension of two months and to go beyond sea.—*S. O 95, A. G. O.*, April 25, 1888.

By direction of the President, PERSONS, REMUS C., *Surgeon*, U. S. Army, is assigned, temporarily, to the charge of the Army and Navy General Hospital, Hot Springs, Arkansas, during the absence, on leave, of Major Richard S. Vickery, Surgeon, U. S. Army, Surgeon in charge.—*S. O. 96, A. G. O.*, April 26, 1888.

WOOD, LEONARD, *First Lieutenant and Assistant Surgeon.*—Granted one month's leave of absence, with permission for an extension of two months.—*S. O. 41, Department of Arizona*, April 18, 1888.

ANDERSON, CHARLES L. G., *First Lieutenant and Assistant Surgeon.*—Granted one month's leave of absence, from June 1, 1888. Resignation accepted by the President, to take effect July 1, 1888.—*S. O. 92, A. G. O.*, April 21, 1888.

AMERICAN MEDICAL ASSOCIATION.

THIRTY-NINTH ANNUAL MEETING, CINCINNATI, 1888.

THE ADDRESS IN SURGERY.

Delivered May 10th.

BY E. M. MOORE, M.D.,

OF ROCHESTER, NEW YORK.

A SKETCH OF THE PROGRESS OF SURGERY.

FROM the broad field of surgery there are many lines of inquiry which might interest its devotees if properly followed. But to treat of any one of them implies special study of the new developments that now abound in the great advances in the arts and the sciences whose discoveries it employs. On a former occasion your reader occupied the same relation to you that he does at this moment. He then prepared himself for the occasion by a series of experiments *in corpore vile*, to illustrate the subject of blood infusion. He believes he had the good fortune to add a thought to knowledge on this topic. It seemed to him that a general view of the relation of surgery, and the surgeon, to the community in which he lives and has lived might be of sufficient interest to justify the spending an hour in its review. This must revive well-known stories, and allude to present movements familiar to all; but they contain triumphs which always stir the heart of the true surgeon. Pope in his mellifluous couplet, which has pleasantly rung in the ears of every physician from his youth up, has interpreted the views of Homer of three thousand years ago, when he sang that,

> "A wise physician, skilled our wounds to heal,
> Is more than armies to the public weal."

Then, as now, the surgeon was most prominently connected in the public mind with the treatment of wounds of accidents, or those of his own making.

Recurring to the subject of wounds, we can, perhaps, at no one point get a better illustration of the movement of discovery than in the changes with reference to their management, and especially of those that the surgeon inflicts in performing the amputation of a limb. It would be idle, in the few minutes at my disposal, to follow accurately even this one line. The attempts at primary union have seldom been other than partial, until the advent of the modern antiseptic methods. In the early part of this century, experiments upon the encysting of ligatures for closing the arteries were tried and abandoned. The movement from the open wound, of necessity, to the closed one antiseptically treated with soluble ligatures and sutures has been long and slow. We had almost come to the definite conclusion to make the open wound as the final judgment of the profession. Hippocrates avoided amputation except in cases of gangrene. In his day it was full of terror. Indeed, there could not be said to be any amputation as we understand the process. Limbs that were crushed or injured by compound fracture were allowed to get well or to mortify. When gangrenous, after the red line was formed, it was made at the border that Nature had decided on as the place of separation between the dead and the living. Such delays in the treatment of severe injuries, with our knowledge, would be simply criminal. But when gangrene has occurred and we wait as we must, except in certain rare conditions generally understood, I am in accord with the custom of Hippocrates. This places me in contrast with a practice almost universal. But, singular as it may seem, an antiseptic dressing will complete the measure of safety incident to the amputation through the dead part.

Reasons for this belief are easily stated, and, of course, are not those founded on the fear of amputation through the living parts as a general measure. But when the red line has formed, Nature has already made the amputation. Following an irregular line, which is lowest down in the integuments and bone, the separation has been made between the dead and the living tissue. The danger arises from the retention of poisonous fluids in contact with tissues now full of vitality. An operation of necessity can be made, closely following the line of demarcation, and it will be found that the endosteum retains its vascularity nearly, if not quite, as far down as the integument does. These are the two factors of an amputation indispensable to its success. The muscles, and especially the fascia and aponeuroses, as well as the periosteum, are apt to die. Deep recesses following the connective tissue will be filled with pus and septic fluids. The amputation may be made as described, with far better hope of success, than higher up through the living tissues. The special dangers of amputation through them are avoided. There are no vessels to tie, there is no fresh absorbing surface to be poisoned by its own secretion, there is no danger from hemorrhage, and more than all, in the enfeebled condition of the patient, there is no shock. The deep recesses are now exposed and can be cleansed. Absorbent cotton, moistened with a solution of mercuric chloride pushed into the open spaces, at once attracts, by capillary attraction, all the fluids. When the succeeding dressing is undertaken, it will be found that every part has the appearance, and, indeed, the reality of having been washed clean. The irregular surface is, however, a granulating one, and for this reason alone has become one that is essentially protected from the dangers of sepsis as soon as a free escape of the fluids can be effected. The periosteum, if destroyed, may result in necrosis of the outer shell of the bone. But the endosteum will maintain it in its integrity sufficient for the length of the stump. The wound being necessarily an open one, closes slowly.

It will be seen that the observation which I urge upon your attention is a return to the ancient method, with two thoughts added to it, which, in my judgment, should change our practice in these cases. They are, as every

surgeon knows, fraught with great danger when the amputation is made above, in the living tissue, for the shock of amputation in the enfeebled state is frequently fatal. The custom of the ancients was to pick away the dead part, and divide the bone high up. They were anxious to disarticulate, if the line of separation had gone to a joint. One stands aghast at the shapes their stumps must have assumed. In recommending the open wound, in these cases, I only do so at points where a proper stump can be made. Take, as an illustration, gangrene commencing in the foot, and stopping on the leg four or five inches below the knee. According to our custom, the amputation must be made through the thigh. But the danger of such an amputation is vastly more than by the Hippocratic method, at the red line, and the lower stump is far better. The choice, in my opinion, should be made at the red line, if possible.

The advent of the gunshot wound occurred at a time when the practice of surgery was at a low point; and the effect of the "villanous gunpowder" was regarded with just grounds of terror. The terrible results were ascribed to poison. Both the lead and the gunpowder were poison. How could such fatality occur unless from poison? Poison wounds should be treated with the hot cauterizing iron, or boiling oil, to destroy the infected surface. The bullet must be extracted, if it be possible; its poisonous character could scarcely be borne by the constitution. The surgeon with such views would be apt to complete the work of the soldier. But time reforms medical as well as other opinions. If easily extracted, all foreign bodies should be removed, even with the present views of the innocuous character of the bullet. This has always been accepted, and expectation has been the practice for a long time. But now we have antisepsis of the track and careful covering of the wound to guard against microbal invasion. How far this may be carried is yet unknown, but great advance has already been gained. It is, however, of recent date that the greatest steps have been taken in the management of this special form of wound. Among the most notable are those announced from this platform. The facts are all known to you. The great cavities of the body have, heretofore, been deemed unapproachable. It was believed that the surgeon, if he undertook their exploration, would render certain what was almost sure to happen. In gunshot wounds of the abdomen there might, perhaps, be one life saved, while ten were lost. Why should this meagre hope be denied?

But all this is changed. I do not report, but only allude to the marvels that are detailed by Drs. Parkes and Senn, marvels that we could only know by the use of vivisection, which, fortunately, has not yet been submerged under a sea of maudlin sentimentality. Here, again, we have the triumph of cleanliness. A gunshot wound of the intestine will inevitably result in the expulsion of some of the contents of the bowels, the vermicular motions of the intestines will surely secure this result, even if, after a while, these motions are arrested, in obedience to the law of inflammation. The cases of recovery were, probably, those where a fortunate apposition of the wound near the abdominal walls circumscribed the area of pollution and nature's active efforts at repair completed the line of circumvallation. The case of the insane woman in Utica Asylum, who punctured the abdomen and drew out a piece of the small intestine, fourteen inches long, and cutting it off with a pair of scissors, threw it on the floor, is widely known. The physician in attendance knew of nothing but expectation in such an emergency. He drew the edges of the abdominal wound together, and waited the event. No remarkable symptoms supervened. The recovery was complete. Many years after, an autopsy revealed the fact that the edges of the intestinal wound had been fastened to the abdominal wall. But such results are too rare to be guides of conduct. The new methods are already accredited with improvement, and as the courage and better diagnosis of the surgeon improve, we shall inevitably place the treatment of these wounds by laparotomy upon a sure foundation.

Every surgeon has seen cases of strangulated hernia where gangrene has supervened, and will bear testimony to the fatal character of the injury. Now, for the relief of this condition enterorrhaphy comes in to take its place as a recognized operation, with large increase in the saving of life. Again, cleanliness is the pivot upon which the whole movement turns. It seems incredible that the peculiar kind of filth that invades the peritoneum in gunshot wounds of the intestine, can be removed sufficiently to secure even such results as have been obtained. Antiseptics of proper strength over this immense surface are dangerous expedients. Are we to see a stream of distilled water, rendered properly saline, carried into and out of the peritoneal cavity long enough to insure cleanliness? Are we to irrigate the surface after inflammatory exudates have actually appeared? The possibilities seem large. That these exudates, when extensive, may accompany a fatal inflammation without the formation of the dangerous ptomaines of microbal creation, it seems to me to be manifest. In the experiments by Dr. Parkes on dogs, one fact is to be especially noted; the frequency of the existence of entozoa and their migration through the wound. It has been my fortune to witness two deaths from rupture of the intestine by external force, without a wound of the abdominal wall, not even a break in the parietal peritoneum. One was in a child of six years of age; the other in a man of forty. The child died in twenty-three hours, and the man in twenty-six. Autopsy revealed a fact exactly the same in each case. The fibrinous exudate of a character sufficiently firm to be lifted upon the handle of the scalpel had extended over the whole surface of the peritoneum, even to its remotest corner. It is a little odd also, that a single lumbricoid worm had crawled through the opening in both cases. The fibrinous material had probably acquired its firmness many hours before death. It is hardly credible that much pathological change could have occurred during the latter hours of life.

Just fifty-one years ago, during my student days, I had the pleasure of an invitation from Prof. Mütter to witness the first operation on the tendo Achillis in Philadelphia, and, as I believe, on this continent. It was his second operation. The antecedent one was upon the hamstrings. Still a young surgeon, he was especially patronized by Dr. John Rhea Barton, who, upon the then recent death of Dr. Physick, was by common consent recognized as the surgical chief of Philadelphia. Dr. Barton protested vehemently against the operation and refused to witness it, being unwilling to give his countenance to anything that was so dangerous. It would certainly blight Mütter's prospects in life. Moreover, the

interests of the patient should stand first and he could not be a party to anything so contrary to good surgery. The great fact of the immunity from suppuration when subcutaneous incision is made, had not yet impressed itself upon the surgical mind. The vast value of direct repair had acquired its recognition under the guidance of John Hunter, but the value of the subcutaneous cut was not appreciated. This marks one of the most magnificent of all surgical movements. The rationale was to be explained to-day. Antisepsis is the legitimate descendant of the subcutaneous cut. The tenotome would almost surely be cleansed as it passed through the skin, and the minute wound would be washed by the few drops of extruded blood. This was clearly our antisepsis. Was not Dr. Barton justified by his experience? With our knowledge his conclusions reached the depth of absurdity. But had he not seen tendons sloughing when exposed to the air? Had not cases enough of accidental incision of the tendo Achillis been reported to prove that if the life, always in danger, was preserved, the limb was likely to be useless from the loss of its great tendon? The surgical world woke to a great fact, and strabismus, torticollis, and all contracted tendons came under the surgeon's knife, until it became almost a craze, when Guerin, for the relief of lateral curvature of the spine, cut every spinal muscle and tendon that he could define, until the chain of bones could be moved like a serpent's back.

At the meeting of the New York State Medical Association last September I led the discussion upon the proper method of treating compound dislocation of the ankle-joint. I found the opinions of surgeons on this point very indefinite, with a strong, even an uncompromising judgment in favor of amputation; notably by Prof. Gross, who would make rare exceptions to this plan. Others advised reduction and a few relied on resection, some of the tibia and fibula with removal of the ends of both bones with their malleoli, while others removed the surface of the astragalus also. Even the most modern writers left the whole subject in a vague way to the judgment of the practitioner. These authors were quoted to show their various opinions, but it would be out of place in this paper. For a long time I had been convinced of the great wrong inflicted by these teachings, which were founded on the statistics of hospitals in large cities before the day of antiseptic surgery. Such advice was even then not applicable to the condition of life in the country and smaller towns, where purer air and better constitutions existed together. I had used resection with good results in three cases, and had seen two cases, in consultation, which had been simply reduced by the surgeon in attendance. The latter made good recovery after a considerable constitutional disturbance, but by ankylosis. But before writing my paper, I had the good fortune to see a case that had been treated by a young friend (Dr. P. G. Udell), which seemed to me an almost ideal result. The foot, movable through a little more than half its normal extent, and free from pain in walking, was enabled to execute its function by the formation of a flail-joint after the resection of an inch and a half of the tibia and fibula. The novelty of the method consisted in leaving the two malleoli attached to the astragalus and bringing their fractured extremities in contact with the resected end of the bone. Granulation was the result, of course. Drainage and carbolic acid solution were employed to secure antiseptic results.

Six months reflection and experience have induced a change in my opinion as to resection of the malleoli in these cases. I would now, in nearly all, reduce and rely on cleanliness and antisepsis. There are cases, of course, where the crush is so severe that there can be no doubt. But when the rupture is great, better opportunities are given for the inspection of the surfaces, than when the opening is small. The resection may be secondary and the amputation tertiary.

The microbal discoveries of Pasteur and Koch and their disciples have placed all of our therapeutics on a new basis. The subject is trite, we hear of little else. No one knows when a real discovery is made how far it will reach. It always seems to run like a thread through the woof of all knowledge. How can we measure the scope of a piece of glass ground to a lens? The spectroscope was a mere philosophic toy at first; what now?—the analyst of the sun as well as of the blood. No one can now measure the possible triumphs of surgery. That which was excellent yesterday must be abandoned to-day. I confess, after long years of practice, to a delight that has the glow of youthful enthusiasm when making a resection of the knee under the use of mercuric chloride, and closing up the wound with silk sutures and applying drainage tubes in each corner of the wound, and then covering the whole with absorbent cotton saturated with the same microbal enemy; to remove the whole at the end of two weeks with complete closure, every suture encysted and not a drop of pus. Of course, there was no fever, only physiological repair. Or even to witness, perhaps, a more difficult feat in a much more common condition, the neat apposition of the tissues of a hand lacerated by machinery, while a stream of the antiseptic solution flows over every part, and the retention of these tissues in their proper position is effected by sterilized catgut, the whole protected with absorbent cotton saturated with the solution. At the end of a fortnight the sutures have disappeared, the repair complete, without a drop of pus. Such are now the experiences of all of you, and need no enlargement of statement. The surgical atmosphere is now antiseptic. Lister must now take his place beside Jenner. For the time, he has added a word to the language, and we do not mean merely carbolic acid and the spray when we speak of Listerism. There is already a wide range of material to choose from.

It is, however, obvious that there is a constant tendency toward the employment of the mercuric chloride, notwithstanding the objection raised by Prof. Billroth and his preference for iodoform. Its accessibility, its inodorousness and enormous power as a germicide will easily account for this. The natural fear of its powerfully toxic effect has rendered us all cautious, but more knowledge of good methods is expanding its application.

Who has not dreaded the care of a compound fracture of the thigh? But now we have report by Professor MacEwen of 1000 cases of osteotomy and no bad results. Who a few years since could have accepted the statement, that the bone could be cut and crushed, the surface broken and driven into the texture of the bone above and below, and yet remain absolutely free from the danger of necrosis and ready for union? The operation is essentially subcutaneous. But Dr. Hahn, of Berlin, boldly incises the soft parts and exposes the surface of

the tibia under a stream of mercuric solution, regarding this operation as secure as the subcutaneous cut, and as the parts can be seen they are more susceptible of proper management. In all these cases merely the quiet necessary to physiological repair, with its antiseptic covering, comprises the after-treatment. Its simplicity and rapidity of result amaze one. Perhaps, however, the best illustration of the value of the treatment that renders wounds aseptic is to be found not in those that MacEwen has made, but in those that have resulted from accident, which we recognize as compound fractures. They are at the deepest part of the limb and present every form of wound in the same case known as incised, punctured, lacerated, and contused. They have always been the terror of the surgeon.

At present the record of the triumphs of antiseptic surgery flows from every hospital. It would be burdensome to quote much, but the tables of Volkmann give at a glance the whole history of the modern leap in surgery. It has always been the misfortune of old hospitals to be the places where the greatest mortality would ensue when a wound was to be treated. It is not necessary to enforce this statement by any large collection of statistics, but I cannot pass by the consideration of this subject without quoting the extraordinary tables of Volkmann. He has collected the facts from the hospitals of Germany and England, and found that the results in all were similar in a very remarkable degree. He found that of 885 compound fractures of the limbs, 339 deaths resulted, whether preserved or amputated, being 38½ per cent. This in civil life. In military hospitals the percentage was $23\frac{6}{10}$. The difference may be easily accounted for by the fact that many of these were recently constructed and often extemporized, and also that the average age of the subject was during the firmest periods of life. The approximation in results in the various civil hospitals is shown very simply.

In Göttingen, the mortality was 38 per cent.					
In Zurich	"	"	"	$38\frac{7}{10}$	"
In Breslau	"	"	"	$40\frac{5}{10}$	"
In Halle	"	"	"	$40\frac{6}{10}$	"
In Bonn	"	"	"	$41\frac{8}{10}$	"

Since the adoption of an antiseptic method, Volkmann makes report of 75 cases in 73 patients with compound fractures and many with injury of the joint, and not a single death. Of these there was the extraordinary number of 21, or 28 per cent. of all cases. 11 of these were treated conservatively, and there was but 1 that resulted in ankylosis. 1 was a shoulder-joint which was resected. The elbow-joint was opened six times, of which there were made one primary, and three secondary resections. 2 were treated conservatively. The knee-joint was opened four times and treated conservatively. The ankle was opened six times. 2 were treated by secondary resection. 1 by amputation. 3 were treated conservatively. The management was simple. In the first place protracted drenching with water, the removal of spiculæ and trimming sharp ends of bones, enlarging the wound always enough to allow exploration with the finger, and then causing it to gap by retractors, while the drenching was going on, not stopping until the last coagulum was disposed of; then completing the irrigation by a drench of carbolized water. After the proper replacement of parts the whole was covered with abundant layers of carbolized gauze, and kept free from accumulation of fluids by drainage tubes. Most of the cases were seen a few hours after the injury. Five, however, were treated after a delay of forty-eight hours.

The great achievement of the day, however, is by common consent the marvellous growth of laparotomy. During my early career, the removal of an ovarian tumor, notwithstanding McDowell's success, was stigmatized as murder, which, indeed, it seemed very often to be. Dr. Atlee was fiercely denounced for his efforts to bring this operation into the ranks of legitimate surgery, which he lived to see fully established. But through what a valley of death have the wonderful results been obtained. It is now but fourteen years since Keith electrified the whole surgical world with the report of ten consecutive cases and only one death. Two years after Dr. Atlee remarked to me, after performing an operation of this kind, that if it should succeed it would be the tenth consecutive good result. It, however, failed. By what slow approach have we arrived at the present simplicity of operating. The manipulation is simple, but delicate beyond the necessities of ordinary surgery. How difficult to apply what we call experience. Surely every surgeon had seen enough of the danger of opening the peritoneum, to fear its terrible inflammation, which we have often seen run over the whole immense surface, even to its remotest recesses, beginning at a wounded point. Experience was ample. How could we dare to defy the results of such knowledge? But from the recognized fatality of the tumor, and the distressing condition under which life was maintained during the latter period of its existence, we should have known but little of the dangers to be avoided and how to combat them. How long a time it required to learn, that, after all, it was not peritonitis that we were chiefly to fear. We had to learn that the whole immense surface was but little else than the expansion of the lymphatic system, as the skin is of the nervous one. And when the blood mixed with the contents of the sac that had been left behind, excited first a secretion from the surface for their solution preparatory to their absorption according to the natural law for their disposal through the blood, we encountered on the autopsy the fearful red serum.

Too much was to be done. Even our therapeutics misled us. I still accept the correctness of the opium treatment in genuine non-traumatic peritonitis. We owe a great debt to Dr. Alonzo Clark for the careful development of its excellence in this condition. But our pathology was a mistaken one, and I cannot but think that the mortality is increased in the cases first mentioned by the use of opium. How much to unlearn and how hard in the face of our experience?

Who has not looked into the peritoneal cavity during an operation and hardly dared to touch it, preferring to leave some blood and sac contents, rather than touch the inflammable surface. But the death of Keith's eleventh case struck the keynote. The peritoneum must henceforth be clean. To our astonished gaze the membrane could be sponged, and washed, and dried, and then it quietly removed the small amount that the sponge could not absorb. From this time the death-rate diminished in the hands of every operator, and the note has become universal that the basis of all antisepsis is cleanliness. Even the exudation from peritonitis must be removed, according to Mr. Tait, who has for this condition washed

out the cavity with water that flowed from the city tap, and which, according to a friend with microscopical knowledge, contained "thirty-six different kinds of beasts." "You reject antiseptic medication," said I to Mr. Tait, who replied: "Yes, it is all rubbish; there is but one antiseptic that I know of." "Pray, what may that be?" "Soap and water." Again it is cleanliness. It would be idle to say that surgeons did not esteem cleanliness as going a long way before godliness in operations. But it was not of the precise and thorough kind that was demanded.

I will leave the statistics that Mr. Tait has given us, out of our consideration. They transcend those of all others who have undertaken to follow in his footsteps; so as to lead one to believe that there are some problems unexplained. The operation for the removal of an ovarian tumor is by common consent, in its various conditions, at times the most difficult one of execution that ever comes under the hands of the surgeon. At other times it is the type of simplicity. These circumstances give an opportunity for a wide difference in the results of operative procedure intended to be similar. There is a preponderating opinion that direct antidotes to the processes that seem to control the poisonous results of suppuration, increase the percentage of favorable termination in cases that have been operated upon. Their use marks another step in the treatment of wounds accompanied by exposure of the peritoneum. Mr. Tait's results are to be regarded as unique, and surgeons are not likely to omit proper antiseptic measures. We are still in the midst of change, but the splendid record of expert operators as we all know, has removed this operation from a mortality that seemed murderous to one that is less than any operation of a capital character. That this result has been obtained by constant attention to the action of natural law is too obvious to be denied.

Several years since I removed a uterus containing a fibroid weighing seventeen pounds. The cut extended nearly the whole length of the linea alba, before it could be drawn through it. The vessels were ligated on the sides, and then I carried out my device for managing the stump, and guarding the peritoneum from the presence of the dreaded foreign body in the shape of ligatures or sutures. A slight incision was made all around the huge mass about three inches from the vaginal junction. This was dissected down and all around to nearly the point above mentioned. The vessels were easily seized and the blood was readily prevented from passing into the cavity of the peritoneum by the cup-like form of the cut. Amputation was made about an inch from its junction with the vagina, and at this point it had, of course, become small. But little blood flowed from this last procedure, for the vessels had already been secured. After hemorrhage had ceased the edge of the cup-like pedicle was pocketed in the linea alba. Thus peritoneal surface was brought against its congener. The intestines had fortunately been kept covered by the abdominal walls. Union of the wound in the linea alba was perfect. A drain down through the neck of the uterus seemed to me the most perfect of appliances. I fondly hoped that this was all that could be desired. But I had at this time no means of antisepsis. Now Péan, as reported by Dr. Senn, closes over the stump with catgut sutures, after having extirpated the mucus membrane of the neck, and brought the abraded surfaces together by a sort of autoplasty, and drops it back into the pelvis. As an operative procedure this seems to me to be final.

But the exposure of a joint to the atmosphere is far more apt to result in inflammation, with a tendency to suppuration, than the peritoneum. But now we follow the nests of bacilli into the joint with a sharp spoon, and filling all nooks with an antiseptic solution, close the capsule with the assurance of freedom from any active inflammation, especially of a suppurative form. This is surely one of the most extraordinary triumphs of antisepsis.

I must not omit, in this sketch, the important step in advance that was declared in the papers by Prof. Andrews and Dr. Watson, delivered before this Association last year, on the treatment of carious wounds by the use of a solution of hydrochloric acid 1 to 20. *A priori*, every one felt that such a strength of acid must be so irritating as not to be tolerated. But coming from such authority I at once adopted the method, and I desire to say, that I regard it, as one of the great advances in surgery, free from danger or even irritation, and replete with power. Moreover, we have at the same time an agent that removes the dead and does not injure the living bone, and is also a valuable antiseptic.

Neither must I fail to speak of one of the stages in the progress of research which is marked by the attempt to obtain sterilized air. As we all know, Lister's spray has occupied the largest place for this purpose, with a reputation much waning, and entirely abandoned as worse than useless in laparotomy. Let any one make the experiment of throwing the spray upon a plate of glass for a few minutes, and he will find, by the employment of a lens, that the rush of the vapor has drawn in and deposited upon the glass every floating particle in the atmosphere, thus concentrating the minute foreign bodies instead of dispersing them. Independent of the poisonous carbolic acid, rapidly absorbed from the large surface of the peritoneum, we would make a special deposit of foreign bodies, which, though minute, could be aught but useful. But long before Lister's time, a plan of enclosing the part to be operated on in an atmosphere of nitrogen was attempted. The difficulty of executing the procedure to a successful termination arrested the experimentation. Many years since I myself entertained the hope that benefit would accrue from the pouring of carbonic acid gas over the wound and into the cavity during a laparotomy, thus excluding the atmospheric air. But without sterilized hands and other necessary apparatus, the method was comparatively useless, and with the proper antisepsis became comparatively unnecessary.

We also find Dr. Prince sterilizing the atmosphere of the whole operating room, and a Boston hospital supplied by air from the roof, which, being carried to the basement, is passed over heated plates in winter, and thence distributed over the building. Burning sulphur is a common method of preparation with which all are familiar. Perhaps we may yet choose a room whose air shall be purified by its passage through sterilized cotton, or through tubes in imitation of Tyndall's glycerine box.

It is the glory of the time that really great men among us are not so marked by a wide separation from their colleagues, such as prevailed one hundred and fifty years ago. Then there was but one John Hunter, and he remained without peer, and with few followers. Meeting one of his contemporaries when he was carrying home

some pig's feet from market, for the purpose of anatomical inquiry, he was sneered at for busying himself about pig's pettitoes. To-day, the pettitoes on such a mission would be enclosed in a nimbus. We have now a Koch who leads, but there is a large following close at his heels. We have Atlee and Spencer Wells, but almost at once, their followers appear everywhere, and outstrip their teachers.

ADDRESS IN PUBLIC MEDICINE.

Delivered May 11, 1888.

By H. P. WALCOTT, M.D.,
CHAIRMAN OF STATE BOARD OF HEALTH OF MASSACHUSETTS.

When a committee of this body invited me to deliver the address which Dr. Cabell felt himself unable to undertake, I accepted the invitation with much hesitation, well aware that in attempting to fill the place which all had hoped to see occupied by the honored head of our first, unfortunately, perhaps, our last national health organization, I should fall far below your just expectation.

Mingled with this natural reluctance is also the knowledge that I have not the oratorical skill to repeat in any new or attractive manner those general statements as to the claims of hygiene and State preventive medicine upon the public and our profession which have been so often and so eloquently brought to your attention.

Neither am I quite willing to limit myself to an attempt to describe the progress of public preventive medicine during the past year. But I shall assume that my text has been given me in the fact which is probably the reason for my invitation to occupy this most honorable place,—I mean my connection with the State Board of Health of Massachusetts, now in the twentieth year of its existence.

This board has passed through experiences which are more or less true of every other State Board of Health in the country; it has sometimes failed where success was due, and has succeeded where defeat seemed inevitable. It has illustrated the various stages of progress in the attempt, on the part of the State, to prevent disease; and has also, at some periods in its history, suffered from the interference of politicians and self-seekers.

This story, interesting as it might be in Massachusetts, would be quite out of place here, were it not true that we also have a fairly kept record of our vital statistics from the year 1842 to the present time.

Therefore, it has seemed to me that it would not be unprofitable, in this twentieth year of State preventive medicine, that I should attempt to answer some of the questions that may fairly be asked of those who have had a share in the public responsibility for the prevention of disease.

You will not need the assurance, I hope, that the example of our own State is used in no limited and provincial spirit. We have not hesitated to borrow, from our brothers in other States and countries, anything that offered the slightest promise of help in the unending struggle for the preservation of human life. We have relied upon their counsel and assistance, and have not been disappointed. On the other hand, the legislative act by which our board was established, has served as a model for many of the organizations subsequently formed. Our interests then have been common; our methods similar; and the results will not be much unlike.

Another reason for using this local experience lies in the fact that our restricted territory and comparatively large population have brought about conditions which, fortunately for the majority of the States of the Union, will remain in the distant future; but which, sooner or later, will come to all, and almost inevitably sooner than they are expected.

That these experiences can be submitted to no tribunal so competent to interpret them correctly as the medical profession, is a proposition which scarcely needs an argument.

The State Board of Health of Massachusetts was established by legislative action in 1869. Local boards of health of not much efficiency had existed from the beginning of the century. The State board entered at once upon its duties, which were advisory rather than executive. Under the lead of wise men the public intelligence was quickened upon all the important sanitary questions to such a degree that the succeeding years brought to the board added executive powers and larger appropriations. Seven thousand five hundred dollars were appropriated for the work of the board in its earlier years, sixty thousand dollars are the conclusive evidence of the peoples' belief in the value of protective medicine, and this does not include the large sum spent upon the registration report.

After ten years of most successful administration, it was thought advisable by the Legislature of the day to extend very widely the functions of the board by reorganization and the addition of the powers of Commissioners in Lunacy, and of the supervision of the public charities. The burden proved too great, and, after a few years, the original organization was restored, with enlarged powers.

The rights of the people to pure air, soil, water, and food, are recognized by the laws of the Commonwealth, and various statutes have been passed to secure these rights, and to prevent their infringement.

The board is charged to some extent with the duty of enforcing these rights, and preventing and punishing any violation of them, having for this purpose powers coördinate with those of the local boards of health.

The business of investigating and gathering information as to any matter pertaining to the public health, and of diffusing such information among the people, is also included in its functions.

Among the matters of which it thus takes cognizance, are the causes and prevention of infective diseases. For this purpose coördinate powers are given to the board with every local board of health, namely, the suppression of nuisances, including the regulation of noxious and offensive trades; the collection and diffusion of information relative to industrial hygiene, or the effects of different occupations, industries, and domestic pursuits upon people at various ages and under various conditions of life; the hygiene of schools, school buildings, and public institutions; the examination and investigation of public water supplies, and the prevention of their pollution; the investigation of drainage and sewerage places or systems, so far as they relate to the public health; the disposal and transportation of the dead; the inspection of food, drugs, and other articles affecting the public health; inquiries relative to the amount of intemperance from the use of stimulants and narcotics, and the remedies there-

for; investigations as to the infectious diseases of animals, so far as they may affect man; the editing of the registration report of the State.

What effect has all this had upon the health of the people as shown by the mortality rate? For that is the only trustworthy standard, under our present means of registration, by which to determine the effect of measures taken for the prevention of disease.

Without the assistance of well-conceived and carefully executed tables of vital statistics, communities are liable to the most erroneous impressions as to the actual effect of their surroundings upon the public health. Hence, our legislation in sanitary matters is in constant danger of becoming the reflex merely of vague rumors, hasty and incorrectly formed conclusions, or statements based solely on commercial and interested motives; unless it is distinctly understood that the devotion of human life, the disease by which it is cut short, and the preventable or inevitable character of the disease, so far as we now understand these qualities, are things which can be determined by intelligent and continuous investigation by experts, and should be no more the subject of guesswork than the truths of mathematics or the facts of chemistry.

Inasmuch as the task I have taken upon myself is the proof of the value of preventive medicine, let us take not the mortality rate as a whole, but the rates from certain specified diseases which are admitted to be controllable by means of vaccination, isolation, disinfection, or suitable sanitary precautions.

Let us then compare these rates in successive years, not only with each other, but also with the rates of those diseases in respect to which we possess no well-recognized powers of prevention. This comparison shall be made during the period of existence of our State Board of Health; not with the presumption that statute regulation, either in the hands of a State or municipal board of health, deserves all the credit of the improvement obtained.

During this period there has been an active and intelligent interest in all sanitary questions, steps have been taken on all sides for procuring purer water supplies, better drainage, food and drugs free from adulteration, tenement houses have been much improved, sometimes by private undertaking, and oftentimes under the compulsion of the law. But in all these movements the influence of the sanitarian has been predominant, and the improvement in the health of the people is regarded as the only just measure of success.

When regard is had to the facts that Massachusetts is one of the oldest settlements in the country, and, with the exception of Rhode Island, the most densely populated State in the Union, it would not be surprising were we to find there a relatively high death-rate. This would be true, even if the conditions which favor health there were equal to those found in other States.

The average death-rate for the thirty-six years, 1851–1886, was 19.40 per thousand living, the lowest death-rate in this period was 16.99 in the year 1867; the highest death-rate, that of 1872, being 22.85 per thousand. It was 18.38 per thousand in 1869, and 18.85 in 1886, the last registration year. So far then as these figures go, we have no changes of consequence.

But if we turn to the general classification of causes of death into zymotic, constitutional, local, developmental, and violent, we find that there has been an almost constant decrease in the class of zymotic diseases during the period now under consideration.

PERCENTAGE OF CAUSES OF DEATH BY CLASSES.

YEARS.	CLASSES.				
	Zymotic.	Constitutional	Local.	Developmental.	Violent deaths.
1870	25.6	26.6	28.1	15.6	4.1
1875	28.6	24.3	31.8	11.2	4.1
1880	24.5	23.7	38.8	10.1	3.7
1885	19.0	23.2	42.7	10.7	3.9

The years taken are census years.

The changes in the class of constitutional diseases have not been so marked as in those of the zymotic class, although the tendency appears to be constant in the direction of a decrease.

In the class of local diseases there has been a decided increase, from 28.1 in 1870, to 42.7 in 1885.

In the class of deaths from developmental causes, the changes in the last three census years are insignificant; as this class contains the deaths from teething and old age, it is to be expected that more accurate diagnosis will diminish its relative importance.

The percentage of violent deaths remains throughout essentially unchanged.

If we arrange the percentages of causes of death from zymotic diseases in two columns of ten years each, we shall find in the first decade, from 1867–1876, the average of these percentages to be 27.94; in the second decade, 1877–1886, the average has fallen to 22.4.

Let us examine more carefully the diseases which we have a reasonable hope of preventing by appropriate sanitary regulation. We shall find at the head of the list a disease which we can with certainty limit, if not abolish. As we pass down the line we shall come to diseases which are more and more dependent upon the special treatment of a physician and surgeon; and which can be but slightly, if at all, affected by the surroundings which the public officer of health can control.

It seems, however, to be true that with each succeeding year a larger and larger number of these are found to be the result of influences that can be removed.

For the first time in the registration history of the State, a year has passed without the record of a single death from smallpox; and this, notwithstanding the fact that we are in continual communication with countries where the protection of vaccination is not so generally given as it should be. One of our chief industries, also, the manufacture of paper, involves the use of materials which always carry with them the possibility of the presence of the contagion of this most persistent disease.

Many years of comparative immunity from smallpox had led to a disregard of the stringent laws for compulsory vaccination; and the State paid the usual penalty in 1872 and 1873; the mortality in the former of these years reaching 2.9 per cent. of the deaths from all causes, with 1029 deaths from smallpox.

The attention of the authorities was aroused, existing legislation was rigidly enforced, and additional powers,

when found necessary, were obtained. There has been no year since 1873, when the percentage of deaths from this cause to deaths from all causes has reached fourteen-hundredths of one per cent. (0.14).

Typhoid fever has, upon the whole, diminished both relatively and absolutely. In 1886, the percentage of deaths from typhoid fever to deaths from all causes was 2.15; in 1872, the year of greatest prevalence within the twenty years, the percentage of deaths from typhoid to deaths from all causes was 4.86—and the death-rate per ten thousand living was 11.1.

The diminution in the death-rate from this disease has been especially marked in cities with pure water-supply and good systems of sewers. The death-rate from this cause is substantially unchanged in the small country towns.

The death-rates from typhoid fever, per ten thousand living, in the census years 1865–1885 have been for the whole State

1865.	1870.	1875.	1880.	1885.
13.4	9.1	6.4	4.9	3.9

Scarlet fever has more than once astonished the medical world by a sudden assumption of great violence and fatality after many years of comparatively harmless prevalence. Graves has called the attention of the profession, in a most instructive manner, to the experience of Dublin, where from 1804, when an epidemic of great malignancy had come to an end, until 1834 the scarlet fever that occurred was very mild, at the latter date the disease burst in upon the city with all its old ferocity. It is, therefore, with some reservation that I use the figures of the registration as to this disease.

The record for thirty years shows a death-rate, per ten thousand living, reduced from 17.2 in 1857, to 1.7 in 1886. It is possible that we are only nearing the end of a series of benignant years, and that another may see the return of an epidemic over which we shall possess little control; still, it is the belief of our best observers that isolation and disinfection have had a sensible effect upon the spread of the disease.

Diphtheria first appeared in our registration in 1858, causing in that year eighteen deaths, reached its highest degree of prevalence in 1877, and since that year has much diminished in frequency, but has not again sunk to the low figures of the years 1870–73, when it constituted less than one per cent. of the deaths from all causes.

If in the present uncertainty of medical *diagnosis* with reference to croup and diphtheria, it is desirable to consider them together, and all deaths from croup are added to those resulting from diphtheria, we should not obtain conclusions essentially different from those above stated. An examination of our record shows that the reported deaths from croup are slowly and steadily falling in number, and that the two diseases rise and fall together in the scale of prevalence.

It is probable, therefore, that a more accurate diagnosis will hereafter transfer to deaths from diphtheria many cases which would in times past have been assigned to croup.

The relation of diphtheria to the grosser forms of insanitary conditions is not yet clearly made out. There is also a probability that some of the lower animals are attacked by it.

The degree of its prevalence in Massachusetts, in the United States Census year 1880, was almost identical with the rate for the whole country; the general rate was 5039 out of 100,000 deaths from all causes, the rate in Massachusetts was 5010 to the 100,000. In England, in 1880, the rate was only 532 per 100,000, which does not vary essentially from the rate of the ten years preceding.

In the city of Boston, a notification to the Board of Health of all cases of diphtheria, as well as of certain other communicable diseases, is compulsory.

The Board in such cases causes a careful inspection of the premises to be made; in the year 1887, when 1049 cases with 316 deaths were reported, 927 houses were examined; 534 were found to be in defective sanitary condition, 393, on the contrary, were in good sanitary condition.

A rigid inspection of 900 houses, taken at random in any city would, I think, not be unlikely to show nearly as large a number of houses that would fail to satisfy an examination which is very apt to start out with the determination to find some sanitary defect.

It is a communicable disease in a very marked degree, but does not appear to have any other relation to filth than this, that the absence of proper cleanliness, and the presence of the material of contagion in the food, person, or surroundings are quite sure to go together.

It may also be assumed to be probable that a number of mild cases of the disease always exist, and are the unsuspected vehicles of the contagion. We know this to be true of almost all the diseases of this class, and I think we have hitherto taken the probable existence of such cases too little into account.

The diarrhœal diseases, including diarrhœa, dysentery, cholera infantum, cholera morbus, and enteritis, have only changed place in the list as cholera infantum has varied.

Cholera infantum during the period of twenty years has diminished, though the fall has not been regular; dividing the period of twenty years into two decades, the average of the first yields a death-rate from cholera infantum of 13.51 per 10,000 living, the second an average of 10.32 per 10,000.

Dysentery, which in the first half of this century had several times appeared in epidemics of great severity, has thus far in the second half been steadily diminishing in importance. The improvement in domestic water supplies appears to have had some influence upon this reduction in number, so far at least as the question has been studied in certain cities in the State. Only 243 deaths out of a total of 37,244 are assigned to this disease in 1886, the smallest number recorded during thirty years.

Malarial fever caused, in 1886, 32 deaths, of which number 20, or 62.5 per cent., occurred in the five western counties which have but 26 per cent. of the population. Although serious epidemics have occurred in the eastern counties during the years 1884–'85–'86, they have thus far had little apparent effect upon the death-rate.

Statistics of disease, as well as those of mortality, would be an additional index of very great value for the sanitary condition of a district. In the case of the disease now under consideration, they would be of unusual value because portions of our State, exempt during the whole existence of our settlement, have been invaded by malarial fevers, and yet the resultant mortality has been insignificant. We can only say that malarial fevers

have increased beyond the increase in our population, and that this tender exotic has in New England found unfortunately some new conditions which favor its development.

The number of deaths from measles has been very variable through this period, this variability in mortality was more noticeable in the last half than in the first half of the period. The average of the latter half was also less than that of the first half. The number of deaths has ranged from a minimum of 19 deaths in 1879 to 428 in 1872.

The number of deaths reported as due to consumption in 1886 was 5897, the percentage of deaths from this disease to deaths from all diseases was 15.83. Arranging the deaths from consumption in two periods, 1867–1876, and 1877–1886, the average of the second decade is found to be 2.5 per 10,000 living less than that of the first decade; that is to say, from 33.7 to 31.2. There thus appears to have been an actual decrease in the deaths from this disease, and more marked in the second decade than in the first.

Our registration in its present form gives us no satisfactory answer to one of the most important questions that arises in the consideration of this disease. How often and under what conditions is the predisposition to consumption hereditary?

It is in the very nature of our life unavoidable that every individual must, at many times, be exposed to the contagion of tuberculosis; and yet it is within every physician's experience that many members of families with distinct histories of consumption in more than one generation do escape.

One of the most important and widely spread influences upon the origin and extension of consumption was announced twenty-five years ago by an honored President of this Association, the father also of State medicine in Massachusetts, and fortunately still living at an age, which, in him, one hardly ventures to call old, Dr. H. G. Bowditch, who, by his announcement and proof of a law of soil moisture and land drainage, in their influence upon consumption, has turned the attention of the world to conditions which can be controlled.

Pneumonia has generally held the second place on our mortality lists, and has not diminished in relative frequency in recent years.

The total number of deaths reported as due to cancer, in 1886, was 1104, the rates of fatal cases among females to the whole number has increased as follows:

1881 . . .	64.4	1884 . . .	66.6
1882 . . .	64.9	1885 . . .	68.8
1883 . . .	67.6	1886 . . .	69.7

If the statistics of cancer for twenty years are divided into two ten year periods, with death rates per 10,000 living, we shall find that there has been an increase, with a certain degree of uniformity, from 2.9 per 10,000, in 1867, to 5.6, in 1886, nearly double. In England and Wales very much the same increase has been noted, the proportion of deaths from cancer has increased regularly from 2.7 per 10,000 living in 1847, to 5.3 per 10,000 in 1882.

The number of deaths, in 1886, from the group of diseases attributed to the brain, was 3844, which, though a little less than in 1885, was still larger than that of any other previous year.

The mortality rates per 10,000 in the Census years, 1860, 1865, 1870, 1875, 1880, 1885, were, respectively, 12.06, 14.39, 14.35, 16.42, 17.0, 20.01.

Deaths from alcoholism appear to have diminished in number, but it is confessed that the death-rate ascribed to intemperance directly is but an imperfect measure of the evils resulting from an excessive use of alcohol. Neither do the figures of the report convey any just idea of the actual or relative prevalence of the venereal diseases.

The fact that Bright's classical description of the diseased processes in the kidney, known by his name, was first published in 1837, and the slow progress made in the accurate medical diagnosis of these diseases during the half century, would lead us to expect in these diseases an apparent, marked increase from year to year. It has been assumed, also, that the conditions of modern life have brought about a large actual increase, either from irregular and luxurious living, or improper indulgence in food or drink. It has been claimed by some that the substances now frequently added to standard articles of food and drink, for the purpose of adding to their keeping qualities, or of fraudulently adulterating them, have an injurious effect upon these organs.

The difficulties of answering these questions is much enhanced by the fact that in the early years of our registration, when the real nature of diseases of the kidney was but imperfectly understood, very many of the deaths really due to this class were registered under the head of dropsy, another large class would appear as diseases of uncertain seat, and diseases "not specified."

With these facts in mind, let us tabulate the deaths from Bright's disease and other diseases of the kidney in one column, and the deaths from dropsy in a parallel column.

From an examination of the registration report of 1850 it appears that out of 16,606 deaths, there were 18 under the heading of Bright's disease, a ratio of 1.1 to total mortality per 1000; from dropsy, 416 deaths were recorded, a ratio to the total mortality per 1000 of 25.

In the years following the number of deaths in the first class has rapidly and steadily grown, reaching, in 1886, a total of 1135 deaths, a ratio to the total mortality per 1000 of 30.5; while the deaths from dropsy have as steadily, and almost as rapidly, decreased from a ratio of 25 per 1000 to 5.9 per 1000.

If we now add the deaths from kidney diseases to the deaths from dropsy, we obtain a ratio to total mortality per 1000, beginning, in 1850, with 26.1, and reaching 36.4 in 1886.

This is an increase startling enough to attract attention, and require investigation, but still not of the alarming character attached to the apparently overwhelming increase of Bright's disease and other kindred affections.

We have no evidence in Massachusetts that any of the substances generally used for the preservation or adulteration of food and drink have a markedly injurious effect upon the kidneys.

Another lesson may be extracted from these figures, it is this, that statistical nosologies, as well as laws for the protection of the public health, are educational, and founded upon the learning of experts, and will inevitably break down if they are too far in advance of the common knowledge.

The figures also show that in a sufficiently extended

series of years an explanation of an apparent discrepancy may sometimes be discovered.

This hurried glance at the registration tables will have shown this, I think, that in all the preventable diseases there has been a steady reduction, most marked in the case of smallpox, a disease that can only seriously affect a community through inexcusable neglect. I will not weary the ears of this assembly by dilating upon a subject on which all health authorities are agreed—the necessity for compulsory vaccination and revaccination, so long as the system is susceptible of the virus.

A single comparison may be made to demonstrate the saving of life in consequence of better sanitary conditions established by the authority of a board of health.

Probably no single instance of a surgical interference in a disease inevitably leading to early death, has attracted more attention, has deserved more admiration or has added more years to human life than the operation of ovariotomy.

The largest number of deaths in any one year in Massachusetts from ovarian dropsy was 51. We will assume that all of these lives might have been saved by ovariotomy.

Let me take now the city of Somerville, a suburb of Boston, with 29,971 inhabitants, by census of 1885, with natural conditions of soil of varied character, partly favorable, partly unfavorable, with a mixed population almost wholly occupied with business, trades, manufactures, and day labor. It has had an energetic and intelligent Board of Health, who have used the large powers conferred by our statutes wisely; they have a system of compulsory notification of the communicable diseases, rigidly enforced; they practise, so far as possible, isolation and disinfection. During their active administration and almost wholly in consequence of it, as I believe, the death-rate of the city has been reduced as follows: The present organization of a municipal Board of Health was established in 1878. In 1875, a census year, the death-rate was 22.86 per 1000; in 1880, 17.1; in 1885, also a census year, 16.68. The improvement is more marked yet, when certain unfavorably situated and crowded quarters of the city are separately examined.

But this examination is scarcely necessary to prove that the interference of a public health authority with ample powers and with such sanitary regulations as we can now carry out has saved more lives in a community of 30,000 people in a single year than could have been restored to health in the same period in a State of nearly 2,000,000 inhabitants, by an operation justly regarded as one of the greatest triumphs of American surgery. It may be objected that with all this apparent diminution in the mortality from selected diseases there has still been no reduction in the general death-rate, so far at least as the figures of the report are to be taken in evidence.

It is unfortunately true, that our reports had in the earlier years a less degree of accuracy than they now have, and that deaths were not so generally reported then as now. The records for the year 1855 were very carefully examined for the purpose of determining the completeness of the enumeration of the deaths in that year. It was estimated by a competent authority, as the result of this examination, that not far from sixteen per cent. of the deaths in that year had escaped registration. It is now confidently believed that this deficiency does not exceed two per cent.; the registration by means of burial permits is now subject to revision by local boards of health as well as by municipal recording officers, and has become much more trustworthy.

Apart from fluctuations in the returns of deaths to the registration offices, there are reasons for believing that some of the conditions are not now so favorable to health as they have been.

The proportion of the population engaged in factories has largely increased; larger numbers of the people absolutely and relatively live in cities subject to the insanitary influences that prevail there.

In 1870, 63 per cent. of the inhabitants of the State lived in cities and towns of more than 5000 people. In 1885, the proportion had arisen to 73 per cent. There has also been a large addition to the native and presumably hardier population of immigrants from foreign countries, whose adaptability to our climate and conditions of life is still uncertain.

Too great expectations seem to have been raised also by the very brilliant results of sanitary work in the older countries. Men had to deal there with all the evils incident to sanitary neglect that had endured for centuries, and in great cities at that. Here, on the other hand, the cities have contained a relatively smaller part of the total population and there has not been the same opportunity given for obtaining a result so striking as the reduction in London's mortality rate; for instance, from the high figures of the beginning of the century to her present fairly earned position of the healthiest very large city in the world.

It may be of interest, in this connection, to call your attention to some of the diseases which have attracted general attention, perhaps excited more interest in the public mind than all the other causes of death combined.

In forty-five years and eight months, ending 31st December, 1886, the registration reports of Massachusetts enumerate the deaths of 1,163,571 persons.

Smallpox has killed 5572 in this period and has given rise to more legislation than any other single disease, and is the one most easy to be controlled. One provision of law is the beginning and end of its regulation—that is, compulsory vaccination and revaccination.

Scarlatina has destroyed 37,666 lives, permanently impaired the value of a very large but unknown number, and the attempt to prevent it by sanitary regulation belongs to recent years.

Typhoid fever has been fatal to 45,781 human beings, generally in the prime of life, with an origin almost always in fecal pollution; it becomes epidemic whenever that pollution reaches a water supply, or food, especially milk. The general conditions which sustain this disease in its endemic form and favor its epidemic spread are the same which produce general unhealthiness. It has been well said that an epidemic of typhoid fever is a sanitary crime, and should be treated as such. But the peculiar history of this disease has had but little influence on legislation of a useful kind at least.

Epidemic cholera, the most persuasive apostle of sanitation that has been permitted to land on our shores, has destroyed, from 1832 to this year, not more than 2000 lives in all. In no one year, excepting 1849, the year of greatest prevalence, has it proved so fatal as scarlet fever, croup, typhoid fever, dysentery, pneumonia, whooping-cough, or apoplexy; and in 1849 even, the deaths from

cholera did not vary much from the greater part only of the deaths from consumption.

Hydrophobia is represented by seventy-two deaths; more than one-half of these occurred in the four years 1876–1879. There have been no deaths from it since 1881.

Thirteen deaths from yellow fever have not been considered of enough consequence to be given a place in the general summary. They occurred at the quarantine station at Boston, and may not, perhaps, have recalled to any public health officer's mind the fact that about the beginning of the century, yellow fever had, in more than one year, been a pestilence in the city itself.

Our experience in State preventive medicine has proved this, that while great good can be done to any community by the establishment of boards of health, whose functions are largely those of instruction and advice, it is certain that, sooner or later, the people will place in the hands of those capable of exercising such powers the machinery for making that advice effectual. And this has happened with regard to every subject which has been successively made an object of inquiry. There is now ample authority for the control of public water supplies and systems of sewerage; sufficient legislation to punish and prevent the adulteration of food and drugs.

One of the most encouraging signs is the more intelligent view taken by the public of questions to which self-interest seeks to attach a sanitary significance.

Perhaps the much-vexed question of "oleomargarine" may be taken as an instance. We have in this substance a legitimate commercial product which, when properly manufactured, is a safe and useful addition to our food supply. It can be so made, and is so made. When sold as natural butter it becomes an impudent fraud, and should be punished as such. But it is no more a matter of concern to sanitarians than the proper making of butter itself is, and some of our legislative bodies appear so to regard it.

It has been well said by one of the most eminent of the executive officers of health, Dr. Russell, of Glasgow, that nothing is more conspicuous than the helplessness of the individual, under the conditions of civilized life, to secure the physical basis of health.

How can any single individual in a crowded city make any successful effort to improve or even to ascertain the quality of the public water supply upon which he is exclusively dependent? What can he do to secure a sufficiently prompt and safe removal of the waste materials of his daily life? How can he analyze the ingeniously sophisticated article of food or medicine which may represent the ingenious employment of all the scientific skill that selfish capital can purchase? How vain it would be for him to attempt to prevent the crowding of the city, or the contamination of the air which he is obliged to breathe. Lastly, how can he recognize the presence of communicable disease, and, recognizing, keep it at a distance?

There is no help but in coöperation on the most extended scale possible—individual, municipal, State, and national. The individual must be compelled to give up his liberty to injure his neighbor. The great city must be restrained from converting the stream that flows past it into a sewer that shall poison the villages that cluster about its banks lower down in its course. The country farm-house must no longer, when a case of enteric fever occurs there, be allowed to be a menace to the water that supplies a thousand city homes. No State should permit its own causes of disease, whether they are persons or things, to be transported into another State, nor pollute the common water supplies. Lastly, the general government should take cognizance of those causes of disease which can be controlled by no other power; or which are so general that the responsibility for them is national; or so overwhelming in their ravages that smaller political bodies have lost the power, if not the will, to protect the people.

Voluntary associations on the part of persons, towns, States, or nations even, will never establish a sufficient safeguard, when one dishonest or ignorant associate has it in his power to nullify all the effects of a neighbor's spirit of self-sacrifice and restraint.

Epidemic disease is an evil that cannot be left to work out its own cure, it widens its circle too rapidly, and the time is long past when any quarantine, using the word in its older sense, would prove sufficient to restrain a pestilence within the limits of the district whose sanitary crimes might have fairly deserved some punishment.

How, then, shall we organize for the protection of the public health?

For the individual, that he may not injure his neighbor through his own ignorance or that of his adviser, let the State give him some assurance that the legally used title of physician designates a person sufficiently qualified to give advice for the prevention and cure of disease, and a certainty also, that the quack who steals the title shall be punished.

Establish, by direct provision of State law, local health authorities for each well-defined unit in our various forms of local government—village, town, city, or country. Place in the hands of these authorities the execution of the laws of the State and all local ordinances and regulations pertaining to public health, impose upon them the duties of watching all those conditions which immediately affect the health of the people: water supply, sewerage, sanitary condition of school-houses and scholars, factories, tenement houses, and the markets; periodic inspection of the inhabitants to prevent the neglect of vaccination; house to house inspection at least annually. In brief, they should have all the powers which society assumes for protecting the public health.

To meet the possibility that some districts may not have intelligence enough to appreciate, or that powerful commercial or other interests may interfere with these laws, there should be a State authority with ample powers.

This would be called upon for the purpose of harmonizing the action of the various local boards, where the interests of various localities were involved.

It should have coördinate power with all local boards in cases of communicable disease, in order that its action may be prompt and salutary. It should be enabled to carry on scientific investigations as to the causes of disease; to suppress noxious and offensive trades, as it will often happen that some great industry will possess in a community an influence sufficient to control the local board of health. This condition did in fact exist in Massachusetts, and no act of our State Board of Health in its earlier years was more commended than that which transformed a town, pestilent and disgusting from some fifty slaughter-houses, into an attractive suburb of Boston. The business of slaughtering and rendering was not driven from the town, but was concentrated into one

well-regulated abattoir, from which there has never come a just excuse for complaint.

This authority should also have the supervision of the laws for the prevention of the adulteration of food and drugs.

It should have the general oversight of the public water-supplies.

It should have charge of the registration of vital statistics, and of the investigations of the diseases of animals, so far as they may affect the health of man.

The educational element should always be present in the work of the State and local boards of health; and as in all other affairs of life, the value of the lesson will stand generally in direct relation to the cost of it.

The person who receives the benefit of a sanitary improvement, should, if able to do so, pay a part, at least, of the cost, and should never be permitted to lose the sense of obligation on his part to prevent the spread to his neighbor of unsanitary conditions of his own making.

All the arguments that have been used for the existence of State health authorities are also available, it seems to me, for the creation and support of some organization for the protection of the public health in connection with the General Government. I think that the medical profession is agreed that no power less than that of the National Government will be sufficient to prevent the introduction of disease from abroad, or control its transportation from State to State.

There is, of course, a question as to what form the central authority should take, and how extensive should be its power.

"The well-being of the country," to use the language of the Constitution, should imply that we must know all that can be known about those diseases and causes of diseases which may affect the whole country.

Although the actual epidemic prevalence of disease of grave and frequently fatal character may be limited to certain districts, still the disturbance of commerce and the relations of life will extend to large sections of the whole country. Therefore, the National health authority should have the power and the means necessary for a thorough investigation of the communicable and epidemic diseases, and of the best means to prevent their spread. These investigations need not be limited to this country, in fact, it is quite evident that several of the most important diseases of this class must be also studied outside of the country, yellow fever for instance.

The General Government should also make available for use in all parts of the land, the information from foreign countries as to the prevalence there of contagious and epidemic diseases. Not simply such communications as may be made by consular officers, for these, as a whole, have probably no great scientific value, but that great mass of information which through one channel or another reaches Washington.

To this should be added the statistics of mortality and disease already published by our very many boards of health throughout the land, and not now readily available for use, except by difficult and tedious search through many documents accessible to but few.

In connection with this statistical work would naturally be associated some arrangement for the prompt receipt of information from all sections of the existence of dangerous communicable diseases, for the purpose of warning from a central office all interested communities.

A voluntary system of notification, established by the National Conference of State Boards of Health, has proved of much service, notwithstanding the fact that some of the great States have abstained from giving this information in a careful manner. But the usefulness of this method of communication has been seriously limited by the want of a central office, and the effective system for sending early advice in any required direction which the General Government alone could easily provide.

Not the least of the very many claims of the National Board of Health upon the medical profession was its attempt to secure uniform systems of registration of vital statistics, and a nosology adapted to the changed views now entertained as to the nature of many diseases. This work should be taken up again and carried on, if necessary, by liberal appropriations for the purpose of encouraging and assisting everywhere a continuous registration of vital statistics in a suitable manner.

Dr. Billings, the wise and experienced officer in charge of the "Mortality and Vital Statistics of the U. S. Census," says:

"But as the United States has no system of registration of vital statistics, such as is relied upon by all other civilized nations, for the purpose of ascertaining the actual movement of population, our census affords the only opportunity of obtaining even an approximate estimate of birth- and death-rates of a much larger part of the country, which is entirely unprovided with any satisfactory system of State and municipal registration; and the data which the census gives, imperfect as they are, are the only ones by which we can compare the healthfulness of this with that of other countries, or can ascertain, even approximately, the relative salubrity or liability to particular forms of disease of different parts of our own territory."

And again.

"Nothing pays better than good book-keeping in national affairs, and in no part of a nation's work is good book-keeping more useful than in keeping records of the life and health of the people."

The most troublesome point in the whole inquiry remains, How far should the general government enter into the management of quarantine?

Though I come from a State which has never asked the assistance of the authorities at Washington, during any pestilence within her own borders, and is not likely to do so in the future, and is at the same time fortunate enough not to have felt for three-quarters of a century the terrors of the pestilence that has wrought such havoc in other States; with all this I say, that it seems to me the duty of the whole country, through the national authorities, to assist those communities which are too weak to help themselves, and to undertake the health functions of local government for those too ignorant to know their remedies.

A satisfactory settlement of the question as to the powers to be bestowed on the national authority depends, it seems to me, very much upon the form of the organization. If that of a board should be selected, with an adequate representation of the separate States, then would there seem to be no serious objection to the bestowal upon this board of a direct control of quarantine. The points in dispute between the general government and the States would appear to be safe in the hands of a board of national authority and directly representative of the States.

It is quite probable that such a board might be somewhat cumbersome in form, and not altogether easy to control—which is far from being an unmixed evil; but there are many contrivances by which a large board can delegate its powers to an executive committee during the intervals between the general meetings of the full board —meetings which could not and should not, in the nature of things, be frequent. I can readily see, however, that this question of form is one for the lawmakers, rather than for our profession.

The only alternative seems to me to be a single officer at the head of a bureau, in connection with some one of the departments at Washington. An officer not charged with great executive powers, who shall have, if it is practicable, unlimited authority to investigate by himself or by competent experts, the questions which directly relate to public preventive medicine. He should be at the head of all the current medical statistical work of the government, with the exception of that of the public services. He should be in constant and harmonious relations with the scattered health authorities of the land, and should be permitted to coöperate with them in sanitary work. He should be subjected to the distractions of no other service; neither of the Army, nor of the Navy, nor of the Marine Hospital service.

The vast dimensions to which State medicine has already grown, the apparently unlimited fields upon which it has only just entered, make it evident that nothing less than all the thought and all the working hours of the best man are not too much to be devoted to the supervision alone of the investigations which ought to be made, not in one year of epidemic panic but through a series of years.

The only manifest advantage to this officer of a board of advice could, and would, almost of necessity, be afforded by some representation of the State Boards of Health, quite similar, perhaps, to that now existing in the National Conference of State Boards of Health. The need of easy and confidential intercourse with these intelligent, active, and responsible bodies would naturally suggest itself to the sagacity of any man who would be likely to hold this important office.

I believe that both the Department of Agriculture and the Bureau of Education have, from time to time, called to their aid, representatives of the agricultural and educational interests of the whole country.

Of the sanitary investigations carried on by the authorities at Washington, with the exception of those under the direction of the National Board of Health, it is not possible to speak with much satisfaction. Not that the scientific men in immediate charge of them were not entirely qualified for their work; it would have been very difficult to find men so competent as the great majority of them have been.

But it was very difficult, in a year of health in this country, to secure the necessary action authorizing investigations of diseases that might at any time enter our country; and there is every probability that it will be equally difficult to secure the means of continuing the work.

Dr. Shakespeare was sent abroad in the autumn of 1885, to make investigations of Asiatic cholera, then raging in Southern Europe. Beyond a few brief notices in the medical journals, one State Board of Health, at least, knows nothing through any official information from any department at Washington, of the results of the inquiry. As the Board of Health alluded to, is charged with the coördinate responsibility of watching the second largest port of entry in the Union, which has a more frequent communication with cholera-infected ports than any other except New York, the failure to impart valuable knowledge, at this important juncture, is inexcusable.

Again, in 1885, at the Washington meeting of the American Public Health Association, as well as at the meeting of the Conference of State Boards of Health, measures were taken for bringing to the attention of Congress some of the alleged facts in regard to the preventive inoculations of Drs. Freire and Carmona.

Congress was asked to appoint a committee of experts to Mexico and Brazil and ascertain the truths of the statements made. Notwithstanding the apparent willingness of the authorities to grant the petition, the inevitable delay attendant upon National legislation prevented action until the summer of 1887, when the appointment of a single expert was authorized. The president, with great promptness, appointed an expert of the highest qualifications—and Dr. Sternberg made a journey to Brazil and subsequently to Mexico. The year does not appear to have been so favorable for his purpose of studying the subject during the general prevalence of the disease as one of the preceding years would have been.

Nor under his rigidly drawn letter of instructions does he seem to have had the advantages that would have accrued to an investigation less controlled by precise orders.

Unfortunately, the evidence submitted by Drs. Carmona and Freire appears to have been entirely insufficient to justify the claims made by them of the discovery of the yellow-fever germ, nor has a prophylaxis of yellow fever, by means of their inoculations, been yet demonstrated.

It is a disappointment not to have reached the result that seems only just beyond our grasp. These claims, however, had been advanced so confidently by men holding honorable positions; inoculations had been practised on a scale so extensive that a formal investigation had become a necessity. Dr. Sternberg's work is worth all the money that has been spent upon it many times over. The way has been cleared for an exhaustive examination of this most virulent of imported pests, an inquiry that should have no limit of time, short of the discovery of a sufficient cause, and, if possible, of a preventive; even if an expenditure of money be required only less than the number of dollars that may measure the country's commercial losses, but would represent most inadequately the country's sufferings under this scourge.

It will be a satisfaction to all of us, I am sure, if Dr. Sternberg is enabled to carry to a successful conclusion the work so faithfully and intelligently prosecuted from the Havana investigation in 1879 to the present day.

But it must be regarded as a misfortune that scientific work of this sort should not be continuous and free from the irksome burden of limited time and meagre appropriations.

I approach the conclusion of this possibly wearisome repetition of commonplaces with much diffidence; for I wish to say a few words about the National Board of Health, still, by act of Congress, in legal existence; by

neglect of Congress in a state of hopeless lethargy. This Board entered upon its work with every promise of success; the members of it were of the best that our profession could offer, its contributions to public hygiene, both by the services of its members and by the work of its experts, have their due and honored place among the records of such work the world over.

It demonstrated for the first time in this country, I venture to say, that local, State, end National health authorities could profitably and harmoniously unite in suppressing an epidemic of yellow fever, and preventing its spread from State to State; and that under the influence of an impartially vigilant sanitary inspection and treatment travel and commerce need not materially suffer.

Yet all this has not saved it from practical extinction. Mistakes were probably made, but they are trivial as compared to the merits of the general work of the Board.

I feel forced, therefore, to the conclusion that its organic form, quite distinct from any body of such powers with which I am acquainted, and, unlike anything in our National government, must explain the failure to survive the unjustifiable attacks made upon it.

The presence upon the Board of representatives of the Army, Navy, and Marine Hospital Service, however conspicuous may have been the merits of their respective representatives, was not advantageous. They represented interests which ordinarily are of far less consequence than those of the cities of New York, Chicago, New Orleans, or San Francisco. Their rivalries, while perhaps not necessary, appear to have been persistent and mischievous.

It would not be possible, I think, to select seven men —that being the number of the appointed members of the board—who should adequately represent the various divisions of the country.

The States are not accustomed to a representation at the hands of other States; and the State not represented will find it difficult to understand the principle of selection.

The great States of Ohio and Pennsylvania have not been represented on the existing Board.

Is it well to wait until a new outbreak of yellow fever, or the landing of cholera, gives us legislation founded only on the weakness of fear?

I cannot but think that it is better to have the substance of things, whether it comes in the form of a Bureau of Health or Board of Health, provided only, that some part of the great resources of the Nation shall be turned to the protection of that property which is, at least, as valuable as the fabrics of a Massachusetts mill or the wool of Ohio's sheep; I mean the protection of that greatest property of all—human life.

GALL-STONES OR SOAP? OLIVE OR COTTON-SEED OIL IN THE TREATMENT OF GALL-STONES.

BY D. W. PRENTISS, M.D.,
OF WASHINGTON, D. C.

QUITE a number of reports of cases have recently appeared in the medical journals, of the treatment of biliary colic by the use of large doses of olive oil, in which relief has been obtained, and in which are mentioned the appearance in the stools of numerous semi-solid, rounded masses of varying size. Some of the reporters have characterized these masses as gall-stones, while others, criticising this diagnosis, say they are concretions from the excess of oil taken, which latter is the correct position. The latest case is reported in the *Medical Record* of April 14, 1888, in which Dr. Thomas W. Street, U. S. N., says they are really gall-stones, for "when dried they exhibit facets."

All the cases heretofore reported have been in reference to the use of olive oil. Considering the fact that cotton-seed oil is so nearly identical in all its properties, I ordered it instead of olive oil in the case here reported; its effects also seemed to be identical.

I first made use of olive oil, eight or ten years ago, in the case of a man who had had repeated attacks of biliary colic, and had previously taken various remedies without relief. After taking twelve ounces of olive oil, he passed, as he thought, a large number of gall-stones, and his health immediately improved. He had no return of the attacks of colic as long as he continued under my observation, which was about two years.

In December, 1886, a case came under my care, of repeated attacks of violent pain in the region of the liver, followed by jaundice.

Mr. R., about forty years of age, Government clerk, with correct habits, an active, hard worker when well, but of spare habit. He became very much emaciated under these attacks, which recurred so frequently that he was continually jaundiced. I could discover no organic disease of the liver. He was under treatment from December, 1886, to June, 1887, by various remedies, among which were quinine, mercurials, terebinthinated ether, muriate of ammonium, and cod-liver oil. But he did not improve, and early in June he consented to take a pint of *cotton-seed* oil, and being a man of resolution, he drank the whole pint, keeping it down with difficulty.

I instructed him to look out for gall-stones, and the next morning his wife brought me triumphantly a number of semi-solid, greasy looking balls of varying sizes, from a pea to a hickory-nut. Mr. R. was greatly relieved, the jaundice shortly disappeared, and he continued well until December, 1887, when the attacks of colic and jaundice recurred. A pint of cotton-seed oil was again prescribed for him, and taken as before—this time, however, with more difficulty in swallowing and retaining it than the first time. The following morning he brought me a dozen or more of these greasy looking, semi-solid balls, taking great comfort in believing them to be gall-stones, and said he had passed a "pint of them." He was relieved, and, up to this date (April, 1888), has had no return of the disease.

I did not undeceive him as to the nature of the concretions, thinking his state of mental satisfaction over this extraordinary discharge of gall-stones could do no harm. Besides, I was not quite sure myself what they were, though believing them to be concretions of the oil taken. I placed them in a wide-mouthed bottle for further examination, and found, after a few days, that they had liquefied.

In talking over the subject with Prof. H. W. Wiley, Chemist of the Agricultural Department, he expressed doubt if the oil could be saponified in the intestines to the extent which the case seemed to indicate, and kindly offered to analyze the specimen. The specimen was sent to him, and I append his report as it was made to the Chemical Society of the District of Columbia. This analysis is of special interest, as it is, I believe, the only analysis of these concretions upon record.

Dr. Robert T. Edes, in his new text-book on *Materia Medica and Therapeutics*, 1887, p. 287, has the following expression: "Large doses (of olive oil), a pint per diem, have been prescribed for gall-stones, with the result of producing discharges of small, semi-solid masses resembling and sometimes mistaken for gall-stones. They are, however, really lumps of soap, formed by the oil with the alkalies of the intestinal secretions." The analysis of Prof. Wiley confirms the statement of Dr. Edes that these masses are true soap.

Prof. Wiley's "Note" is as follows: "The action of the gastric juice on fat seems to be confined to separating therefrom all connective and enclosing tissue, and thus setting the fat free. It is found in the stomach in large globules, and passes the pylorus unchanged. The pure intestinal juice seems to exert no action whatever on fats, and these substances are said by Busch to appear in the feces unchanged, when subjected to the action of the intestinal excretions alone.

"Flint says, that while the action of the pancreatic juice in emulsifying fat is undisputed, there is no evidence that in normal digestion there is ever any saponification. The fats found in the thoracic duct are always neutral, and do not contain any free fatty acid. On the other hand, Bernard has shown that the pancreatic juice outside of the body has a distinct power of saponifying fats. Landois and Sterling, however, recognize the saponifying power of the pancreatic juice in normal digestion, but attribute the result to a fat-splitting ferment called steapsin. The process of emulsification is said to go on with much greater rapidity when the fat in question contains a trace of free acid. The surface of each fat globule becomes coated with a thin film of soap, which is soon detached, carrying with it minute particles of fats. The repetition of this process secures finally a complete emulsification. Both the soap and emulsion are absorbed. The authors state further that soluble fat soaps represent only a fraction of the fats which are absorbed, the greater part of the neutral fats being absorbed in the form of an emulsion. Absorbed soaps, however, have been found in the chyle.

"Dr. Prentiss, of this city, administered to a patient a large dose (a pint) of cotton-seed oil. In the dejecta were found large numbers of moderately hard, ovoid bodies which the patient thought were gall-stones. They were brought to Dr. Prentiss, who preserved them in a stoppered bottle, and sent them to me for examination.

"On reaching me the whole had melted to a viscous mass resembling soft soap. On examination, it proved to be a true soap, easily soluble in alcohol, yielding fatty acids, insoluble in water on treatment with an acid. After saturation with hydrochloric acid, the chlorides of the alkalies were separated from the fatty acids by filtration, evaporated to dryness, ignited to low redness to drive off any ammonia and to destroy organic matter; the residual chlorides dissolved in water, filtered through a small filter, evaporated nearly to dryness, dissolved in alcohol, and treated with platinic chloride: a distinct precipitate of potassio-platinic chloride was formed. The chief part of the alkali, however, was soda. This is an interesting case, showing the complete saponification of a large quantity of oil by the pancreatic juice and bile, and the passage of the greater quantity of soap thereby formed, unabsorbed, through the alimentary canal.

"Since the favorable effect of alcohol in promoting saponification is so well established, the deportment of the patient in question in respect of the ethics of temperance would be a matter of interest."

A CASE OF CLUB-HAND.

BY JAMES K. YOUNG, M.D.,
ASSISTANT SURGEON TO THE ORTHOPEDIC DISPENSARY OF THE UNIVERSITY OF PENNSYLVANIA.

MY attention was recently called to a case of club-hand of traumatic origin, which presented some etiological features of interest.

The mother aged eighteen, primipara, illegitimate; father healthy, large-boned man. No history of nervous disease or deformity. The labor was very tedious, and forceps had to be applied at the superior strait. The pelvic measurements were probably justo-minor of very slight degree, about one-half an inch in every diameter. The extraction lasted about three hours, and was very difficult.

On delivery the head was found to measure fifteen inches in fronto-occipital circumference. On the forehead to the left of the frontal suture was an open wound, three-fourths of an inch long, through which projected a sharp spicula of bone. The fragment was replaced, the wound dressed antiseptically, and apparently healed; but about the second day there ap-

peared a large hematoma at the site of the wound and at the same time the following deformity was noted: The fingers and thumb of the right hand were flexed, the hand was markedly adducted, somewhat flexed at the wrist, forming almost a right angle with the radial side of the forearm, in the radio-palmar position. The muscles were firm on the radial aspect of the forearm.

The child died on the fifth day, and the deformity disappeared some twenty-four hours before its death. The hematoma was deeply incised under the impression that suppuration had occurred. This was, however, a mistaken idea, but a large quantity of blood escaped at the time, and was followed by a consecutive hemorrhage, so that the child was very anæmic up to its death. Some time after this hemorrhage the deformity disappeared, probably upon the removal of pressure. At the autopsy a T-shaped fracture ran to the left of the frontal suture, each arm extending five-eighths of an inch. The skin over it was beginning to slough, and in the dura mater immediately beneath the fracture was a dark, congested area of beginning slough. The brain was intensely congested, and there was a marked serous effusion, the cause of death.

This case, then, presents for study one of those rare deformities, club-hand, the cause of which was a lesion of the cerebrum received during extraction.

In man, records of destructive lesions of the motor areas, in the whole or part, of the cerebral cortex, have now accumulated to a sufficient extent to leave little doubt that if there be a destructive lesion of the middle third of the cortex of the ascending[1] frontal or ascending parietal convolution, there will be paralysis of the arm of the opposite side. The fracture of the skull was about in this position. But in this case the deformity was not one of paralysis, but of contraction of one group of muscles over another. Bovior,[2] in his excellent article, has placed these cases of club-hand under the second head, "contracture of certain groups or isolated muscles."

This contraction Gowers[3] has described as "initial rigidity," due to irritation, and that this was probably its nature is confirmed by its disappearance upon removal of the cause.

The interesting facts in the case are the occurrence of club-hand coincidently with hæmatoma, and its disappearance on the subsidence of the latter.

222 SOUTH SIXTEENTH STREET.

MEDICAL PROGRESS.

The Treatment of Pruritus Pudendi by Peppermint Water.—ROUTH has used peppermint water as a lotion in pruritus at Charing Cross Hospital, and describes his mode of use and results as follows:

The B. P. preparation of aq. menth. pip. answers well, but is bulky for carrying about, and is incapable of concentration unless rendered alkaline. This is best done by borax, as being in itself soothing and antiseptic. Patients can easily make their own lotion, as required for use, by putting a teaspoonful of borax into a pint bottle of hot water, and adding to it five drops of ol. menth. pip., and shaking well, the parts affected to be freely bathed with a soft sponge.

If no cracks or sores are present, this lotion will remove the itching, but if there be eczema, etc., or rawness from scratching, it is inapplicable, olive oil, with five grains of iodoform to the ounce, being then more useful. The greatest and most permanent relief is afforded in the neurosal form, especially in the reflex pruritus which often accompanies pregnancy, and which then may take the place of reflex sickness or vomiting. It is also very useful in the pruritus which occurs in the climacteric, or in elderly women, in whom it may be only part of a general pruritus, and also in those cases of women of all ages, where the urine simultaneously becomes of very low specific gravity, without any evidence of having a gouty or granular kidney as a remote cause.

In pruritus due to pediculi, ascarides, an irritable urethral caruncle, an endocervical polypus, early cancer of the cervix, distention of Bartholini's ducts or glands, the leucorrhœa of vaginitis, endocervicitis, and metritis, or the irritating discharges of advanced carcinoma uteri, or to a gouty or diabetic diathesis, the drug excels all others, cocaine inclusive, in affording relief, whilst endeavors are being made to remove the cause.

In two obstinate cases of uncontrollable pruritus of pregnancy, where this remedy gave only temporary relief, the patients were cured by applying iodine liniment to the angry-looking cervix uteri, which method has been used successfully by Dr. John Phillips and others for the similarly severe vomiting of pregnancy.—*British Medical Journal*, April 14, 1888.

The Transplantation of Mucous Membrane.—At the recent Congress of German Surgeons, WÖLFLER, of Gratz, spoke of the value of transplantations of mucous membrane. He said that where cicatrices are produced in cylindrical organs of the body, which are lined with mucous membrane, an operation could only be useful if it were possible, after excision of the scar, to unite the mucosa. But that is impossible in many cases. Therefore he had employed the method of Thiersch (the transplantation of portions of epidermis) with great success. After having excised the thickened and indurated tissue from impermeable urethral strictures, he transplanted mucous membrane from a prolapsed uterus. The operation was completely successful. In the same manner he transplanted mucous membrane from a prolapsed rectum on to the conjunctiva in a case of blepharoplasty. He succeeded even in transplanting mucous membrane from frogs, pigeons, and rabbits with good results.—*British Medical Journal*, April 14, 1888.

Strophanthus as an Antipyretic.—DR. A. ROVIGHI, of Bologna, in experimenting on the effect of tincture of strophanthus (prepared according to Professor Fraser's directions) in cases of cardiac disease, came to the con-

clusion that it was much inferior to digitalis and caffeine in its power of regulating disordered action of the heart, relieving dyspnœa, and increasing the excretion of urine. He was, however, struck by the way in which it seemed to lower the temperature; and he, therefore, tried it in various febrile affections with very satisfactory results. Thus in four cases of pulmonary phthisis, in which for months there had been considerable pyrexia, and in which other antipyretic remedies were useless or were badly borne by the patient, tincture of strophanthus in doses of from four to six minims every six hours reduced the temperature by two or three degrees. In a lad suffering from tubercular disease of the intestine with peritonitis, with a temperature of 104° F., three minims of the strophanthus tincture every six hours brought the temperature down to 98.5° F. in the course of twelve hours, and as long as the remedy was continued the temperature never rose beyond 99° F. In a patient with tubercular disease of the left hip, a pyrexial temperature of 103.5° F. fell to 98° after the administration of fifteen minims (five every six hours) of tincture of strophanthus. In a case of typhoid fever in the second week four to six drops every six hours lowered the temperature by two degrees. In all these cases the drug eased headache, lessened the quickness of the pulse, and produced a feeling of comfort in the patient, and did not in any instance give rise to symptoms of collapse, nor to disturbance of the gastro-intestinal canal, nor profuse sweating. Dr. Rovighi states that these clinical observations were confirmed by experiments on rabbits, in which tincture of strophanthus in doses of ten or twelve minims lowered both the general and the local temperature to a very marked degree. On the other hand, Dr. V. Martini, of the University of Siena, has (*Sul Valore Antipiretico della Strofanto*, Siena, 1888) tested the alleged antipyretic properties of strophanthus with absolutely negative results. He used a tincture prepared by Merck, of Darmstadt, of the same degree of concentration as Fraser's, and also one made by Messrs. Burroughs, Welcome & Co., according to Professor Fraser's latest formula. He tried it in cases of phthisis, tubercular peritonitis, broncho-pneumonia, acute rheumatism, erysipelas of the face, acute purulent cystitis, and hysterical pyrexia. From ten to fifty drops were given daily in three, four, or more doses at regular intervals. The thermometric readings were carefully noted every three hours for three or four days before and after each experiment, as well as during the course of it; in some cases the temperature was taken every hour whilst the drug was being administered. In the majority of cases no effect whatever on the temperature was observed; in a very few instances there was a slight fall, extending only to some fractions of a degree, which was followed almost immediately by a return to the former level. Dr. Martini concludes that strophanthus has not the slightest value as an antipyretic.—*British Medical Journal*, April 7, 1888.

Antipyrin in Diabetes.—At a recent meeting of the Therapeutical Society of Paris, Dujardin-Beaumetz reported that he had given antipyrin in doses of from 8 to 30 grains to three diabetic patients, and had observed a diminution in the quantity of urine passed, the quantity decreasing from five or six quarts to two or three quarts in twenty-four hours. The quantity of glucose passed was now lessened.

Féréal had begun the treatment of a case of diabetes with antipyrin in doses of 25 grains daily; the treatment was interrupted by loss of appetite and vomiting, on giving antipyrin.

Paul had overcome the tendency to nausea by giving bicarbonate of soda with antipyrin.—*Gazette Hebdomadaire*, April 6, 1888.

Iodine in Malarial Cachexia.—Miraschi, of Salonica, prescribes as follows for severe malarial cachexia:

Tinct. iodin. comp.	12 gtt.
Tinct. nucis vom.	10 gtt.
Aquæ,	
Glycerin.	āā 1½ ℥.

To be taken in three doses, half an hour before meals.—*Revue Gén. de Clin. et de Thérapeutique*, April 5, 1888.

Extirpation of the Larynx in Italy. — Cacciopoli, of Naples, is reported by the *Journal of Laryngology* for April, 1888, as having performed the following operation:

A woman, fifty-two years old, was operated upon December 14, 1887, for a large tumor (soft sarcoma) of the thyroid gland, which interfered with the breathing, and the weight of which (as stated after the extirpation) was about two pounds. Three weeks later there was a recurrence, which was treated with Volkmann's spoon and cauterization. A later recurrence necessitated a third very difficult operation, during which the Professor was able easily to convince himself that the tumor was adherent to the thyroid and cricoid cartilages and the first rings of the trachea. On February 7th a new tumor was found, involving the right half of the thyroid cartilage. Laryngectomy was decided upon, and performed on February 19th. The abstractor, who had the honor of being present, was very happy to congratulate the operator. Up till now everything has progressed satisfactorily. The larynx and the first six rings of the trachea were extirpated, and it is to be hoped that the thirteenth laryngectomy practised by Italian surgeons may be crowned with complete and satisfactory success.

Papoid Digestion.—Ruttan, of McGill University, in the *Medical Herald* for April, 1888, reports his conclusions from experiments with papoid, as follows:

Papoid is especially useful for removal of diphtheritic membrane. The conditions present in the pharynx are just those which retard the action of pepsin and pancreatin, but do not influence papoid. The medium in which it is required to act is practically a neutral one and the temperature low; there is present, besides, a large excess of the products of digestion which does not affect papoid—indeed, it is most energetic in a concentrated medium. Moreover, papoid has been shown clinically to lessen very greatly the disagreeable fetor of the disease. Painting on a five per cent. solution, freshly made, every two or three hours, has been found to give the best results: the fetor disappears in a few hours and the membrane in from twelve to eighteen hours becomes thin and glairy.

It would seem to be especially indicated in those forms of dyspepsia in which peptic digestion is greatly impaired and in which the secretion of gastric juice is very weak.

Papoid, therefore, promises to be a powerful auxiliary in combating those two great diseases—diphtheria and dyspepsia.

Chlorate of Calcium in Eczema.—LIER, in the *Monatshefte für Praktische Dermatologie*, No. 8, 1888, gives the following formula for the use of chlorate of calcium in eczema:

Ung. zinc.		20 parts.
Talci,		
Ol. cadin.	āā	5 "
Aq. dest.		10 "
Calcii chlorat.		2 "

This paste has been found especially useful in chronic, obstinate eczema.

Acetic Acid and Ergot as Ecbolics.—MAHOMED, in the *British Medical Journal* of April 7, 1888, writes as follows on this subject:

Since Dr. Grigg called attention to the value of vinegar as an ecbolic, I have frequently used it for that purpose. And I have also found that four drops of the strong acetic acid (representing nearly half a drachm of vinegar) combined with strychnine have been successful in bringing about contractions of the uterus after ergot had failed. In one noteworthy case where in a very weak and anæmic woman the pains, after continuing feebly for a day or two, seemed to be leaving her, and ergot had been exhibited (the waters having broken), I found acetic acid and strychnine produce sharp and effectual pains.

The same thought, therefore, occurred to me as to Dr. Francis, of the possibly good results of combining it with ergot, and, in addition, observing that acetic acid could extract the active principle from colchicum and ipecacuanha, I asked Messrs. Corbyn to make a preparation of ergot, using acetic acid as a menstruum, with a standard surplus of free acid. In a short time I received from them two samples, one of ergot extracted by acetic acid, of which a fluidrachm represented sixty grains of ergot with ten minims of free acid; the other an alcoholic extract of ergot, which also represented sixty grains of ergot and ten minims of free acid to each drachm.

Both preparations had the color of the ordinary extracts, but the acetic acid frothed when shaken, which, of course, the alcoholic extract did not do. The acetic acid process should be more economical than the spirit method.

In a case where there was retained discharge after labor I gave some of this extract, and when the medicine was exhausted wrote a prescription for a similar dose of *B. P.* extract, to which I also added some bromide of potassium, which is stated to aid the involution of the womb. The case was still unrelieved on my next visit, the uterus being obviously distended, so, after syringing out the cavity, I told them to have the medicine made up again, when the patient said, "Oh, sir, the medicine you gave me at first brought away something every time, but this medicine has done no good." This seems like a comparative test in favor of the acetic extract.

In a case of flooding, due to a large fibroid, I found that twenty minims injected deeply into the buttock gave rise to no local irritation, and there was no bleeding the night following, but there needs further experience before attributing this result to the drug. Ergotine disks did not always control it.

Corrosive Sublimate for Hardening the Brain for Anatomical Study.—DIONRIDOFF, of St. Petersburg, has employed a 7 per cent. solution of corrosive sublimate to harden the tissues of the brain and nervous system. Small pieces of tissue were placed in this solution from seven to nine days, after which they were put in alcohol, 50, 70, and 96 per cent., for twenty-four hours. This method of hardening preserves the contour of the cells; the tissue so hardened cuts and stains well, and is easily preserved.—*Fortschritte der Medicin*, April 15, 1888.

The best Solvent for Corrosive Sublimate.—GARRÉ is quoted by the *Fortschritte der Medicin* of April 15, 1888, in reporting his experiments on permanent solutions of corrosive sublimate. He found acetic acid the best adjuvant for dissolving corrosive sublimate, as follows:

Acid. acetic. concen.	♏ 8.
Hydrarg. bichlor. corros.	gr. 15.
Aquæ font.	1 quart.

The Actual Cautery in Epilepsy.—At a recent meeting of the Société des Hôpitaux of Paris, M. FÉRÉ presented a patient who, six months after an attack of hemiplegia, was seized with epilepsy, the attacks recurring every fortnight. The actual cautery was applied to the side of the head supposed to correspond to the cerebral lesion, and the result was that in the space of one year the patient had only three attacks, and it is now five months since the last one. M. Féré treated seven other patients under similar conditions, and the amelioration obtained was very satisfactory.—*Medical Press*, April 11, 1888.

The Prognosis of Extirpation of the Larynx.—MAYDL, of Vienna, relates that in one of his cases which had been free from recurrence for twenty-five months, this afterward occurred, and he, therefore, believes that a case cannot be considered to be definitely cured until three years after operation, merely because recurrence has not been observed within this time. Of sixty-five cases operated on, thirty died in a short time after operation, twenty died within nine months after operation from recurrence. Eight cases were at this time without recurrence, but in only two cases could it be said that a definite cure had been effected (thirty-four months and four years after operation).—*Journal of Laryngology*, April, 1888.

A Hypnotic for Use in Alcoholism.—MANN, of Brooklyn, in reporting good results in the treatment of alcoholism, states that he found the following a useful hypnotic. At night two tablespoonfuls were given:

℞.—Tr. opii deod.,		
Ext. hyoscy. fld.	āā	℥j.
Chloral hydrat.,		
Pot. bromid.	āā	℥j.
Tr. capsici		℥ss.
Tr. aconit. rad.		♏v.
Aq. menth. pip.	q. s. ad.	fl. ℥iv.—M.

—*Brooklyn Medical Journal*, April, 1888.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,
PER ANNUM, IN ADVANCE . . . . . $5.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MAY 12, 1888.

THE CINCINNATI MEETING.

CINCINNATI, May 10, 1888 (*By Telegraph*).—The meeting of the American Medical Association this year has proved a notable success. The attendance was large, and represented every section of the country. Near the centre of population, Cincinnati, by the convergence of many railroads, is a focal point for travel, but this does not wholly account for the presence of the unusual number of men of mark, particularly from the cities of the Atlantic states. The differences growing out of the organization of the International Medical Congress appear to have ceased with the occasion that gave them birth. In this respect private advices amply confirm the impression received from the public addresses. The assiduity of a few mischief-makers has not availed to stem the current that sweeps the Association into its ancient course of national good feeling. This consummation is of no small importance to the future welfare of the Association.

The past has shown that the most certain and not the least valuable function of the Association is to bring into community of sentiment men of widely separated areas, who have common needs for State legislation. The appeal in the President's address for burial of recent contentions was warmly applauded. His main topic was medical education. In spite of the fact that the subject has been thrice beaten by the flail, he managed to separate some grains of value from a study of the statistics of the Bureau of Education. Acknowledging that all attempts of the Association to regulate the medical colleges have so far proven conspicuously futile, he still hoped that there are means not yet exhausted. His proposition is that by combined action of committees of legislation, every State could be induced to make laws requiring of the colleges the highest standard under penalty of revocation of their charters. Anyone at all familiar with the ways of thought of the average politician sees at once that this proposition must remain a dream. Dreams have their uses in the way of suggestion, and however unpractical the reform proposed, the feeling of discontent with the present methods spreads, and a needed impulse is given in the right direction.

In his Address in General Medicine, Dr. Bartholow presented some new facts to support the view that the best, if not the only, reliable basis for scientific therapeutics is the knowledge of the action of drugs on the tissues and organs. This basis is to be acquired largely by inferences from physiological experiments. As a clear and cogent statement it merited the warm approval, which was by common assent, accorded to it.

Dr. W. W. Dawson, of Cincinnati, was elected President, and after a spirited contest, Newport was chosen as the place for the next meeting. In selecting Newport, the Committee very properly recognized the claims of a State and of a city which has never before had the honor of entertaining the Association. Notwithstanding this valid reason the invitation of Philadelphia came within a few votes of being accepted.

CONTACT-LENSES.

IN the *Archiv für Augenheilkunde*, xviii. p. 283, DR. EUGEN FICK, of Zurich, describes his attempts to correct irregular astigmatism by the use of a glass shell inserted like a watch crystal or an artificial eye, immediately in front of the affected cornea. The intervening space being filled with fluid, the irregularities of the corneal surface are practically wholly substituted by the regular curve of the "contact-glass," with the result of raising the vision in one case from $\frac{1}{30}$ to $\frac{1}{6}$ of the normal. His experiments

were begun with puppies; and after finding that clouding of the intervening fluid, with roughening of the corneal epithelium and injection of the conjunctiva, followed the wearing of the glass for several hours, he reached the result that, by use of a sterilized two per cent. solution of grape sugar, this was obviated, and the glass could be worn without irritation for eight or ten hours. Six patients of Prof. Haab's Polyclinic were then tried, with the notable result above given in one case—the others showing little improvement of value. As the number of suitable cases is naturally limited, he commends the method to others who may have opportunity of employing it, without waiting till he himself shall have wider demonstration of its utility.

As the glass is practically invisible, moves freely with the eye, and is free from the limitation of the field of clear vision, which is such a drawback in the wearing of ordinary spectacles, especially when strong, the method gives promise of real usefulness, not only in cases not otherwise corrigible, but even in conical cornea and other extreme errors of refraction where good central vision is obtainable in the usual way. Any desired curve may be given to the new cornea, so as to correct a regular as well as the irregular ametropia. Protective glasses might be required to make the patient feel safe from accident by splitting of the delicate shell, although hardly more fragile than an ordinary artificial eye. The method was experimented with by Young, in the early part of the century, but Fick none the less deserves credit for its clinical application.

THE Committee of Arrangements of the Congress of American Physicians and Surgeons makes the preliminary announcement that this Association will hold its first triennial session in the city of Washington, during the 18th, 19th, and 20th of September next. The meetings of the Congress will be held in the evenings, beginning at 8 P. M., and those of the societies composing the Congress will be held during the daytime, according to the programme each may respectively provide. The sessions will be open to the profession.

The Local Committee of Arrangements of the Congress has secured places of meeting for the Congress and each society in close proximity, so that the members of the respective societies can interchange attendance at pleasure, without inconvenience.

It is the intention of the Executive Committee of the Congress to print the programmes of all the societies by August 15th.

The Committee of Arrangements is composed of one member of each society represented in the Congress, and its Chairman is Dr. S. C. Busey, of Washington.

THE Georgia Medical Association recently held, at Rome, its annual session. The following officers were elected for the ensuing year:

President.—Dr. J. S. Todd, of Atlanta.

Vice-Presidents.—Dr. J. B. S. Holmes, of Rome; Dr. E. R. Anthony, of Griffin.

Secretary.—Dr. K. P. Moore, of Macon.

The next meeting will be held at Macon, on the third Wednesday in April.

AT the last meeting of the College of Physicians of Philadelphia, a handsome gavel, consisting of the bust of Hippocrates, admirably carved, was presented to the College, with a note from Dr. A. Jacobi, President of the Academy of Medicine, of New York.

On the gavel was a silver plate with the inscription, "Presented to the College of Physicians of Philadelphia by the New York Academy of Medicine."

It is always pleasant to record such fraternal courtesies between distinguished bodies.

AGAIN has smallpox stolen past the quarantine at New York harbor, and made its appearance in Brooklyn. The case, or cases, came from Aspinwall, on the steamer "Newport," arriving April 12th, with eleven steerage passengers, and also the ship's surgeon, down with the disease. On the 16th, it is asserted, the Health Officer permitted fifty cabin passengers to "come up," and among these was a child of sixteen months, who, with her mother, was taken to Brooklyn. The child had been vaccinated at quarantine, but it nevertheless developed the disease, and was discovered by the medical inspector on the 26th. It is now known that the "Newport" had one or more cases of smallpox on board on her last southerly trip.

AT the commencement of the University of Pennsylvania, held last week, the degree of M.D. was conferred upon 114 graduates. The class presented to the institution a portrait of Dr. R A. F. Penrose, who has just resigned the Chair of Obstetrics, after

a service of twenty-five years. The Trustees, last Tuesday, elected to fill the vacancy created by this resignation, Drs. Barton Cooke Hirst and Howard A. Kelley, as Associate Professors of Obstetrics and the Diseases of Women. Both appointees are well equipped for their work, and their selection gives general satisfaction, and it is believed will tend to maintain the high reputation of the Chair of James, Dewees, and Hodge, with which are associated many of the brightest traditions of obstetric teaching in America.

Dr. C. D. Palmer, Professor of Obstetrics in the Medical College of Ohio, was thrown from his carriage by an ungovernable horse, and severely, it is feared fatally, injured, last Sunday in Cincinnati. Fracture of the skull and cerebral laceration are feared.

The meagre authentic information given to the public as to the condition of the Emperor of Germany, indicates that the disease is making steady progress, notwithstanding the temporary improvement which follows the occasional exacerbations. Our contemporary, the *British Medical Journal*, in its issue of April 28th, states, on the authority of a special telegram from Charlottenberg, that it will be understood that the reported improvement in the condition of the Emperor refers only to the incidental complications which have recently arisen, and not to the essential disease, which appears to make steady progress, though with alternations of quiescence and activity which have already on several occasions given rise to delusive hopes, followed by paroxysms of somewhat exaggerated alarm. It further states that "from information we have received from a trustworthy source we have reason to believe that a false passage was made in replacing the tracheotomy tube, as this operation was followed by considerable hemorrhage; but it can, we are informed, be clearly proved that neither of the Emperor's English medical attendants is responsible for this unfortunate occurrence."

The same journal's Berlin correspondent writes that "the *Kölnische Zeitung* recently stated that Mr. Hovell had irritated the wound in attempting to replace the tube. Mr. Hovell has written to that journal flatly denying this. He asserts that there was no bleeding till Professor von Bergmann vainly tried to introduce the new canula—an operation which had finally to be performed by his assistant, Dr. Bramann. As Dr. von Bergmann has not contradicted this statement, it may be accepted as true. Immediately after the introduction of the new tube the Emperor's temperature became raised, and there was a purulent discharge from the wound. For two days it was feared that pyæmia would set in. Professors Leyden and Senator, who were called in, agreed that the lungs were not affected. Since then no authentic news has been published. The official bulletins tell little or nothing of any real importance. The fever is believed to be due to some accumulation of pus in the neighborhood of the trachea. One thing is unfortunately too clear, namely, that the illness is rapidly tending to a fatal issue."

A prize of $500 from the Elizabeth Thompson Science Fund of Boston, has been awarded to Professor Rosenthal, Professor of Physiology at Erlangen, for "Investigations upon Animal Heat in Healthy and Diseased Organisms."

The initial article in this month's *Scribner* is an interesting story of pilot life and sighting a wreck, by Dr. W. P. Northrup, which shows that its talented author is as much at home in seafaring life and the use of nautical terms as in the pathological laboratory or the demonstration of O'Dwyer's intubation tubes. "In the Steamers' Track" is a well-told tale, amply meriting the leading place it occupies.

Dr. Edward Swift Dunster, for fifteen years Professor of Obstetrics and Diseases of Women and Children in the University of Michigan, died on the evening of May 3d, of pneumonia. He was born in Maine in 1834, and received his education in the arts at Harvard, and graduated in medicine at the University of the City of New York, in 1859. In 1861 he entered the regular army and served as a surgeon in the Army of the Potomac, and subsequently became medical inspector. He resigned in 1866 and recommenced the practice of his profession in New York. From 1866 to 1871 he was the editor of the *New York Medical Journal*. He was Professor of Obstetrics in the University of Vermont from 1868 to 1871, and in the Long Island Medical College from 1869 to 1875. In 1873 he was appointed to the same chair in the University of Michigan, and he removed to Ann Arbor, where he soon acquired a large practice. He was deeply interested in the subject of medical education, and did much to shape the present course at the University of Michigan.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Thirty-ninth Annual Meeting, held at Cincinnati, May 8, 9, 10, and 11, 1888.

(Specially reported for THE MEDICAL NEWS.)

(*By Telegraph.*)

TUESDAY, MAY 8TH.—FIRST DAY.

THE Thirty-ninth Annual Meeting of the American Medical Association assembled amid clouds and rain at 11 o'clock in the Music Hall. The war of the elements was not sufficient, however, to prevent the assembling of about fifteen hundred members and spectators. On the platform were the officers, newspaper representatives, and others.

At the hour named the assembly was called to order by Dr. W. W. Dawson, Chairman of the Committee of Arrangements; and the meeting was opened with prayer by Rev. Robert Gibson, D.D.

The President, DR. A. Y. P. GARNETT, of Washington, took the Chair.

Vice-Presidents Duncan Eve, of Tennessee; Darwin Calvin, of New York; C. J. Otagan, of North Carolina; and A. Stedman, of Colorado, were called to the platform.

AN ADDRESS OF WELCOME

was made by the Hon. Amos Smith, of Cincinnati. He said: "There are sometimes events that come upon us where one man is appointed to set forth all that which may be wished by an entire people; but it has befallen me, as Chief Executive of the City you have honored with your presence to-day, to endeavor to speak for its citizens a welcome that they feel that you are deserving of, and if words do not suffice from my tongue to-day to make you feel that you have been most heartily welcomed, then may I say that I do not fear that within the coming days of stay among us the actions of our fellow-citizens will be such that you will not leave the gates of Cincinnati without feeling that you have been most hospitably received, and judging by the hospitality with which you have been received will know that the welcome must have been most cordial. Such action as was taken by the Mayor of this City when your Association met here twenty-one years ago is now not necessary. It is related that the police were instructed that if they heard laughing or perhaps a little noise upon the streets, it was only those rollicking doctors, and they were not to disturb them. I can assure you that you will not be disturbed in your enjoyment, and I bid you a hearty welcome."

DR. C. G. COMEGYS then welcomed the Association on behalf of the profession of Cincinnati. He said—"Mr. President and Gentlemen of the American Medical Association: On the part of the medical profession of this city, I am happy to welcome you to Cincinnati, and to assure you that we, all the citizens, feel greatly honored that you have selected this, the most central city of the Nation, for the Annual Congress. Twice before—in 1850 and in 1867—the Association has held its annual councils here, and your professional brethren and the people cordially united to make those occasions encouraging and profitable. It is sad to feel that the majority of those who then assembled and those who greeted you, have passed away. But it is evident from the numbers, freshness, and manly vigor seen on every side that their genius and spirit still live, yea, are augmented and fully competent to carry forward the great purpose of your predecessors. These large assemblies of medical men in increasing members, prove indubitably that the value of the Association is no longer questioned, to say nothing of the scientific dimensions involved. It is clear that the meetings of the Association give satisfaction to all. It is certainly a great pleasure for men who are engaged in common duties and modes of life, in widely separated areas, to be thus brought together for the establishment of acquaintanceship and friendship that promote community of action for a higher performance of their beneficent work among the people.

"It is a wonderful sight to behold so large a body of cultured men who are striving, always and everywhere, to enlarge public happiness by investigations for the prevention of those causes and agencies that undermine public health and welfare, when if complete success should crown their lofty aims, the remunerative part of their labors would be extinguished. The medical profession is unceasing in its labors to trace devastating epidemics to their lair, to avert the march of infectious diseases, to isolate those who are suffering therewith, to disinfect localities, to point out the most healthful modes of living in regard to light and sun, purity and abundance of water supply, the evil of adulterated food, the overtaxing of labor, the prevention of ill-assorted and consanguineous marriages, and abuses of the brain, and suppression of those two giant evils of civilization, intemperance and prostitution.

"This period of your assembly is one of extraordinary interest to our people, for this is the centennial year of the settlement of Cincinnati. It is an heroic age and a glorious race which we seek to commemorate. One hundred years ago a body of adventurous men with their families descended the beautiful Ohio, on rudely constructed barges and landed on this shore.

"It seemed to be a stupendous undertaking then to plant themselves in the primæval forest on this wild coast with no means of immediate sustentation but the stores in their barges and what they might hunt in the wilderness.

"But they were men of no common mould. They brought with them courage, culture, and integrity, and were full of the high aims of the eastern people who had first conquered their independence and secured the vast British possession south of the Canada line. They were imbued with the loftiest motives that can animate the soul, and fearing nothing but God, they confronted the wilderness and its warlike denizens with that dauntless courage which renders individuals and communities where their cause is just unconquerable. There was no lack of cultivated people; indeed, in the pulpit and at the bar and in medicine there were men possessed of acknowledged ability and collegiate training, and several of them had a national reputation; but there was no master mind who, as a leader, could bring into combined action all the needs and desires of a growing and refined community, for the establishment of institutions for instructions in higher learning.

"In the meanwhile, however, there was growing to manhood, in the wilds of Kentucky, one whose sons had

caught the spirit of the times and who at length came to Cincinnati with the largest desire to take part in her future welfare. Such a mind, so full of enthusiasm for knowledge in Nature's arcana, could not remain in the dull routine life of the planter. It was happily directed toward medicine, and Daniel Drake came to this city in the first year of the century and apprenticed himself to Dr. Goforth as his office boy, student, and apothecary. His opportunity for formal instruction in books had been very limited, but the lack of opportunity was greatly compensated by his habits so thoroughly acquired of observation, comparison, and meditation. After a patient and methodic service of six years in which he had made himself familiar with the best books, he felt he must go to the famous school where Rush, Physick, and Wistar taught. With scanty means he completed his long journey on horseback and gratified the wish of his heart. On his return with enlarged views of culture, he entered busily into practice and rose rapidly in public estimation. Besides medicine, he investigated at large, subjects in natural history and physics, and also studied the aborigines and the monuments that marked their residence in our valleys. He wrote also descriptions of the rising city, the Miami valleys, and their prospective wealth. These writings, particularly the scientific ones, attracted wide attention, so that when, at a later period, he returned to Philadelphia to attain his degree, he was received by the faculty of the University and the distinguished society of Philadelphia as a savant.

"To the south of them, in Kentucky, lay another flourishing frontier town of nearly equal population with Cincinnati. It was not only distinguished for the heroic patriotism of its people, but also for their high social culture and the organization of the Transylvania University. Lexington first held aloft the torch of science in this wild world, and was recognized as the Athens of the West. There, under the auspices of Professor Dudley, in 1817, the first medical school of the West was organized, and Drake was elected one of its professors. Dudley and Drake were of the same age, and both Kentuckians. They first met as students in Philadelphia. Dudley graduated in that year, 1806, and four years later went to France, joined the French army as a junior surgeon, and served on Larrey's staff in many battles ending, I believe, at Waterloo. Drake was a voluminous writer on professional and general topics, but his greatest work was his systematic treatise of the diseases of the interior valley of North America, to which he devoted more than twenty years of travel throughout the vast Mississippi valley. Though Drake has long been dead, yet all his great undertakings remain and are flourishing."

Referring to the present of Cincinnati, Dr. Comegys said: "The medical college of Ohio, now a medical department of the University of Cincinnati, was never more prosperous; the clinical and pathological school of the hospital is attended by 400 students. It has a large and growing library and museum.

"Drake's great example and his precepts have continued to affect medical life in Cincinnati. I think it my duty to say to the members of the American Medical Association that a spirit of original research has ever been carried forward here; and in a period of forty years of professional life in this city I have never known so many young men of thorough training as in our own schools, and supplemented by severe study in the clinical schools of Great Britain and the Continent, as are now among our active practitioners.

"A few last words about our city at large. We hope that you will take a general view of its poetical situation. It is peculiar and striking. If you ascend our hills you will find that they are built of those stratified sedimentary masses that belong to the lower Silurian epoch. Between all of these layers quantities of marine shells are found, that prove that they formed the bottom of a great salt sea."

Dr. Garnett then delivered

THE PRESIDENT'S ADDRESS.

He chose as his subject the mission of the American Medical Association; its paternal relation to the entire profession of the United States imposes upon it duties and responsibilities of the gravest character. He said: "Taking a retrospective view through nearly half a century of existence we have no reason to be discouraged. But while we feel gratified by contemplation of the fruits of our labors in the past, it is obviously important that we should not be flattered into a belief that we have accomplished our mission, and permit ourselves to lapse into supine indifference with regard to a preëminently important object which remains to be worked out, through the instrumentality of this Association. I refer, gentlemen, to radical and thorough reform in the present system of medical education in the United States." The present faulty methods of education were then reviewed in connection with statistical tables of methods of instruction and requirements for admission into the various institutions of our country. He then submitted the following propositions:

"*Proposition first.* That a standing committee, to be called the Committee on Legislation, shall be appointed for each State and Territory, and the District of Columbia, to consist of five members of the medical profession in good standing, three of whom shall have no official connection with any medical school or college, whose duty it shall be to carry out, as far as possible, the following instructions:

"*a.* Each one of said committee, or a majority thereof, shall attend the sessions of their respective Legislature from time to time, as their duties may require, for the purpose of using all honorable means looking to the reduction of medical schools in the United States, and the consequent diminution of the annual number of graduates; that, as a practical measure to this end, they urge the passage of a law requiring that in the future granting of charters for creating medical schools there shall be a clause in every such charter requiring that all schools or colleges thus created shall demand a full term of four years' study before granting a diploma thereof, and that no student shall be admitted to matriculate who has not passed satisfactory examination, oral and written, in the ordinary branches of academic study; and further, that any college failing to show a greater number than fifty matriculates annually for three consecutive years shall forfeit its charter and be abolished.

"*b.* That they use all diligent efforts to secure an ordinance creating in each State or Territory, where no such board at present exists, and in the District of Columbia, a board of medical examiners which shall have no connection with any medical school, and which shall be required to examine all applicants for license to practise

medicine in the States, Territories, and the District; and that any person who may be detected practising any branch of the healing art without a license granted by the said board, shall be subject to such penalties as the law may provide.

"That this committee may be authorized by statute to select and nominate to the Governors of the States, Territories, and the District of Columbia, seven competent, learned members of the medical profession, to constitute such a board of examiners, who shall have exclusive power to issue licenses to practise the art and science of medicine and surgery.

"*c*. That the Chairman of the said committee of five be required to submit at each annual meeting of the Association a report embracing a full statement of what has been accomplished by each.

"*Proposition second*. That the faculties of the several medical schools within the limits of the United States be once more urgently requested to call a convention at some central point for the purpose of consultation and adopting some general and uniform system of medical education, more comprehensive and rigid in its requirements, and more in accord with the spirit of the age and advanced progress of medical science, suggesting four years term of study, the requirements of a preliminary education including some knowledge of the classics. That any college or school which shall refuse to enter into such arrangement as may be decided upon by the said convention, shall be excluded from all connection with the American Medical Association, and its Alumni shall not be recognized as members of the regular profession."

He urged the adoption of more active steps toward the erection of the Rush Monument, as proposed at a former meeting. "We owe it to ourselves," he said, "to recognize the fact that in honoring the memory of such a representative of the medical profession we do honor to ourselves." He concluded by congratulating the Association upon the proud and enduring position occupied. "Resting as it does upon solid foundation, a moral, intellectual, and scientific basis, it has steadily increased from birth, gained in strength and influence, and won for itself the support and approval of our brethren throughout this country—to-day more powerful, more self-reliant, more progressive and stronger in the affection of its members than at any former period of its existence."

DR. W. W. DAWSON, Chairman of the Committee of Arrangements, announced an

INFORMAL RECEPTION

at the Burnet House at eight o'clock in the evening, to which ladies were invited.

SECTION MEETINGS.

DR. N. S. DAVIS announced that as some Sections had too much work on the programme for sessions of usual length, he would offer a resolution that the Sections be permitted to meet at eleven o'clock in the morning. Adopted unanimously.

DR. N. S. DAVIS announced that as the Secretary of the

JUDICIAL COUNCIL

had tendered his resignation owing to ill health and removal to the Pacific Coast, no preliminary notification of the meeting of the Council had been given. Fortunately there was no work before the Council. He then gave notice of a meeting to be held in the Burnet House parlor May 9th, at nine A. M., for the purpose of organization and to consider whatever might be referred to the Council.

INVITATIONS

were read inviting the Association to visit the Chamber of Commerce, the College of Music, and the Technical School of Cincinnati.

WEDNESDAY, MAY 9TH.—SECOND DAY.

The Association was called to order at 10 o'clock by the President.

DR. ROBERTS BARTHOLOW, of Philadelphia, delivered the

ADDRESS IN MEDICINE,

which will appear in full in our issue of next week.

The report of the Trustees of

THE JOURNAL

was read by Dr. J. H. Hollister, Secretary. The number of members and subscribers was stated to be 4572, exchanges and extras, to complete files, raised the total weekly issue to 5000 copies. The receipts above the dues paid to the Treasurer of the Association, embracing subscriptions, advertisements, etc., for the year ending March 31st last, was $11,897.98, or $4,317.35 above the receipts for the preceding year. The total expenditures for publishing for the year ending March, was $16,261.67, being an increase of $3099.66 over the preceding year. The increase was caused by the addition of four pages of reading matter and of four to six pages of advertisements, and by the sending out of sample copies.

The *Journal* is, therefore, an actual source of revenue to the Association, and the Board of Trustees recommended that the increased receipts be expended in improving the *Journal*. They have decided upon using new type and better paper during the next year. They recommended an enlargement of the editorial corps, and requested that the exchanges and books sent for review be placed at the disposal of the editor instead of being sent to the library of the Association.

The report of the

COMMITTEE ON DIETETICS

was presented by Dr. E. A. Wood, of Pittsburg, Chairman. It recommended the importance of forming a section on dietetics and dwelt upon the recent prominence given to the subject, and the necessity for its greater recognition by the profession.

DR. WOODBURY, of Philadelphia, presented the report of a sub-committee on infant feeding, and

DR. L. A. SAYRE, of New York, moved that the committee be authorized to give the work a proper place in the programme for next year's meeting. Adopted.

DR. BENJAMIN LEE, of Philadelphia, moved that the committee be continued, with instructions to present at the next meeting a report embodying the general principles to be observed in a rational system of dietetics. Adopted.

DR. N. S. DAVIS, of Chicago, moved the adoption of the three proposed amendments to the constitution: First, to amend Section 2, relating to *Membership by Ap-*

plication, by substituting the following: "Membership by application shall consist of such members of the State, County, and District Medical Societies entitled to representation in this Association as shall make application in writing to the Treasurer, and accompany said application with a certificate of good standing, signed by the President and Secretary of the Society of which they are members, and the amount of the annual membership fee of five dollars. They shall have their names upon the roll and have all the rights and privileges allowed to permanent members, and shall retain their membership on the same terms." Adopted.

Second, to amend Section 5, relating to *Standing Committees*, "The *first and third paragraphs* should be stricken out, leaving intact only the second paragraph, relating to the Committee of Arrangements. In place of the first paragraph to be erased, your committee recommend the insertion of the following important provision, viz.:

The General Committee or Council shall be composed of *two members* from each State and Territorial Medical Society entitled to representation by delegates in the Association, and from the Medical Departments of the U. S. Army, Navy, and Marine Hospital Service. They shall be chosen by the members registered and present at each annual meeting, from each State, Territory, and from the Medical Corps of the U. S. Army, Navy, and Marine Hospital Service, acting separately, on the third day of each annual meeting; each delegation reporting the names of the members chosen to the Permanent Secretary of the Association on the same day, that they may be announced by him at the opening of the morning session of the fourth day. At the first election each delegation shall choose *two* members of the General Committee, one of whom shall serve *one* year and the other *two* years, and at each annual election thereafter one member shall be chosen to serve for two years, thus making the term of office of members of the General Committee *two* years. It shall be the duty of the General Committee, thus constituted, to organize by choosing annually a Chairman and Secretary, and such sub-committees as may be found necessary to facilitate the work that may be assigned to it; to meet annually at the place and on the day preceding each annual meeting of this Association, and as often during that week as may be necessary; to nominate, on the third day of each annual meeting, all the general officers of the Association (none of whom shall be members of its own body), the members of the Committee of Arrangements, the Committee on Necrology, seven member of the Judicial Council, and three members of the Board of Trustees for Publication for election by the Association; to recommend the place and time of holding the next annual meeting; and to consider and report upon all subjects that may be referred to it by vote of the Association. The presence of one-third of the whole number of members elected to the General Committee shall constitute a quorum for the transaction of business. If, at any annual meeting of the Association it shall be found at the close of the general meeting of the first day that a quorum of the General Committee is not present, it shall be the duty of the President and Permanent Secretary to fill the vacancies in the Committee temporarily by selections from the lists of delegates registered as present from the States to which the vacancies belong.

In place of the third paragraph, the following:

"The *Board of Trustees* shall consist of nine members, three of whom shall be elected annually on the nomination of the standing General Committee, and shall serve for three years. It shall be the duty of the Board to provide for and superintend the publication and distribution of all such proceedings, transactions, and memoirs of the Association as may be ordered to be published, and in such manner as the Association may direct; and in doing this, it shall have authority to appoint an editor and such assistants, and determine their salaries, and procure and control such materials, as may be necessary for the accomplishment of the work assigned to it. Further, to facilitate its work, it shall be the duty of the Secretaries of the Association and of the several Sections, during each annual meeting, or as soon thereafter as practicable, to deliver to the Board, or such editor or agent as it shall appoint, all such records of proceedings, reports, addresses, papers, and other documents as may have been ordered for publication, either in the general sessions or in the sections. All moneys received by the Board of Trustees or its agents, resulting from the discharge of the duties assigned them, must be paid to the Treasurer of the Association, and all orders on the Treasurer for disbursements of money in any way connected with the work of publication, must be endorsed by the President of the Board of Trustees. It shall be the further duty of the said Board of Trustees to hold the official bond of the Treasurer for the faithful execution of his office; annually to audit and authenticate his accounts, and present a statement of the same in its annual report to the Association; which report shall also specify the character and cost of all the publications for the Association during the year, the number of copies still on hand, and the amount of all other property belonging to the Association under its control, with such suggestions as it may deem necessary."

DR. J. M. KELLER, of Arkansas, strongly objected to the proposed amendments.

DR. J. B. MURDOCH, of Pittsburg, moved to recommit the amendments.

DR. N. S. DAVIS, of Chicago, stated that their object was to imitate the British Medical Association, and take all the duties connected with the management of the Association from the general meetings, and confine it to the scientific and social features.

DR. VAUGHAN, of Ann Arbor, thought the very reasons given by Dr. Davis the best reasons for opposition to the amendments; the Association has no desire to abandon the management of its own affairs.

DR. MURDOCH moved that the amendments be made the special order of business for Thursday, at twelve o'clock, and his motion was carried.

THE COMMITTEE ON NOMINATIONS

was announced as follows:

Arkansas.— P. O. Hooper, M.D.
Colorado.—H. S. Orme, M.D.
Connecticut.—W. C. Wile, M.D.
District of Columbia.—D. W. C. Patterson, M.D.
Georgia.—R. Battey, M.D.
Illinois.—C. Gilman Smith, M.D.
Indiana.—T. B. Harvey, M.D.
Iowa.—P. W. Lewellen, M.D.
Kansas.—J. E. Minney, M.D.

Kentucky.—D. S. Reynolds, M.D.
Louisiana.—T. G. Richardson, M.D.
Maine.—A. Garcelon, M.D.
Maryland.—J. J. Chisholm, M.D.
Masssachusetts.—Charles J. Belch, M.D.
Michigan.—W. Brodie, M.D.
Missouri.—F. J. Lutz, M.D.
Minnesota.—A. J. Stone, M.D.
Nebraska.—R. C. Moore, M.D.
New Jersey.—I. N. Quimby, M.D.
New York.—L. D. Bulkley, M.D.
Ohio.—Thad. A. Reamy, M.D.
Pennsylvania.—A. M. Pollock, M.D.
South Carolina.—T. J. Ellis, M.D.
Tennessee.—T. K. Powell, M.D.
Texas.—J. Bell, M.D.
Vermont.—M. H. Chandler, M.D.
Virginia.—W. G. Eggleston, M.D.
Wisconsin.—J. T. Reeve, M.D.
United States Navy.—W. T. Heard, M.D.
United States Marine-Hospital Service.—John B. Hamilton, M.D.

THURSDAY, MAY 10TH.—THIRD DAY.

The Association was called to order at 10 o'clock by the President.

Resolutions from the Kansas and Arkansas State Medical Societies

DENOUNCING QUACKERY,

and the advertisement of irregular practitioners in the daily and religious papers, were read.

The Committee on Nominations presented the following list of nominees as

OFFICERS FOR THE ENSUING YEAR:

President.—W. W. Dawson, M.D., of Cincinnati.
Vice-Presidents.—Drs. W. L. Schenck, of Kansas; Frank Woodbury, of Pennsylvania; H. O. Walker, of Michigan; J. W. Bailey, of Georgia.
Treasurer.—R. J. Dunglison, M.D., of Philadelphia.
Secretary.—William B. Atkinson, M.D., of Philadelphia.
Librarian.—C. H. A. Kleinschmidt, M.D., of Washington.
Chairman of Committee of Arrangements.—Horatio R. Storer, M.D., of Newport, R. I.
Trustees of Journal.—Drs. E. M. Moore, of Rochester; J. H. Hollister, of Chicago; J. M. Toner, of Washington.
Judicial Council.—Drs. A. M. Pollock, of Pennsylvania; W. C. Van Bibber, of Baltimore; J. F. Hibberd, of Indiana; Charles S. Wood, of New York; J. McF. Gaston, of Georgia; W. H. O. Taylor, of New Jersey; George L. Porter, of Connecticut.

To fill a vacancy, W. B. Phillips, M.D., of Kansas.

To deliver addresses in

General Medicine.—William Pepper, M.D., of Philadelphia.
Surgery.—P. S. Conner, M.D., of Cincinnati.
State Medicine.—W. H. Welch, M.D., of Baltimore.

The following sub-committee was appointed to fill vacancies in case of the declination of any of the appointees to deliver general addresses: Drs. J. B. Hamilton, of Washington; William Brodie, of Detroit; and A. Garcelon, of Maine.

Next place of meeting.—Newport, Rhode Island.
Time.—First Tuesday in June.

The Committee on

THE RUSH MONUMENT FUND

submitted a report stating that the collection of subscriptions was slow and unsatisfactory, although the project received universal approval and commendation. The Committee expressed the hope that the requisite money would soon be collected.

THE TREASURER'S REPORT

exhibited receipts to the amount of $25,649.90, expenditures, $23,242.07; and showed a balance of $2407.83.

DR. KLEINSCHMIDT reported that the

ADDITIONS TO THE LIBRARY

for two years numbered 369 distinct titles. Total number of volumes in the library 7500, comprising 2850 titles. He recommended a subscription of ten dollars to the *Index Medicus*, which was ordered.

THE AMENDMENTS TO THE CONSTITUTION

were then considered.

DR. N. S. DAVIS moved that they be laid on the table for one year. Adopted.

The following new amendments were then offered:

To strike out the last clause in Section 7, requiring delegates to affix their names to the Constitution. Also to form a Section on Pharmacy to meet with the Association, but to have no voice in its transactions.

It was resolved that in future delegates and permanent members when registering shall

INDICATE THE SECTIONS THEY WILL ATTEND

and in which they will vote for Section officers.

DR. W. H. DALY, of Pittsburg, moved to reconsider the permission given for the

MEETING OF SECTIONS IN THE MORNING,

and after animated discussion this was carried.

THE PHARMACEUTICAL DISPLAYS.

DR. WM. BRODIE moved that hereafter the Committee of Arrangements be instructed not to arrange for a display of drugs, etc., in connection with the meeting.

DR. I. N. QUIMBY thought that this was going too far, as it might be interpreted as opposition to education by the Association.

The motion was laid on the table.

RESOLUTIONS FROM THE WOMEN'S CHRISTIAN TEMPERANCE UNION,

urging physicians to substitute other stimulants for alcohol, were read and then tabled.

THE OFFICERS OF SECTIONS

were then announced as follows:

MEDICINE.—*Chairman*, F. C. Shattuck, M.D., of Boston. *Secretary*, G. A. Fackler, M.D., of Cincinnati.

SURGERY.—*Chairman*, N. P. Dandridge, M.D., of Cincinnati. *Secretary*, W. O. Roberts, M.D., of Louisville.

STATE MEDICINE.—*Chairman*, J. B. Lindsley, M.D., of Nashville. *Secretary*, J. Armstrong, M. D., of Massachusetts.

Ophthalmology.—*Chairman*, G. E. Frothingham, M.D., of Ann Arbor. *Secretary*, G. O. Savage, M.D., of Tennessee.

Diseases of Childrex —*Chairman*, J. A. Larrabee, M.D., of Kentucky. *Secretary*, C. J. Jennings, M.D., of Michigan.

Medical Jurisprudence.—*Chairman*, J. G. Kiernan, M.D., of Chicago. *Secretary*, —— Evans, M.D., of Baltimore.

Obstetrics.—*Chairman*, W. H. Wathen, M.D., of Louisville. *Secretary*, A. B. Carpenter, M.D., of Ohio.

Dentistry.—*Chairman*, —— Rebwinkel, M.D., of Ohio. *Secretary*, E. P. Talbot, M.D., of Chicago.

Adjourned.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, April 20, 1888.

Dr. Trenholme in the Chair.

Dr. Trenholme exhibited a large

multilocular ovarian cyst,

weighing twenty-eight pounds, which he had removed from a woman aged forty. The case presented no unusual difficulties and was doing well. It had been first noticed eighteen months before and had grown very rapidly.

Dr. Lafleur presented the specimens obtained from an old man who had died after perineal section which had been performed for

urinary infiltration.

The patient, a man aged seventy-two, was suffering from severe urinary infiltration, which had come on after the use of instruments for retention of urine. He was admitted into the general hospital, under Dr. Shepherd, who immediately performed perineal section, and evacuated a large quantity of stinking, purulent urine and sloughing tissue, which occupied the perineum and had separated the rectum from the prostate gland. No trace of a membranous urethra could be found at the time of the operation, so a catheter was introduced into the bladder through the prostatic urethra, and the bladder thoroughly washed out with a solution of boric acid. The catheter was left in for drainage. The man at the time of the operation was in a very bad condition, and survived only thirty-six hours. At the autopsy the following conditions were found: œdema and gangrene of the scrotum, edges of the perineal wound sloughy; an abscess cavity about the size of a large walnut was found between the neck of the bladder and the rectum, and contained a little foul urine and shreds of necrosed tissue. No trace of the membranous urethra. Prostate gland enlarged. Both kidneys enlarged; the pelvis of right kidney distended and filled with urine, the pelvis of left kidney filled with pus; ureters much thickened. On section of left kidney spots showing commencing abscess. Pneumonia of lower lobe of right lung; upper lobes hyperæmic; commencing pneumonia of base of left lung. Heart pale, soft, and friable. Patient evidently died of heart failure occurring in course of pneumonia.

Dr. Lafleur also presented the specimens obtained from a patient under the care of Dr. Bell, who died from the effects of

abscess following perforation of the appendix, complicated with iodoform mania.

The case was interesting also because the man during treatment had been affected with mania supposed to be due to iodoform. Dr. Bell gave the following history:

The patient, a very stout man, aged forty-five, of unsteady habits, was admitted into the general hospital in July 1887, suffering from symptoms of perityphlitis. He was discharged, apparently cured, in a few weeks, but returned in December with numerous sinuses in the lower part of the abdomen and scrotum. All these sinuses led to the right iliac fossa, which was occupied by much dense inflammatory tissue. These sinuses discharged a large amount of fetid pus. Dr. Bell, under whose charge the patient was, opened up and scraped the sinuses, and evacuated many pockets of pus, but could not find the source of the pus in the iliac fossa. The wounds were packed with iodoform gauze and a dressing of washed gauze applied. The temperature of the patient, which had ranged from 100° to 103° F., became normal, and he gained strength rapidly. Three weeks after he suddenly became maniacal. After this no dressings could be kept on and the patient's condition gradually grew worse, temperature became high and irregular, and two weeks after he died suddenly apparently from collapse. He never recovered his sanity. No family history of insanity. At the autopsy Dr. Lafleur found the following conditions: Abdomen distended, peritoneum contained five ounces of turbid fluid with flakes of lymph; no evidence of recent peritonitis. Appendix firmly matted to surrounding structures; perforation about a quarter of an inch long about its middle. Deep pigmentation and inflammatory thickening of tissues about the appendix. From the appendix sinuses, all of them with indurated and deeply pigmented walls, ran in three directions. (1) The oldest sinus beneath the cæcum upward and backward beneath the sheath of the psoas muscle to the internal arcuate ligament of that side, where it ended in a cul-de-sac. (2) The second sinus ran outward and forward over the iliacus muscle and divided in the abdominal wall into several branches which ran parallel to the fibres of the external oblique and opened externally to the lower wall of the abdomen. (3) The third sinus ran downward and forward through the pelvis and opened into the perineum externally. There was no abscess cavity about the cæcum or appendix. The liver was enlarged, and on the under surface of the right lobe there was a fluctuating swelling the size of a large orange, which on incision was found to contain five ounces of stinking pus. Another abscess was found on the upper surface of the right lobe near the coronary ligament. There were no thrombi in portal or hepatic veins. Spleen enlarged and soft. There is no doubt these abscesses were pyæmic.

Dr. Bell read a paper on

some rare forms of urinary extravasation.

The first case was that of a sailor, aged thirty-two years, who was admitted into the hospital September 3, 1887, with retention of urine. He had suffered from stricture for fifteen years, and had been treated in marine hospitals all over the world. He was in the habit of passing himself a No. 2 silver catheter when he had attacks of retention; this time he failed to introduce the catheter or the stilette which he had tried. The house surgeon

passed a No. 2 catheter to draw off the urine, this was followed by a temperature of 105°. When he recovered sufficiently Dr. Bell performed internal urethrotomy, and dilated the canal to No. 34 French. There was only one stricture, viz., at the root of the penis. The following day patient complained of pain about the anus, and there was considerable tenderness in the perineum, but no swelling. Urine passed freely; the inflammation about the rectum and anus increased, and on the 12th of September it was found that the lower end of the rectum was everywhere surrounded by pus; a deep incision was made posteriorly through the sphincter for drainage, and the parts thoroughly washed out. Three days after a piece of the rectum, measuring nearly four inches in length, sloughed away. The patient after this rapidly improved, and left the hospital on October 24th. Defecation and micturition were normal. Dr. Bell said that he had no doubt that this patient, in passing a fine catheter, when thrust under the neck of the bladder about the apex of the prostate, made a false passage, behind the posterior layer of the triangular ligament, and that urinary infiltration took place in the peri-rectal cellular tissues, and caused the slough.

The second case of extravasation occurred into the pelvis from the reopening of a wound in the bladder which had been accidentally inflicted during the performance of an ovariotomy. The bladder when wounded had been immediately closed with Lembert's suture. The patient went on well for twelve days, the urine being drawn off with a catheter. On the thirteenth day a small painful lump was felt at the lower end of the abdominal incision; on the eighteenth day this lump suddenly disappeared, and at the same time there was pain and tenderness in the left iliac fossa and diminution in the quantity of urine evacuated by the catheter. The lower end of the wound was reopened and urine immediately flowed, and with the finger an opening could be felt in the fundus of the bladder. A sinus led down into the left side of the pelvis, through this a drainage tube was passed into the vagina, the whole cavity and bladder were then thoroughly washed out with boric acid solution, the wound freely dusted with iodoform, and a gauze dressing applied. Patient immediately improved. Four days later sloughs began to come away in enormous masses. To facilitate the separation of the sloughs an incision was made into the left loin. The parts were daily irrigated, and afterward dusted over with iodoform. By the 20th of October the wounds were looking healthy, and all serious symptoms had disappeared. The woman apparently was progressing toward recovery. On November 1st she suddenly developed an acute mania, and from this time, although the local conditions continued to improve, the patient had to be forcibly restrained, she refused food, and was in a continuous state of maniacal excitement. She died on November 8th, much emaciated. No autopsy could be obtained.

Dr. Bell regarded the acute maniacal condition as the immediate cause of death, and he thought the mania due either to the toxic effects of the iodoform or the absorption of ptomaines and leucomaines from the urine retained and decomposing in the cellular tissue of the pelvis.

There was no history of insanity in patient's family. Dr. Bell also said that this case more fully impressed him than ever with the unreliability of catgut as a suture to retain the contents of a hollow viscus. Catgut was used in this case because no suitable silk was at hand.

A third case was mentioned, in which during the performance of an ovariotomy a strong fibrous band connecting the tumor with the base of the bladder was stripped off from the latter, tearing away a small portion of its peritoneal covering. Two weeks after the operation a small inflammatory mass appeared at the lower angle of the abdominal wound from which amber-colored fluid escaped. A large soft catheter retained in the urethra for ten days not only gave immediate relief to the symptoms, but effected a complete cure.

Dr. Fenwick had listened to Dr. Bell's paper with great interest. Speaking of the case of ovariotomy where the bladder was accidentally wounded, he said that sometimes this accident was unavoidable; he himself had, once wounded a prolapsed bladder when operating for hernia, but the patient ultimately made a good recovery. He had seen several cases of mania produced by iodoform, the most recent case was that of a stout old man on whom he had performed lateral lithotomy, iodoform was introduced into the wound, and the patient several days after became affected with mania which lasted about two weeks; he, however, recovered perfectly.

Dr. Shepherd said that the autopsy in the case of perforation of the appendix showed that death had been due to septic poisoning. He did not attribute the fatal result to iodoform poisoning, though the man never recovered his sanity. He had assisted Dr. Bell when the numerous deep sinuses were laid open, and confirmed his statement of the great difficulty of tracing them to their source. Although a pericæcal abscess was suspected, yet, owing to the enormous thickness of the abdominal walls, the great amount of inflammatory tissue, and the severe hemorrhage, it was felt that further exploration was not justifiable. The autopsy showed that even had the abdomen been opened it is very probable the small abscess connected with the appendix would not have been found. The case of urinary infiltration following wound of the bladder during the performance of ovariotomy was also most interesting, from the fact of the probability of death being due to iodoform poisoning. He had had several cases of mania following operations, in all of which iodoform had been used, though only in small quantities, and he was in doubt whether or not to attribute the mania to iodoform, to the anæsthetic, or to traumatism. In all these cases there was an hereditary taint. Only one died, a case of sequestrotomy of the femur in a man aged twenty-five. Acute mania came on five days after the operation, only about one drachm of iodoform was used. In another case where a peri-cæcal abscess was opened in a man aged forty, acute mania came on the second day and continued one month; the patient recovered perfectly. A very small amount of iodoform was used, and only at time of operation. Several of the patient's immediate relatives died insane, and he himself was subject to fits of ungovernable temper. The third was a case of amputation of the breast in a woman aged sixty. A mild form of insanity immediately followed from the anæsthetic, and the woman never completely recovered up to the time of her death, a couple of years after, from cerebral hemorrhage.

Dr. Roddick was much interested in the cases of iodoform poisoning; he had seen one case follow excision of the breast. There was a history of insanity in the

family. The mania lasted only ten days. He thought iodoform should be used with more care, large quantities are not necessary; he had often found it produce severe eczematous irritation of the skin. He now used carbonate of bismuth in preference to iodoform, as it is non-irritating. He also sometimes employed boric acid and naphthalin. Lately he had been using hydronaphthol with benefit. It is odorless and non-irritating. Referring to the case of urinary infiltration reported by Dr. Bell, he thought the explanation of the case by supposing perforation of the prostate and posterior layer of the triangular ligament was not necessary, as it is well known that when the membranous portion of the urethra is perforated and urine escapes behind the anterior layer of the triangular ligament, the tendency of the fluid is to infiltrate backward toward the rectum and not to come forward. If the posterior ligament is perforated, then the infiltration extends behind the pelvic fascia into the pelvis and is generally fatal.

DR. STEWART had seen Dr. Bell's first case and considered it a case of iodoform poisoning. It is well known in these cases of mania from any cause that the mania remains long after the removal of the cause.

Cases in which there is much adipose tissue are more liable to poisoning, because the fat decomposes the iodoform.

DR. ARMSTRONG asked if it was necessary to use iodoform; it has been proved to have no germicidal qualities. He thought its use entirely unnecessary in the treatment of sinuses.

DR. TRENHOLME, referring to the case mentioned in Dr. Bell's paper, where the bladder was wounded, said that the bladder should never be emptied before operation. Should it be accidentally wounded then sutures of shoemaker's thread or silk should be used, not catgut, which is very unreliable.

THIRD FRENCH CONGRESS OF SURGERY.

Held in Paris from March 12 to 17, 1888.

(Specially reported for THE MEDICAL NEWS.)

(Concluded from page 502.)

LARYNGOTOMY AND TRACHEOTOMY IN CASES OF FOREIGN BODIES IN THE LARYNX.

DR. LABBÉ, of Paris, presented a small metallic star, which he extracted from the larynx of a child who had swallowed it, by laryngotomy; it had implanted itself exactly between the two vocal cords. At the moment the child did not complain, but during the night symptoms of suffocation set in; the physician called thought he had to deal with a case of spasmodic laryngitis. A few days later the child was brought to Dr. Labbé; he tried to take out the foreign body by the mouth, but finding it impossible to do so, he resorted to thyrotomy. He did not follow the good advice given by Morell Mackenzie, of performing tracheotomy before the other operation. Thyrotomy was performed at once, the thyroid cartilage opened on the median line; but at the moment M. Labbé was about to seize the foreign body a few drops of blood fell into the trachea and caused most dangerous fits of suffocation, which necessitated immediate tracheotomy. Respiration was only restored forty-five minutes later by artificial means. The heart, however, continued to beat strongly during this interval. The cartilage was then replaced, also the soft parts. The canula could only be taken out on the eighth day. On the fifteenth the child was perfectly well. This shows the necessity of a preliminary tracheotomy before the extraction of foreign bodies can be made with security.

CHOLECYSTOTOMY IN CHILDREN.

DR. VINCENT, of Lyons, presented the history of a girl eight and a half years old, who had an enormous biliary tumor, containing three quarts. The diagnosis was made by elimination. The incision was made along the external border of the rectus muscle, which brought the operator on the convex surface of the liver; the incision had to be extended to the umbilicus, to reach the bladder, which was then extirpated. On the fourth day, a severe hemorrhage, coming from the liver, which had rubbed against the abdominal sutures, appeared, and the patient died. In children, the median supra-umbilical incision is to be preferred to the classical lateral incision, because the liver being drawn down, and the bladder carried to the median line, the median incision allows one to explore much better the biliary vesicle and ductus choledochus; also, it prevents the placing of sutures on a level with the liver, and so produces ulceration and fatal hemorrhage. The median incision allows also the early exploration of the left surface of the biliary tumor, to ascertain the presence or disappearance of the ductus choledochus, and, as in this case, to meet with the juxtaposition of the duodenum and bladder, and proceed to enterochlecystotomy—that is, the establishment of an artificial perforation which will allow the passage of the bile into the intestine, when the duct cannot be found.

TREATMENT OF ERECTILE TUMORS BY ELECTROLYSIS.

DR. BORIES, of Montauban, presented a case of arterial angioma of the upper lip, which had a great tendency to extend and produce very grave hemorrhages. During four months, for every day, he treated his patient by electrolysis. Each sitting lasted eight to ten minutes, but contrary to the practice of MM. Schwartz and Redard, who introduce only the positive needle, he introduced both needles, one at the side of the other; the hemorrhage accompanying each operation was insignificant. At the end of the four months coagulation was complete; to correct the deformity he used Cangoin's arrows and made an autoplasty.

RAPID MEASURING OF ASTIGMATISM.

DR. JAVAL, of Paris, said that astigmatism being one of the most frequent ocular affections which we have to remedy, it becomes important to find out means for the rapid measurement of this faulty vision. To appreciate the inequalities of the corneal curve, Helmholtz invented an ophthalmometer thirty years ago. But to utilize the instrument, it is necessary to spend a week's study on one eye, and to make complicated calculations. The ophthalmometer which he constructed in 1881 permitted one to measure a corneal astigmatism in less than a minute. To-day, by the aid of a quadriprism, he thinks he can make this measurement instantaneously.

TREATMENT OF SUPPURATION CONSECUTIVE TO EYE TRAUMATISM.

DR. ABADIE, of Paris, said that the conjunctival surface is covered with microbes, and particularly its cul-de-sac.

Out of 178 cultures practised with a little mucus from the superior conjunctival cul-de-sac, 139 produced vegetations, 39 remained negative. After any traumatism, and before resorting to an operation, one must make a sub-palpebral irrigation sufficiently strong to wash away mechanically all the microbes. The liquid used does not need to be irritant, it must only be aseptic. If, notwithstanding every precaution, he finds inoculation and suppuration at one point, as strong antiseptic solutions are not tolerated, he proceeds as follows: He touches lightly the centre of the purulent spot with the galvano-cautery at white heat, and he repeats these cauterizations every twelve hours. If the suppuration occurs after a cataract operation, the little cautery points are applied along the wound without extending over the neighboring tissue. Systematically repeated every twelve hours, they arrest completely the diseased condition, and often save the cornea from certain destruction.

TREATMENT OF DISPLACEMENTS OF THE WOMB.

Dr. Doléris, of Paris, said that since 1885 he has adopted the following treatment for displacements of the womb. His method is based on the conditions of the pelvic equilibrium studied experimentally on young girls at the time of puberty, after partial operations, and after interventions for the restoration of the organs as regards the normal status of the uterus. He then studied the variable displacements of the womb and their usual complications: deviations of the neck, hypertrophic or atrophic conditions of certain parts of the womb, displacements or hernias of the bladder and rectum (rectocele, cystocele), laceration of the perineum, chronic inflammations. The plastic operations are insufficient, they only mask the lesions, without curing them. Prosthetic operations, pessaries, shortening of the round ligaments, were also insufficient; most of the time, the cure of inflammatory conditions is only a temporary one, and comes back if the displacement persists. The factors of uterine equilibrium are of three kinds: 1. The ligaments, or suspensory apparatus; 2. The central apparatus for attachment of the ligaments; 3. The pelvic floor, or sustaining apparatus. Basing his operative interferences on these indications, he has made 30 operations with success, combining the shortening of the round ligament with colporrhaphy or perineorrhaphy.

WOUND OF THE STOMACH - CURE.

Dr. Reynier, of Paris, communicated the case of a man who had a stomach wound produced by a revolver ball a quarter of an inch in diameter. The stomach was empty at the time of the accident, there being no great amount of hemorrhage, of meteorism, or symptoms of peritoneal reaction. M. Reynier did not interfere. The cure was completed without accident. He does not, however, on account of this lucky case, recommend systematic abstention in cases of wounds of this kind. The wounding of an empty stomach, without signs of important hemorrhage, does not necessitate an immediate interference, on the contrary; it becomes necessary when the lesion has been produced, on a stomach containing food, or else the contents would go out into the peritoneum.

NEW OPERATION TO REMEDY AN OLD DISLOCATION OF THE PATELLA.

Dr. J. Lucas Championnière, of Paris, presented the following new method to the Congress. A man, aged twenty-eight years, with an outward dislocation of the knee, which had lasted for more three months, came to him on January 28, 1888. This man walked very badly, his thigh atrophied more and more every day. The patella dislocated outwardly could be brought to its place, but on the least flexion it returned to its abnormal position. He then thought he might create a new place for the patella. On February 16th he opened the articulation by a long incision, inside of the patella, the patellar tendon, and the rectus femoris, then with the chisel and hammer he cut a deep cavity in the bony substance of the internal condyles, extending somewhat on the cartilage. The patella placed in this position was maintained in place by the crest, by a regular wall placed to the outside. He applied catgut sutures to the rectus femoris and patellar tendon; superficial and deep sutures. A drainage tube left in the inferior portion of the articulations was taken away at the first draining on the fourth day. At the second dressing, on the tenth day, the wound was healed, and from that date he began to move the articulations. He did not know what would become of the patient. He thought, however, that this operation might be of service in analogous cases.

RIZZOLI-ESMARCH OPERATION.

Dr. Leorat, of Lyon, presented the case of a child, six and a half years old, suffering from unilateral ankylosis of the maxillary joint. The ankylosed ramus of the jaw was cut without entering the mouth, and the periosteum was completely destroyed. He then left the parts in this state, expecting a non-consolidation and the formation of a pseudo-arthrosis on that side, as the other side was normal. He would probably have succeeded had the consolidation not been interfered with by scarlet fever. The patient then could separate his incisor teeth to the extent of half an inch; at the end of a year he could masticate meat.

THE FOLLOWING OFFICERS WERE ELECTED FOR THE NEXT CONGRESS.

President.—Baron Larrey, Surgeon-General, French Army (Retired).

Vice-President.—Prof. Guyon.

General Secretary.—Dr. Pozzi.

Secretaries.—Drs. Castex, Coudray, L. H. Petit, Picqué.

CORRESPONDENCE.

THE AMERICAN MEDICAL ASSOCIATION.

(*By Telegraph from our Special Correspondent.*)

Cincinnati, May 10, 1888.

Taken all in all, the Thirty-ninth Annual Meeting of the American Medical Association has been a grand success. Both scientifically and socially it is an advance over the meetings of the last few years. The advance in the character of the scientific work is nowhere more markedly apparent than in the surgical section, where owing to the efficient efforts of its Secretary, Dr. B. A. Watson, no less perhaps than to its President, Dr. Donald McLean, a number of representative men, who in the past have to a great extent stood aloof from the Association, have this year been induced to take part in the proceedings. A glance into the hall of meeting might well lead one to suppose that the American Surgical Association was in session.

Abdominal surgery is almost the exclusive topic of discussion. Papers of rare interest were read. Dr. Senn, as usual, was a most valuable contributor. This time he excelled all his previous contributions by his demonstration of his infallible method of diagnosis of intestinal perforations by the rectal injection of hydrogen gas. Three experiments on dogs made before the Section were perfectly successful, and demonstrated the practicability of the method; while reports of similar experiments on human subjects showed its applicability to surgery.

Almost without exception general and perfect harmony has prevailed. But few contentionists were present, and all past unpleasantness seems to have been buried and forgotten.

The amendment proposed by Dr. N. S. Davis taking the executive power from the Association was not acceptable, and is thought not to be in keeping with the character of American institutions.

The election of Dr. W. W. Dawson, of Cincinnati, to the presidency gives general gratification, especially to the Cincinnati profession, who earnestly desired for their popular representative this mark of distinction.

The great social event of the meeting was the reception on Thursday night. It was not only one of the most magnificent receptions ever tendered to the Association, but was the most brilliant gathering that for years has graced this city.

A MODIFIED LITHOTOMY STAFF.

To the Editor of THE MEDICAL NEWS,

SIR: In your issue of May 5th I see that Professor John H. Brinton, M.D., of the "Jefferson Medical College," claims a modification of the groove in a staff for lithotomy. I should like to remark, through your paper, that the staff with the grooved modification, which is described by Professor Brinton, was first used by the late Nathan R. Smith, M.D., late Professor of Surgery in the "University of Maryland," and is still used by Christopher Johnston, M.D., Emeritus Professor of Surgery in the same university, and also by my father, Alan P. Smith, M.D., who has used it in eighty odd cases. Feeling sure that this is merely an error of Professor Brinton's, I will close by quoting a paragraph from a work entitled *Hints on the Operation of Lithotomy*, by Nathan R. Smith, M.D., which was published in 1831, in which Professor Smith says:

"I would here remark, that the staff which I prefer to employ is grooved neither directly on its dorsum, nor yet on its side, like that of Mr. Bell, but obliquely and midway between these two aspects. This is to enable the operator, after having introduced his knife into the grooved staff, to give its edge an outward and downward inclination, so as to make the incision in that direction without danger of the knife being thrown out of the groove of the staff by the prominence of the edge which is on the side of the staff."

Very truly,

NATHAN R. SMITH, M.D.

BALTIMORE, MD., May 7, 1888.

LAPAROTOMY FOR PERITYPHLITIC ABSCESS.

To the Editor of THE MEDICAL NEWS,

SIR: May I change a statement made by Dr. Mears in your issue of May 5th relative to the time of opening a perityphlitic abscess from perforation of the appendix, since I am quoted as fixing the time of operation at the fifth day of the disease? Permit me to say that my rule is somewhat different, viz., if a tumor is present, I prefer to ascertain by an aspirator puncture, repeated several times if necessary, whether pus be present, and then to operate irrespective of any fixed time. If a tumor be present, and no pus be detected by aspiration, and, moreover, if no marked symptoms of peritonitis be present, *i. e.*, general pain or persistent vomiting, one may wait. Should, however, with a right iliac tumor the above symptoms be associated, in my judgment a lateral exploratory incision should be resorted to.

Dr. Morton, who in the same journal has reported a recovery from what appears, from his statement that he "washed out the abdominal cavity," to have been a case of general suppurative peritonitis, is to be congratulated on his success, for it is the first that has occurred in some sixteen instances in which this operation has been done. I leave out of this collection the case of Homans, and those more recently reported by Elliot and Sands, as these were localized intra-peritoneal abscesses, and in them the general abdominal cavity was not invaded by the disease. Yours, very truly,

R. F. WEIR.

NEW YORK, May 7, 1888.

NEWS ITEMS.

Sir Morell Mackenzie's professional brethren have been greatly gratified by the confidence placed in him by the Emperor Frederick, and by the extraordinarily warm appreciation of the English physician's services which His Majesty has expressed both by word and deed. In conferring on Sir Morell Mackenzie the honors and decorations which he has so well earned, the Emperor added immensely to their value by a letter written with his own hand, of which the following is the full text:

"CHARLOTTENBURG, April 9, 1888.

"MY DEAR SIR MORELL: You were called in to me at the unanimous desire of my German doctors who were treating me. As I did not know you personally I had confidence in you on account of that recommendation, but I soon learned from personal experience how to value you. You have rendered me most valuable services. In recognition of those services, and as a souvenir of my accession to the throne, I have pleasure in conferring upon you the Comthur Cross and Star of my Royal Order of Hohenzollern. Your well disposed

"TO SIR MORELL MACKENZIE." "FRIEDRICH."

One does not need to "read between the lines" of this letter to perceive its significance. The first sentence fully disposes of various mythical accounts of the way in which Sir Morell Mackenzie was called in to the case which have been current in the profession and in society. Before subjecting the heir to the Imperial Crown of Germany to a formidable operation—which might, possibly, be attended with disastrous consequences, not only to the august patient, but to the whole of Europe—Professor von Bergmann naturally wished to have the sanction of an expert whose authority would be generally recognized. The choice lay between the leading English laryngologist and Professor Rauchfuss, of St. Petersburg, and the former was selected, as the Emperor says, "at the unanimous

desire of my German doctors." The concluding words in which the Emperor speaks of his accession to the throne prove beyond all doubt that His Majesty believes that it is to Sir Morell Mackenzie's "masterly inactivity" that he owes his present position, with all that it involves. We are pleased to see that the people of Germany are beginning to judge Sir Morell Mackenzie's conduct of a most difficult and anxious case in a fairer spirit than some persons there seemed at first inclined to do.—*British Medical Journal*, April 21, 1888.

The Life of Matthew Arnold, from a Medical Standpoint.—The *British Medical Journal* of April 21, 1888, writes that the life and death of Mr. Matthew Arnold have a lesson of hope and a warning for the large number of persons who suffer from heart disease. Twenty-five years ago he consulted Dr.—now Sir Andrew—Clark, and was told he had valvular disease of the heart, but advised that if he exercised reasonable care it need not at all interfere with his career. For many years he rigidly adhered to the recommendations as to regimen and exertion which were given to him, and it is interesting and encouraging to recall that all his serious work in criticism, education, and theology was done within the last twenty-five years. His reports and essays on middle-class education, the *Essays in Criticism*, *Literature*, *and Dogma*, all belong to this period. Such a life is a striking proof that heart disease, even of a type generally accounted serious—for Mr. Arnold had disease of the mitral and aortic valves—need not interfere with the labors or the enjoyments of a successful career, provided only that the limitations and moderate restrictions to which the individual must submit are frankly recognized. Emboldened by long impunity, patients are disposed to come to believe that the precautions have been unnecessary, and to relax their vigilance at the very time when the approach of old age renders all more or less liable to weakness of the heart. The Arnold family are a remarkable instance of family predisposition to disease of particular structures; the father of Dr. Arnold, of Rugby, Dr. Arnold himself, and now two of his sons, have all succumbed to chronic heart disease.

A Bequest.—The late Professor Wagner, of Leipzig, left between $7000 and $8000 to found a Home for the School Children of Leipzig.

To Test a Wall for Dampness.—Nessler, in the *Chemiker Zeitung*, says that a sheet of gelatine laid against a wall suspected of dampness curls away from the surface if the suspicion is well founded.

NOTES AND QUERIES.

Early Laparotomy in Appendicitis.

To the Editor of THE MEDICAL NEWS,

SIR: In my remarks upon the specimens presented by Dr. T. G. Morton, at the meeting of the Philadelphia Academy of Surgery, held April 2, 1888, from two cases of removal of the appendix vermiformis by abdominal section, an error occurred in the statement that Dr. Weir fixes the time for operation by the lateral incision at *five* days. It should have read *two* days, and quoting Dr Weir *verbatim*, it should read "within *forty-eight hours* from the inception of the disease." Please insert this correction, and oblige, Yours respectfully,

J. EWING MEARS.

PHILADELPHIA, May 5, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING MAY 5, 1888.

HORD, W. T., *Medical Director*, and WOOLVERTON, T., *Surgeon*.—Ordered as delegates to represent the Medical Department of the Navy at the meeting of the American Medical Association, May 8th, at Cincinnati, Ohio.

BRADLEY, GEORGE P., *Surgeon*.—Ordered to Navy Yard, Brooklyn, N. Y., without delay.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM MAY 1 TO MAY 7, 1888.

DE LOFFOE, A. A., *Captain and Assistant Surgeon*.—Granted leave of absence for six months, on surgeon's certificate of disability, with permission to go beyond sea.—*S. O 99., A. G. O.*, April 30, 1888.

LAUDERDALE, JOHN V., *Captain and Assistant Surgeon*.—Ordered from Fort Clark, Texas, to Fort Davis, Texas.—*S. O. 98, A. G. O.*, April 28, 1888.

EDIE, GUY L., *First Lieutenant and Assistant Surgeon*.—Now under orders to report for duty to the commanding officer, Fort Douglas, Utah Territory, will accompany the Eighth Cavalry from the Department of Texas to the Department of Dakota, and, upon completion of this duty, will proceed to Fort Douglas.—*S. O. 99, A. G. O.*, April 30, 1888.

MCCAW, WILLIAM D., *First Lieutenant and Assistant Surgeon*.—Relieved from duty at Fort Leavenworth, Kansas, and ordered for duty at Fort Crawford, Colorado.—*S. O. 48, Department of Missouri*, May 1, 1888.

RAFFERTY, OGDEN, *First Lieutenant and Assistant Surgeon* (recently appointed).—Ordered for duty at Fort Clark, Texas.—*S. O. 98, A. G. O.*, April 28, 1888.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING MAY 5, 1888.

BAILHACHE, P. H., *Surgeon*.—Ordered to proceed to New York, N. Y., for temporary duty, May 1, 1888.

HUTTON, W. H. H., *Surgeon*.—Detailed as President of the Board to report as to the Quarantine establishment at North Chandeleur Island, Gulf of Mexico, May 4, 1888.

WYMAN, WALTER, *Surgeon*.—Granted leave of absence for fourteen days, May 4, 1888.

STONER, G. W., *Surgeon*.—Detailed as Chairman of the Board for the Physical Examination of Candidates for Appointment and Promotion, Revenue Marine Service, May 5, 1888.

MEAD, F. W., *Passed Assistant Surgeon*.—Detailed as Recorder of the Board for the Physical Examination of Candidates for Appointment and Promotion, Revenue Marine Service, May 4, 1888.

CARTER, H. R., *Passed Assistant Surgeon*.—Detailed as Recorder of the Board to report as to the Quarantine establishment at North Chandeleur Island, Gulf of Mexico, May 4, 1888.

DEVAN, S. C., *Passed Assistant Surgeon*.—Relieved from duty at Sapelo Quarantine; ordered to assume charge of the Service at Savannah, Ga., May 3, 1888.

WHITE, J. H., *Passed Assistant Surgeon*.—Relieved from duty at Savannah, Ga.; ordered to assume charge of Sapelo Quarantine Station, May 3, 1888.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LII. SATURDAY, MAY 19, 1888. NO. 20.

AMERICAN MEDICAL ASSOCIATION.

THIRTY-NINTH ANNUAL MEETING, CINCINNATI, 1888.

THE ADDRESS IN MEDICINE.

Delivered May 9th.

BY ROBERTS BARTHOLOW, M.D., LL.D.,

PROFESSOR OF MATERIA MEDICA, GENERAL THERAPEUTICS AND HYGIENE, IN THE JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA, ETC.

MR. PRESIDENT AND GENTLEMEN: The last International Medical Congress, in some respects, was the most important of the series. In the discussion of those great topics included within the domain of state or preventive medicine, matters of high interest for all educated people, of the greatest importance to the well-being of society, and that exhibit in the clearest manner the disinterested benevolence of the medical profession, were fully considered. To an unprejudiced observer it would seem that matters of such high interest would receive respectful attention, and such practical benevolence be gratefully appreciated by the great organs of public opinion—the daily newspapers: it must be admitted that it did not prove to be so.

It is a remarkable fact that the proceedings of the Congress were revealed to the universal public in a manner that is not too strongly characterized by the word *flippant*. In explanation of this phenomenon it was said that such is the usual attitude of the press toward the medical profession; that these representatives of current opinion do not take the profession "seriously," but rather view the men, and the work of the Congress, as a comedy performance, to be criticised and laughed over on the same lines. If the great metropolitan dailies stood alone in this attitude, it were the less surprising; but, unfortunately, others participate. No thoughtful observer can have failed to see that such is the disposition of the press throughout the country toward all medical organizations. The same position is assumed by a certain element in American society that delights to be considered "*cultured*." By these, a physician is a "medico," and the art and science as a profession or business, is no higher esteemed than such shows as Barnum's woolly-horse, or Chang the Chinese giant. Recently at a meeting of a medical jurisprudence society, several members, scientific men, questioned the accuracy of some statements made by the author of a paper who is connected officially with the Coroner's office. For thus presuming to question an official, they were sharply criticised by the Prosecuting Attorney, who happened to be present, and he also chided them in a manner befitting a pedagogue to his naughty boys, rather than members of a scientific body.

The causes of this state of things are not far to seek. Every one here present must be familiar with them. I purpose only to consider those which have to do with the therapeutic art—the most important.

Not a little of the ignorance, the crudities, the vague theories of the eighteenth century still linger in the nineteenth century near its close. It is yet understood by many that the therapeutic art is based on some *ism* or dogma. "Allopath" and "homœopath" are still bandied about as having vital power, when they were long since relegated to the lumber-room of the past by modern science. We yet hear of "new school" and "old school," as if notions brought out near the close of the last century, compounded of the vagaries of Hahnemann and the mysticism of Mesmer, could still continue guides to practice. The contentions of so-called "schools," the noisy demonstrations of the Thompsonians, and eclectics, and physio-medicals; the rabid water-cure, and the innumerable special cures, have produced in the popular mind a distrust of all systems.

The cry of "new school" has proved the most sympathetic; but the attractive sugar pellets, and tasteless liquids, carry with them their own destruction, for, in the deeper consciousness of men, lies the fatal objection that great results are not to be accomplished by such slender means. Hence, left to its own course, homœopathy has practically died out on the Continent. On this side of the Ocean it still maintains a certain influence, because of social conditions and prejudices that are only possible in free communities.

The success of such wretched puerilities, such inanities as the homœopathic practice consists of, does more to lower the position of the medical profession than any other cause. The false statistics published as actual fact, accepted as true, and passing unchallenged, are at this moment doing an almost incredible amount of mischief. Two years ago a pamphlet was very widely distributed throughout the West, as a trade document, containing much falsehood in the way of statements of pretended scientific truths, and fictitious statistics, that placed legitimate medicine in a false position, and discredited its practice to a most serious extent. This pamphlet was issued by a St. Louis homœopathic pharmacy, and was written by a Dr. Somers, who had been a professor in the faculty of Iowa University, and it had, therefore, an air of authority that materially contributed to its success. The usual tirade against allopathy—its past errors, and its present uncertainties—occupied much of this pamphlet, but its really effective part consisted in statistics made up out of the whole cloth. These statistics, it is asserted, were obtained from official publications, and gave the results in numbers of the comparative success of homœopathy and allopathy, in the cities of Boston, New York, Philadelphia, and others. It was thus shown by pretended official figures, that homœopathic practice is invariably from 30 to 50 per cent. more successful than allopathic.

What answer can be made to such statements, apparently supported by official figures? I am informed by a physician of the best reputation, living in a large city of the West, that this pamphlet was sent to every householder in a considerable town, that legitimate practice

was in a short time completely destroyed, and every regular physician reduced to extremity. We need not be surprised. How could any physician answer those immutable figures? Those who suffer from the effects of such misrepresentations are clear that an adequate answer should be made, although the profession is averse to medical polemics—for, wherever this lying paper has gone, the regular practitioner is silenced. Here are the official figures—what will you do about it? It remains unanswered, and is yet doing its work efficiently as a trade circular.

When this pamphlet was brought to my notice, I communicated with the official authorities to learn about the source and probable value of these pretended official figures. I expected to discover manipulations which made the figures tell the story that suited the purposes of the St. Louis drug house; but I was amazed to hear that no statistics of this kind exist at all, that a return showing the effect of a system of practice on the mortality rates had never been made, and therefore never published, and hence the figures given in the pamphlet were made out and out. I ascertained on further inquiry that though every aid were given, it would be a matter of infinite difficulty to get such figures, and to assure their accuracy would require an amount of time and trouble that hardly any one could give to such a task.

We cannot but regret that such misrepresentations should go unexposed. No other argument were needed to demonstrate the falseness of a system, maintained by frauds of such a shameless character; but meanwhile the advocates of the system profit by the forbearance of the medical profession in the attitude of maintaining its dignity.

The one remedy for existing ills—and to put the medical profession in its proper attitude as a scientific body—is to improve the art. How can the application of remedial agents be rendered more certain?

As a teacher of therapeutics for many years, I could not fail to observe that the attainments of the profession in respect to the powers of medicines are not as fully developed as they ought to be. They do not have that familiarity with the physiological powers of drugs which the effective use of remedies demands. It thus happens that the highest precision is not attained. Vague notions take the place of scientific accuracy when such has been the progress in this department, that a considerable degree of certainty should be the rule.

It must be admitted that the acquisition of therapeutical skill has been greatly hampered by the complexity of the materials. The barnacles of a century have been accumulating on the framework, and the new knowledge has been thrust into the crevices of old notions until all is made to appear confused and uncertain.

The subject should be divested of its superfluities. The list of preparations given in the *U. S. Pharmacopœia*—our only official authority—can be greatly curtailed with advantage. Remedies long in use and of comparatively little value are overloaded with formulæ. The preparations of iron given by the *Pharmacopœia* are thirty-eight in number, of mercury twenty-five, of rhubarb fifteen, of aloes as many. One-third of these could perform the duty of all. The botanical and pharmaceutical details are such that to master them would require the whole of the time given to the medical studies. If obtained, such knowledge is of small value to physicians: therefore it should be turned over to the pharmacist, to whom it properly belongs.

It needs no argument to show that to accomplish the best results, not only the remedy in its crude form but its constituents must be accurately known. Whenever an active principle is not available, the most concentrated preparations should be prescribed. In an especial degree is it necessary to have complete information regarding the dosage and actions of alkaloids. Let me emphasize in the most positive manner the importance of using the alkaloids and active principles, for by them we have minuteness of dose, singleness of action, and precision of effect.

In these "flabby days," as Mr. Froude entitles the present time, we must pay deference to taste, and secure the administration of a remedy which in a crude form may be rejected.

Under the name "*dosimètrique*" a system of therapeutics has been brought forward within a few years past, in which the point of departure is the exclusive use of the alkaloids and active principles made into granules. I will not enter into the theoretical notions on which Burggraeve bases his system. Dr. von Penterghem has done me the honor to send me his volume, which contains the dosimetric system fully elaborated, but I do not find that there is any truth which can be considered new, except the form of the medicament. Furthermore, their work is superficial. Dosimetric practitioners are imperfectly acquainted with the physiological action of remedies—their point of departure. This so-called system is, therefore, little more than a name which it was hoped, there is reason to believe, might play the *rôle* once the fortune of homœopathy.

That to attain to any degree of accuracy the administration of active principles is necessary is obvious enough. Crude drugs have a varying constitution due to climate, character of season, mode of manipulation, and other accidents. A notable illustration of this truth is afforded us in the composition of Pilocarpus. It contains two active principles: one *Pilocarpine* constant in form and powers; another *Jaborine* variable. The proportion of jaborine found in different lots of the drug pilocarpus varies one from another, and the process of separating the alkaloid also affects the quantity. Now as jaborine is an analogue of atropine, and therefore opposed in the entirety of its actions to pilocarpine, it is clear that the crude drug must be uncertain in its effects and one specimen vary from another in the most radical manner. In this way only can be explained the conflicts of observation first noted; for the alkaloid pilocarpine acts in a uniform manner, and must continue to do so. To obtain the desired results it is clear that the alkaloid and not the crude drug must be used.

There are many illustrations of the same truth: for example, in the actions of cinchona and quinine, opium and morphine, nux vomica and strychnine, etc.

There can be but one basis for the administration of remedies. That must be a true, exact, and intimate knowledge of the manner in which they act on the tissues and organs of the body. This knowledge, as it now stands only in part developed, is large, somewhat complicated, but quite available, and will richly compensate all who will master its spirit and form.

It is within a comparatively short period that the study of the physiological action of remedies has been the

basis of a scientific therapeutics. The opening of the present century marked the very beginning of this movement, which, even now, is far from maturity. We owe to the genius of Magendie, seconded by the labors of Bichat, the fundamental principles, and to Bernard their practical execution. It is a curious fact, that when the foundations of physiological therapeutics were being laid, Hahnemann was developing his notion of the spiritual essence in medicines under the tuition of Mesmer, who, at that time, was firing the heart of female Paris with his magnetic force. To-day, under the title of "New School Medicine," we have this eighteenth century mysticism unchanged and unchanging, whilst legitimate medicine has been continuously developing, under the inspiration of all forms of physical science. To admit that homœopathy had any influence in the shaping of scientific medicine, is to admit its right to a hearing. It had nothing to do with the new forms scientific knowledge was taking, especially not with biology. Physiological therapeutics being the form the art of cure must, of necessity, assume, is there any law or rule which may serve as a guide to practical use? Of this there can be no doubt. The law of antagonism of action is such a guide within its proper range. By this is meant such a balancing of effects that the morbid action ceases. A capital illustration of the action, and of its consequences, is afforded us in the use of amyl nitrite in the relief of that form of angina pectoris with high tension of the vessels, and of fibroid kidney by the use of nitro-glycerine. Here tissue changes are held in check, and ultimately removed, by remedies that oppose the morbid action, or that maintain a balance of effects until the lesions no longer exist.

Besides the antagonism that is direct, there is an antagonism that is similar. That a remedy which has a selective action on any tissue will have a curative action in the diseases of that tissue, is a proposition that is generally true. If the therapeutic action is similar to the morbid, the curative effect is in inverse proportion to the closeness of the correspondence.

If there be similarity of action merely, the curative effect is trivial or is entirely wanting. To illustrate: Pilocarpus is the most powerful sudorific we possess; but it is the least effective agent in the arrest of sweating. On the other hand, atropine is the most effective, and this, as all the world knows, dries the skin by stopping the action of the sudoriparous glands. If we place together the physiological agents now used to arrest sweating, we find that they are powerful in proportion to the degree in which they lessen the functional activity of the sweat-glands. Thus we have atropine, picrotoxin, strychnine, and pilocarpine. Such a fact is conclusive against the theory and practice of homœopathy.

Next to the action of physiological antagonism as a means of securing accuracy in our therapeutical methods, must be placed the use of the physical forces. The important one, and that only to which I can allude, is electricity.

Infinite harm has been done to this subject by specialism. It is not yet divorced from charlatanry of the worst sort—the pseudo-scientific. The most serious embarrassment in assigning electricity to its rightful place in our Materia Medica, is the complexity of the subject. Unfortunately, no man can use the agent rightly who is unacquainted with its physics and physiology. Within the sphere of its curative action, it is simply unrivalled. That this strong statement is not universally accepted, is due to the fact that this force is not sufficiently studied, and not appreciated because its powers are not utilized. Professional scepticism, added to the ill-repute which comes of inveterate quackery, acts in turn on the minds of patients, and thus prejudice is engendered that constantly interferes with the proper development of the science.

Notwithstanding the scepticism, or the positive unbelief, there are two facts that cannot be explained away or denied—for they rest on the immutable basis of physical truth.

The first fact is, the power of galvanism to affect the circulation.

The second fact is, electrolysis, or electrolytic decomposition.

Late researches have shown that a moderate galvanic current increases the vermicular action of the vessels and thus increases the blood supply to a part, and the activity of the function of nutrition. On the other hand, strong currents tetanize the vessels and thus lessen the amount of blood passing to a part, diminishing congestion. The same laws hold good of the faradic current if the parts to be acted on are so situated that the electrodes come in contact with the tissues.

As respects electrolysis, scepticism has no ground of opposition. The same laws that regulate polar action in electrolytic decomposition, must be equally applicable within the body as without, the same substances being acted on. The action of the electrical current on the vessels, the electrolytic decomposition of materials that can be thus acted on, have brought about results not hitherto attainable. Merely as indicating results now of daily procuring, and which, no doubt, receive full consideration in the Sections, I mention only the remarkable effects had in the treatment of pelvic congestion, inflammation and its products, of stricture of the urethra, and similar lesions. Again, in affections of the trophic system, cutaneous diseases, etc., quite a different aspect has been given them by electrical treatment. Nor should I fail to mention the quite remarkable results which have been lately achieved by the combined currents—galvano-faradic.

Will my brethren who practise the obstetric art permit me to ask why post-partum hemorrhage shall not be promptly arrested by the faradic current, instead of by ergot, friction of the abdominal walls, and other reflex stimuli intended to secure uterine contractions?

There is a vast field needing cultivation in the application of hygiene to therapeutics. The comparatively new method of the dietetic treatment of disease offers us remedial agencies which certainly approximate to exactness in method, and surety in result. Time and the occasion permit me only to offer the merest hints for your serious and wise consideration.

THE CARTWRIGHT LECTURES.

ON THE GENERAL PATHOLOGY OF FEVER.

Delivered before the Association of the Alumni of the College of Physicians and Surgeons, New York, April 12, 1888.

BY WILLIAM H. WELCH, M.D.,
PROFESSOR OF PATHOLOGY, JOHNS HOPKINS UNIVERSITY, BALTIMORE.

LECTURE III.

THE ETIOLOGY OF FEVER.

WE considered in the last lecture the experimental evidence concerning the effects of increased bodily tem-

perature. An advantage of the experimental over the clinical method of investigating this subject is that it enables us to study the effects of heat upon the whole body and its various functions without the intervention of disturbing factors, such as infection, which complicate the clinical analysis of febrile phenomena with reference to this question.

We found that animals may be kept at high febrile temperatures for at least three weeks without manifesting any serious symptoms. The only functional disturbances which could be attributed directly to the influence of the elevated temperature were increased frequency of respiration and quickened pulse. The rapid respiration was found to be due partly to stimulation of the skin by external heat and by the warmed blood, and partly to the action of the warmed blood on the respiratory centres. The quickened pulse could be positively referred to the effect of the warmer blood upon the heart itself. No definite relation could be established between the variations of arterial tension which occur in fever and the height of the temperature.

Although the experiments narrated showed that prolonged high temperature is an element in the causation of fatty degeneration of the heart, they also indicated that other factors, such as infection, are concerned in the production of this lesion. Moreover, experimental evidence was found in support of clinical facts showing that this alteration may exist without serious interference with the functions of the heart, so that the conclusion seems justified that failure of the heart's power in fever is less an effect of high temperature than of other concomitant conditions.

Of the other disturbances in fever we learned that the increased consumption of tissue can be explained only in relatively small part by the elevation of temperature. The lessened perspiration, the renal disorders, and the digestive disturbances (with the possible exception of constipation) are referable also chiefly to other causes than the increased temperature. Both experimental and clinical observations strongly support the view now widely accepted that the disturbances of the sensorium which constitute so prominent a part of the group of so-called typhoid symptoms, are dependent in far higher degree upon infection or intoxication than upon the heightened temperature.

Although no attempt was made to analyze in detail the clinical evidence relating to the effects of high temperature, attention was called to the fact that the absence of all serious symptoms in many cases of relapsing fever, and in the so-called aseptic fevers in spite of prolonged high temperatures, strongly support the conclusions derived from the experimental study of the effects of heat upon man and animals. Even in fevers, such as typhoid fever and pneumonia, where the height of the temperature is undoubtedly a most important index of the severity of the disease, there exists no such parallelism between the temperature and the nature and the severity of the other symptoms as we should expect if these symptoms were caused by the increased heat of the body.

It was emphasized that the results of experimental investigations should not be permitted to control the treatment of fevers, more particularly the use of so-called antipyretic agents. These agents, whether hydrotherapeutic or medicinal, influence, as is well known, many functions besides reducing the temperature. I need only refer to the powerful influence of cold baths upon the circulation and the nervous system, and to the action of antipyrin and other antithermic drugs upon the nervous system.

Reasons were given for assigning to hyperpyrexia and insolation a position separate from other febrile conditions in the discussion as to the effects of elevated temperature.

Before leaving this subject of the effects of increased temperature, I wish to call attention to one consideration which should perhaps influence our opinion on this much disputed question. Is it a matter of indifference, so far as the effects of febrile temperatures are concerned, in what manner the increase of temperature is brought about? We have seen that heat regulation, heat production, and heat loss are disturbed in fever; but, as experience shows, not always in the same manner or the same degree. In one case the incoördination of the regulating mechanism may be most apparent, the temperature fluctuating strangely up and down; in another case the heat-producing processes are excited to the utmost; and in another the circulatory changes in the skin, the vasomotor disturbances, are the most prominent phenomena. Now this varying interplay of the factors which cause febrile rise of temperature doubtless corresponds to varying conditions of innervation, of structure and of function of certain tissues of the body. May we not reasonably suppose that these varying conditions of the tissues directly associated with the rise of temperature may influence their tolerance of increased body heat? We have not the experimental or the clinical data which would enable us to give a definite answer to the question here propounded, and it would lead me too far from the theme of the present lecture to attempt to sift the equivocal evidence which might be gathered. I suggest this question, however, as one worthy of more attention than it has hitherto received.

I wish now to invite your attention to some considerations concerning the etiology of fever. In this era, when etiological studies occupy the foremost rank in medical science, it will naturally be expected that a discussion of the general pathology of fever, even though it does not aim at completeness, will not leave wholly untouched the etiological aspect of the subject.

The general etiology of fever relates mainly to a consideration of the agents producing fever, the so-called pyrogenic substances. It is, moreover, only certain general characters of these agents which can be properly considered here. Most of the questions which at present engage so prominently the attention of physicians concerning the specific causes of individual fevers belong, of course, to the special etiology of fevers, and therefore do not lie within the limits of our subject. But even with these limitations we cannot in treating of the general etiology of fever consider the febrile processes so much in the abstract as we have done hitherto. We must come into closer contact with the individual forms of fever.

At the start it should be said that probably in no instance are we acquainted with the actual substance or substances upon which the febrile disorder of animal heat immediately and directly depends. We deal here, as elsewhere in medicine, not with direct but with remote causes. But in no department of etiology have we ad-

vanced nearer the proximate causes than in many of the infectious fevers. To be convinced of the immense progress which has been brought about by the etiological study of fevers, let one glance over some of the older books on fevers, such as Percy's or Selle's,[1] with their endless divisions into symptomatic genera and species, and their barren speculations. Percy, for instance, describes no less than one hundred and fifteen different kinds of fever.

In all ages it has been customary to divide fevers into two great groups, viz.: those which are secondary to some local cause, usually an inflammation, and those which cannot be explained by the presence of any local lesion. The explanation of the symptomatic seemed so much clearer than that of the essential fevers that attempts have repeatedly been made to place all fevers in the symptomatic group. It is a curious fact that the two methods which have been of the greatest service in the study of fevers, each, when first introduced, led to an entire misconception of the nature of fever. Boerhaave, who was the first to make any extensive use of the thermometer at the bedside, supposed that this instrument indicated a reduction of the bodily temperature during the febrile chill. He therefore taught that increased frequency of the pulse and not the elevation of temperature is the constant and essential symptom of fever. If we except de Haen's correction, which never became widely known, it was not until the middle of the present century that Boerhaave's error was overthrown. A no less serious misconception sprang from the study of the pathological anatomy of fevers in France during the early part of the present century. The exaggerated ideas of the immediate followers of Bichat as to what can be accomplished by pathological anatomy led them to the belief, for a long time widely accepted, that there is no such thing as an essential fever, that all fevers are symptomatic of some local disease. This error of Broussais, one of the most influential and eloquent medical teachers of this century, is plainly traceable partly to the fact that his autopsies were chiefly of typhoid fever, and partly to the belief that the lesions found at the autopsy suffice to explain all of the manifestations of the disease during life. But we need not stop to trace the fate of the various attempts to overthrow the doctrine of essential fevers. I have mentioned one attempt chiefly on account of the suggestive lessons it conveys rather than from a desire to enter into historical details which I have hitherto purposely avoided.

The division of fevers into symptomatic and essential fevers is one of undoubted practical utility, and is not likely to be abandoned. But it cannot truthfully be said that this popular classification has been of much assistance in advancing our knowledge. Close inspection shows that the boundary lines between the two groups of fevers are vague and shadowy. Probably no one any longer believes that traumatic fever, the principal type of the symptomatic group, is due to increased production of heat in the seat of inflammation, which, acting like a furnace, was once thought to warm the whole organism, or to the irritation of nerves connected with the inflamed region. The opinion of Billroth and of Weber is now generally accepted, that traumatic fevers are caused by the absorption of pyrogenic substances from the inflamed district. Symptomatic fevers as well as essential fevers, therefore, are dependent upon the presence within the blood of fever-producing agents. Many essential fevers, moreover, resemble the symptomatic ones in the existence of inflammation, or necrosis at the portal where there is reason to believe that the pyrogenic agents gain access to the general circulation. A distinction in these cases cannot be based on the ground that in symptomatic fevers only chemical substances, although possibly the products of bacteria, enter the circulation, and in essential fevers microörganisms invade the blood, for such a distinction would place cholera and possibly tetanus and typhoid fever among the symptomatic fevers. These considerations show how vague and unsatisfactory are the distinctions between symptomatic and essential fevers. Still, similar criticisms can be made of many of our artificial classifications which nature is under no compact to observe, and we should undoubtedly be put to great inconvenience if we attempted to dispense with the epithets symptomatic and essential as applicable to different forms of fever. There are, however, other points of view which seem to me more fruitful in the study of the etiology of fever than those embodied in these distinctions. I refer to the differences in the nature of fever-producing agents, concerning which our knowledge, although still very imperfect, has been materially increased within recent years. And here again we are greatly indebted to the results of experiments upon animals.

Much light has been shed upon the causes of a certain class of fevers by a series of experiments, which received their impulse from the important studies of Alexander Schmidt and his pupils upon the physiology of the blood. A particular direction was given to these experiments by the often repeated observation that fever and other injurious effects may follow the transfusion of blood, especially when the blood of one species of animal is transfused into an animal of another species. In order to test the supposition that these bad symptoms are due to an excess of fibrin ferment Köhler[1] injected into the vessels of animals blood made rich in fibrin ferment and fibrino-plastic substance, and found that this blood when injected in large amount into the jugular vein causes sudden death by rapid coagulation of the blood in the right heart and pulmonary arteries, but when injected in smaller amount or in a different manner produces a typical febrile attack bearing a close resemblance to that following the injection of putrid fluids. Angerer[2] then found that a similar fever, although less intense and more gradual in its development, may be produced by the injection of blood into the peritoneal cavity or the subcutaneous tissue, or even by an extravasation of blood. Although in these experiments it was believed that fibrin ferment is the pyrogenic agent, Edelberg[3] was the first to produce fever and other symptoms of intoxication by the injection of this ferment isolated according to Schmidt's method.

[3] Edelberg: Arch. f. exp. Path. u. Pharm., Bd. xii.

In the light of these experiments it was to be expected that other ferments would be examined with reference to their pyrogenic power. Schmiedeberg[1] discovered that injections of histozyme into the blood of dogs produced high fever associated with general illness, and particularly with diarrhœa. The ferment to which Schmiedeberg has given the name histozyme he believes to be present normally in small amount in the body, and to be concerned in the dissociation of the nitrogenous constituents of the tissues. He concludes from his experiments that an excessive accumulation in the body of this normal ferment gives rise to fever with increased metamorphosis of nitrogenous materials. Schmiedeberg thinks it probable that the fibrin-ferment solutions employed by Edelberg in his experiments contained also histozyme, and that the pyrexia was due to the latter substance.

Following these observations concerning the pyrogenic power of fibrin-ferment and histozyme comes the discovery of von Bergmann and Angerer[2] that injection of pepsin and of trypsin into the blood of dogs causes a well-marked fever with characters like those of the other ferment intoxications described. A valuable calorimetrical study of pepsin and trypsin fevers has been made by Wood, Reichert, and Hare.[3] These authors, as well as Ott,[4] have demonstrated that it is not the pepsin and the trypsin ferments themselves which constitute the pyrogenic agents, but some contaminating substance, which seems to be a peptone. That peptones artificially prepared contain poisonous principles has been known for some time, and Brieger[5] has succeeded in isolating a crystallizable poisonous ptomaine, called pepto-toxin, from commercial peptone and from that formed by the artificial digestion of fibrin. This ptomaine, however, is not identical with the pyrogenic agent found by Ott and by Wood and his colleagues in commercial pepsin. To this list of pyrogenic substances obtained from impure ferments may be added leucin, and, according to Ott, papayotin and neurin which produce marked fever when injected into the blood in small quantity. The substance sold under the name of papoid possesses marked pyrogenic power when its filtered aqueous solution is injected into the blood. This substance contains principles belonging to the peptone or albumose group. Dr. Mall, Fellow in Pathology at the Johns Hopkins University, has isolated from commercial papoid a bacillus, which in pure cultures exerts a powerful peptonizing action on fibrin and on connective and elastic tissues. The bacillus itself is not pathogenic, but an albumose or some similar substance produced by its activity, has pyrogenic power when injected into the blood.

It does not appear that any one has actually isolated the pyrexial agent from the various ferments employed in these experiments. Certainly no such agent has been obtained in a crystalline form, which is the test of its purity, if we except Brieger's pepto-toxin, the pyrogenic capacity of which has not been established. It has been alleged that the fever-producing agent is the same in all these ferment intoxications, but this has not been proven nor does it seem probable.

[5] Brieger: Ueber Ptomaine, Berlin, 1885.

On better grounds it has been urged by von Bergmann and Angerer, that all of the substances in the group of pyrexial agents now under consideration, cause fever by producing the same change in the blood. These authors claim that this change is the formation in the circulating blood of an excessive amount of fibrin ferment, which leads either to coagulation or to stasis in the capillaries, particularly those of the lungs and of the intestines. One of the main arguments for this view is the fall of blood pressure which von Bergmann and Angerer observed after injections of pepsin and of pancreatin, but this fall can be explained in other ways than by supposing that the pulmonary capillaries are occluded, and, moreover, Wood, Reichert, and Hare find that the blood pressure often rises in the course of pepsin fever. It does not seem to me that we are any more able to explain in exactly what manner the pyrogenic substances act in this class of fevers than in other fevers. The idea, however, that the liberation of fibrin ferment in abnormal quantity is capable of causing fever, finds support not only in experiments which have been mentioned, but also in the fact that injections of hæmoglobin solutions, and of large quantities of water into the blood, produce fever.

But you, perhaps, by this time have asked yourselves what bearing all of these experiments with various pyrogenic substances have upon the etiology of human fevers. They have, in my judgment, an important bearing on this subject. However obscure may be the explanation of the mode of action of these substances, however doubtful may be their exact chemical composition, they have certain common characteristics which are calculated to shed light upon the causation of some obscure febrile disorders of human beings. In the first place, the members of this group of pyrogenic substances, if not identical with certain physiological ferments, are readily produced by them, quite independently of the action of bacteria or other microörganisms. In the second place, some of these substances are present normally in small amount in the body, and if their elimination is impeded, or their formation is excessive, there is reason to believe that they become efficient causes of fever. In the third place, these pyrogenic substances may be produced, again without the action of bacteria, in extravasated blood, or by the abnormal disintegration of tissues, and if they are absorbed from these sources in such a condition, or in so large an amount that nature cannot render them harmless, they are capable of producing fever. It is customary to call the morbid condition produced by the absorption of these substances, ferment intoxication in analogy with the term putrid intoxication, applied to the diseases caused by the absorption of the products of putrefactive bacteria. The term ferment intoxication seems to me to imply more than our knowledge warrants, but it is not of much use to contend against names which have gained currency. It is probable that some of the pyrogenic agents in this group belong to the class of leucomaines, but our present information regarding these bodies does not justify any positive statements on this point.

Although the etiology of individual fevers does not belong to our subject, I cannot forbear calling your attention to certain febrile conditions which seem to be produced by the accumulation of substances that are either normal constituents of the body or are the result of chemical processes, differing but little from physiological ones.

To this category probably belongs the so-called aseptic fever, first described by Genzmer and Volkmann.[1] These surgeons have established the fact that there are traumatic fevers not caused by the absorption of septic material, and that severe injuries and wounds which pursue an entirely aseptic course, are not infrequently associated with considerable elevation of temperature. This aseptic fever is usually to be observed with extensive wounds or injuries in which there is much lacerated tissue or extravasated blood to be disintegrated and absorbed. It occurs not only with wounds correctly treated by antiseptic methods, but also with subcutaneous injuries, particularly fractures of the large bones, where there can be no suspicion of the action of bacteria. Aseptic traumatic fever differs by such marked characteristics from septic fever, that there can be no doubt that the two types of fever are etiologically distinct. Aseptic fever has no prognostic significance; its only symptoms are the elevation of the temperature, which may mount to 104° (40° C.), or even 105.8° (41° C.), and the increased frequency of the pulse. The entire absence of all the intoxication symptoms of septic and infectious fevers, such as the benumbed sensorium, the dry tongue and skin, the lessened secretion of urine, I have already referred to in confirmation of the belief that these symptoms are not dependent upon the rise of temperature. Genzmer and Volkmann assign as the cause of aseptic traumatic fever, the absorption of substances resulting from the disintegration of the wounded tissues and of the extravasated blood, and state that these substances probably do not differ markedly from those produced by physiological tissue metamorphosis. This explanation certainly has received decided support by the experiments which I have described in this lecture, a large part of which have been performed since the publication of Genzmer and Volkmann's article. It has been suggested that aseptic traumatic fever is a reflex neurosis, and this suggestion cannot be absolutely rejected as a possible explanation, but for various reasons, which cannot here receive further consideration, the usually accepted explanation is the more probable one.

An instructive case of ferment intoxication has been reported by Cramer.[2] There existed in a young woman a cyst, the size of a goose's egg, between the fibres of the semitendinosus muscle. The cyst was developed from a cavernous angioma, and was filled with dark fluid blood. The patient had had fever for almost two years up to the day of the operation. The cause of the fever could not be discovered. Immediately after the removal of the cyst the fever stopped and did not return. In this case the cavernous structure of the cyst wall accounts for the ease with which we must suppose a considerable quantity of the pyrogenic substance was continuously absorbed from the bloody contents of the cyst. The results of Angerer's experiments, already mentioned, enable us to explain the source of the fever in this case.

Another instance may be cited in which fever is probably to be explained by the accumulation within the body of products of normal metabolism. More or less fever appears to be a constant accompaniment of the agonizing method of treatment known as the Schroth cure. In this treatment the patient is kept for a number of successive days on dry food with scarcely any fluids. Both Bartels and Jürgensen,[1] who have investigated the nutritive changes of individuals under this treatment, believe that the body becomes so poor in water that some of the products of regressive metamorphosis cannot be carried out of the system. This certainly seems very probable, and, if true, it affords in the light of recent experiments an explanation of the accompanying fever.

I believe that good reasons can be adduced in support of the opinion that the febrile conditions sometimes associated with leucocythæmia, profound anæmias, and chlorosis belong to the group of fevers we are now considering. It is probable that some of the obscure ephemeral fevers are also to be included here. But to consider these febrile disorders in detail would lead us into the domain of special etiology upon which we have already perhaps encroached too far. My purpose has been to bring before your attention only a few clinical examples in illustration of the experimental results.

I think that you will agree with me in the conclusion that experimental and clinical evidence justify us in recognizing as a distinct group of pyrogenic agents, substances which have no necessary connection with microorganisms, and which are either not foreign to the healthy organism or are readily formed by unorganized ferments from normal or abnormal constituents of the body. These substances may be described as homologous in distinction from the heterologous agents concerned in the production of septic and infectious fevers.

A class of pyrogenic agents of far greater clinical importance than those previously considered is formed by the products of microörganisms which in themselves are not pathogenic. A considerable number of bacteria, which when inoculated in pure culture into the body are not capable of further invasion or of multiplication, produce in culture fluids and in dead animal or vegetable material poisonous substances often of great virulence. Exception may be taken to the description of these organisms as non-pathogenic, inasmuch as the products of their activity are poisonous, but the epithet pathogenic is usually assigned by bacteriologists only to such microorganisms as are capable of multiplication within the body. If we called all of the microörganisms pathogenic which produce poisonous ptomaines we should have to include in this category a far larger number of the known species of bacteria than has hitherto been customary.

The best known and most important of the fevers produced by chemical products of saprophytic bacteria are those grouped under the name putrid intoxication. Until the introduction of the modern era in bacteriology by Koch nearly all of the experimental work on the etiology of fevers related to the causation of the septic and putrid fevers. It is instructive with our present knowledge to follow the experiments on this subject from the period of Gaspard, Magendie, and Sedillot up to recent times. What light has been shed upon the mass of contradictory and perplexing results of experiments with putrid fluids by the recent chemical and biological studies of putrefactive processes? Some of the putrid substances experimented with undoubtedly contained parasitic microorganisms, and others contained only obligatory saprophytes. Some were rich in poisonous ptomaines, and

[1] Genzmer and Volkmann: Volkmann's Sammlung, No. 121.

[2] Cramer: Verhandl. d. Deutschen Gesellschaft f. Chirurgie, 13th Congress, 1884.

[1] Jürgensen: Deutsches Arch. f. klin. Med., Bd. i.

others were nearly devoid of them. The whole doctrine of the parasitic nature of infectious fevers seems to have hinged in the minds of some upon the determination of the question whether septic and putrid fevers are produced by the absorption of chemical substances, or by the invasion of pathogenic bacteria. The ideas concerning putrid intoxication dominated at one time the whole field of fever etiology, and were applied not only to septicæmia but to typhoid fever, typhus fever, yellow fever—in fact, to nearly all infectious fevers. Nor have the echoes of this period even now entirely died out.

Panum was the first to isolate from putrid materials some chemical substance or substances in tolerable purity, certainly free from bacteria. This substance, when injected into animals, produced symptoms of putrid intoxication. Subsequently, von Bergmann and Schmiedeberg isolated from putrefying yeast a poisonous crystalline substance, their celebrated sepsin. For a time the opinion prevailed that this sepsin is the source of all putrid intoxications. Thanks to the investigations of Nencki and others, and particularly of Brieger, we now know that many alkaloidal substances can be separated from putrefying materials. Some of these so-called cadaveric alkaloids or ptomaines are poisonous, fever-producing, others are harmless. There is no reason to suppose that the list of the ptomaines of putrefaction has been exhausted, nor is it necessary to believe that all of the poisonous constituents of putrefying materials are of an alkaloidal nature.

Most of the bacteria concerned in ordinary putrefactive processes are purely saprophytic. They are incapable of multiplication in the living animal tissues. In a mixture of putrefactive bacteria it is not, however, uncommon to find genuine pathogenic or parasitic bacteria. It was from such sources that the bacilli of mouse septicæmia and of rabbit septicæmia (Koch) were obtained. The bacillus of malignant œdema is also often found in the early stages of post-mortem decomposition.

There is, of course, no doubt that the absorption of the chemical products of putrefaction may produce fever with septic symptoms, quite independently of the penetration and multiplication within living tissues of bacteria.

Here belong certain cases usually described as septic, in which fever and other bad symptoms subside upon the thorough cleansing and disinfection of a foul wound, or of a puerperal uterus. The majority of cases of septicæmia are not to be included here, for they depend upon the invasion of pathogenic bacteria. But, excluding the cases of genuine septicæmia, there remain the putrid intoxications which result from the absorption of poisonous substances produced in necrotic or disintegrating tissues, or exudations, or extravasated blood, by the action of purely saprophytic bacteria. The ideas which I have expressed on this subject are now so generally admitted that they require no further elucidation.

It is probable that fever, with symptoms of intoxication, although generally of a much milder nature than in the class of cases just considered, may be produced by abnormal fermentations and putrefactions caused by saprophytic bacteria in the alimentary canal. But here the essential morbid conditions seem to be abnormalities in the gastric and intestinal contents, due partly to the character of the ingesta, but chiefly to alterations of the digestive juices. Fermentative and putrefactive bacteria are normally present in the intestinal canal, and have abundant opportunities to gain access to this situation. The number, however, which can multiply and thrive there is quite limited, for under normal conditions, according to Escherich, only such bacteria can multiply to any extent in the intestinal canal as are capable of growing with little or no oxygen, and of deriving their nourishment from the anaërobic fermentation of the food supplied to them in this situation. Suitable conditions for the excessive multiplication of putrefactive or fermentative bacteria may, however, be furnished by abnormalities of the gastric or intestinal contents.

Of a far more serious nature are the putrid or ptomaine intoxications which result from the ingestion of substances which have undergone outside of the body putrefaction, or changes which lead to the formation of poisonous ptomaines. To this group of cases belong at least many of the instances of poisoning which have been caused by eating certain kinds of meat, sausage, fish, cheese, etc. In some of these instances poisonous ptomaines have been isolated from the suspected substances, but we know scarcely anything of the microörganisms which are concerned in their production.

It is important to bear in mind that it is not stinking putrefaction alone which gives rise to poisonous products. Brieger has found that such products may be absent in very advanced decomposition, and that in general the most virulent products are formed in the early stages of putrefaction. We know, furthermore, that putrefactions and fermentations differ in the character of their products. There are differences according to the kind of bacteria present, according to the substances decomposed, and according to various other conditions, such as the presence of oxygen, the temperature, etc. This is not the proper occasion to discuss these details.

Enough has been said to prove that we are justified in recognizing as a second class of pyrogenic agents substances which are the products of bacteria in themselves not pathogenic. These pyrogenic agents may be formed on or within the body, or they may be produced outside of the body. I would not by any means have you infer that it has been proven in all of the special examples which I have mentioned, that the bacteria involved are not pathogenic, or capable of multiplication within the living tissues. We have not sufficient knowledge to assert or to deny this in every instance, but I do not think that it is likely exception will be taken to the classification which I have adopted for most of these cases. As has repeatedly been mentioned, our purpose here is not an analysis of individual cases of fever, but an attempt to classify systematically the various pyrogenic substances.

(To be concluded.)

ORIGINAL ARTICLES.

A PRELIMINARY CLINICAL NOTE ON A FEBRILE EXANTHEM (ROSEOLA VACCINA) ACCOMPANYING VACCINATION.

By DAVID DENISON STEWART, M.D.,

Chief of the Medical Clinic in the Jefferson Medical College, Physician to St. Christopher's Hospital for Children.

Out of ten recent vaccinations with bovine points procured from a reliable apothecary, the Philadelphia agent for a New England vaccine company, it has

been my somewhat remarkable experience to encounter two[1] very severe cases of this peculiar and rather rare rash, the course of which was so typical, and the accompanying febrile disturbance so pronounced, that a recital of the histories as a preliminary note may not be uninteresting, prior to presenting a more extended report on similar cases which I have seen, occurring in the practice of other physicians.

Case I.—Henry L., aged four and a half years, a well-grown, strong, hearty boy, was vaccinated on April 20th. On the morning of the eighth day subsequent to vaccination, an irregular, rather large pustule, surrounded by a deep, highly inflammatory areola, occupied the site of vaccination. The whole arm was red, much swollen, and several enlarged, painful glands occupied the axilla of the same side. Slight feverishness had been remarked for twenty-four hours, associated with anorexia, nausea, and a heavily furred tongue. The fever had been decided on the evening before, and was accompanied by delirium, restlessness, and a discrete, small, very slightly raised, rose-colored erythematous rash, which was noticed first on the vaccinated arm, but which on the morning of the eighth day was evenly though lightly distributed on the extremities, face, neck, and trunk. During the early evening of this day I was summoned in alarm by the parents, the fever and rash having greatly increased. The latter now covered the entire body, and had become largely confluent in parts, particularly about the extremities and face, the latter being decidedly tumefied; while the abdomen, chest, back, and neck were very plentifully and regularly spotted with roseolous maculæ and soft, very slightly raised papules, so that no part of the surface of the body was free, though the wrists, flexures of the knees, and ankles were but slightly discolored. Considerable pyrexia was present, judging from the bounding pulse, surface heat, and great thirst. The temperature was not then taken.

At ten P.M., during a restless sleep, a severe general convulsion occurred, lasting nearly an hour, and consisted of alternate tonic and clonic spasms, but especially the former. It was repeated at three on the following (the ninth) morning. The temperature was then 106⅘°, the pulse 160, the extremities cold, and the body surface of a burning heat. The throat was not sore, the glands of the neck not swollen, and no catarrhal symptoms or cough were present. Potassium bromide and a fever mixture of aconite and spirits of nitrous ether were administered, a large enema was given to clean out the bowels, which, however, were said to have been loose on the preceding day. These means, combined with heat to the lower extremities, and constant cold to the head, probably prevented a return of the convulsions, but did not assist materially in lowering the temperature, which at eleven in the morning was 106⅖°, and the pulse 150.

The vaccinated arm was now exceedingly swollen, painful, and angry, while the areola about the pustule had become part of the general redness. The eruption was fully out. It had not the distinctive appearance of the rash of measles, scarlatina, or rötheln, but closely resembled the prodromic exanthem of variola, the *roseola variolosa*, and consisted of a hyperæmic macular erythema, which through the intensity of the systemic disturbance had become largely confluent. At first the maculæ and small papules—the latter of which throughout the disease were soft, and but very slightly raised, and at no time became vesicles or pustules—disappeared on pressure, but soon pressure ceased to efface them, and, about the back, thighs and legs, the diffused rash became decidedly purpuric, leaving, as it faded, subcuticular stains which persisted for a number of days.

On the morning of the tenth day, active antipyretics having been used in the interim, there was a decided improvement in his condition, the temperature was but 101°, the mind was now clear and the tongue less furred. There had been restlessness at intervals through the day and night with slight mental wandering and clonic masticatory spasm, which had ceased as the fever lessened. The urine was examined for albumin during the height of the fever, but with negative results.

I did not have an opportunity of seeing this case again until the fourteenth day following the vaccination. Pyrexia was then absent. The mother thought it had been slightly present on the eleventh day, but she had not observed it since. The rash, on this visit, presented the appearance described above.

Case II.—J. P., a hearty boy of four years, was vaccinated on April 17th. His was a primary vaccination, as, indeed, were all the six cases in which I have met this rash. The course pursued by the vaccination in this, as in Case I., was scarcely typical; no distinct papule had formed on the fourth day, and when seen again on the seventh day, a small irregular foveated vesicle was present, containing opaque lymph and an areola was in process of formation. The arm was then much swollen and so continued for a number of days. The pustule appeared early, was large and somewhat irregular, and the areola present rapidly spread until the whole arm became intensely red. On the evening of the sixth day of the vaccination signs of constitutional disturbance appeared, such as vomiting, furred tongue, anorexia, fever and delirium. These continued, and, on the evening of the seventh day, a rash having the characteristics of that described in Case I., was noticed about the chin, chest and back, which on the eighth day had spread to all parts of the body. It was quite as intense as that of Case I., and, like it, consisted of slightly raised soft papules and large and small roseolous maculæ, which formed, as it progressed, more or less confluent patches in some situations, notably the arms, thighs, nates, and portions of the back. Unlike the rash in Case I., some of the patches at first assumed an irregular

[1] Since writing the above, another case has come to me, making the number three out of seventeen. This one is of a milder type than either of the two described. It is that of an infant aged eight months, in St. Christopher's Hospital.

crescentic shape, somewhat suggestive of measles, but this was very transitory. On the most dependent parts, such as the back, nates, and posterior aspect of the thighs, where the rash later became largely purpuric, the color was, even from the first, decidedly purplish. Coincident with the generalization of the rash the temperature mounted, reaching 105½° at noon of the eighth day; but shortly after its full appearance a rather rapid fall took place, with an amelioration in the other symptoms. At noon on the ninth day, the temperature was 102⅗°, and on the following day the mother believes there was slight, if any, pyrexia present. There were no catarrhal symptoms and no sore throat; the urine was not examined.

Slight desquamation, not observed in Case I., accompanied in some situations, notably the back, the fading of the rash. Purpuric stains persisted on the thighs and nates for some days subsequent to recovery.

Under the title vaccinal eruptions are described a variety of acute eruptive disorders occasionally accompanying vaccinia, few of which can be regarded of special significance, since their presence may be explained more readily by extraneous causes than by any supposed specific action of the vaccine virus. I shall omit special mention at this time of the various local and general vesicular, pustular, urticarial, bullous, erysipelatous, and gangrenous rashes which, from their polymorphous character, irregular period of onset and erratic course, may well be considered to owe their existence to constitutional peculiarities, or to impure lymph,[1] or to accidental inoculation with septic matter at the time of the vaccination, or to the absorption of septic material from the ruptured or unruptured pustule.

We must, I believe, look elsewhere for the cause of the febrile roseola. In the six cases which I saw the incubation period seemed so exact, the characteristics of the eruption, its life history, and the constitutional disturbance were so similar as to indicate the presence of an element of specificity not manifested by the other varieties I have mentioned. Indeed, one cannot but be struck with the resemblance between this rash and the most frequent of the occasionally occurring prodromal exanthems of smallpox, the roseola variolosa, and I am inclined to believe this resemblance is more than superficial. I am in agreement with those who, like Friedinger,[1] look upon this rash, when occurring after vaccination, as an evidence of systemic infection by the vaccinia and that a direct relationship probably exists between it and the contagium of the disease.

Hebra speaks of a local vesicular rash occasionally following variolous or vaccinal inoculation as a part of a general disease, but he regards the roseola vaccinia as the commonest and most significant of the general rashes, and believes it due to the contagious principle causing a lymphangitis which, when it assumes a severe type, may be the cause of extensive cutaneous inflammations, such as erysipelas, cellulitis, abscess, etc. He places the date of appearance of the roseola between the third and the eighteenth day, and considers its duration ephemeral and the constitutional disturbance slight.

Behrend,[2] who gives a succinct, though in parts superficial, account of the various vaccinal eruptions, but whose acquaintance with the form under consideration seems slight, mentions it as appearing on the eighth day in two cases observed by him. In all of the six cases that I saw it appeared between the seventh and the ninth day.[3]

The question may perhaps be asked if this rash is not an accidental accompaniment of the vaccinia, why is it not encountered oftener? and it would be as difficult to answer as the same question regarding the infrequency of the prodromal rashes of variola. The whole subject of vaccinal eruptions merits and would well repay a careful reinvestigation.

2628 North Fifth St., Phila.

[1] An interesting account has just appeared in the Report of the Royal Bureau of Hygiene, of Berlin, concerning certain eruptions attending successful vaccination with lymph from young kine on the vaccine farm at Eberfeld. The rashes were of the nature of aggravated forms of urticaria, herpes, and contagious impetigo and pemphigus. The constitutional symptoms were so severe that several deaths occurred among children. The cause was at first a mystery, as the farm was in apparent good order and the officials reliable and skilful. By order of the Government three suspected heifers, in which, however, no disease could be discovered, and the various appliances used in inoculation were destroyed, after which no more rashes occurred.

[3] In two of my cases at the end of the seventh day; in the third, on the seventh or eighth; in three on the ninth, seen through the kindness of Dr. Wm. M. Angney and Dr Charles Pottberg.

NOTES ON THE EMPLOYMENT OF URETHAN AND OF AMYL HYDRATE IN INSOMNIA.[4]

By J. P. CROZER GRIFFITH, M.D.,
Assistant Physician to the Hospital of the University of Pennsylvania, Pathologist to the Presbyterian Hospital.

AND

ELWOOD R. KIRBY, M.D.,
Resident Physician to the Hospital of the University of Pennsylvania.

Owing to the demand for some efficient and safe internal remedy in insomnia, the number of hypnotics is constantly assuming larger proportions. We shall enter into no discussion of the merits of some of these. The disadvantages of opium, and the good and bad points of the bromides and of Cannabis Indica, are well understood. Hyoscine

[4] Read before the Philadelphia Neurological Society, January 26, 1888.

has undoubted hypnotic power, as common experience proves; but it can by no means be placed in the list of *pure* hypnotics, and its use is often accompanied by very unpleasant secondary effects; besides being not devoid of danger in dose sufficient to produce sleep. Chloral, though perhaps after all more sure and powerful than any of its cogeners, often has great disadvantages attending its employment. Its hypnotic action is very commonly preceded by delirium, and sometimes this is the only result of its administration; or there may be no effect at all observed. Moreover, cases have been reported by different observers where a single and even small dose has proved fatal; and on account of its depressing action on the heart, respiration, and nervous system generally, it cannot be called a pure hypnotic. Then, too, there exists the danger of the *chloral habit* and of chronic chloral poisoning, if the employment of the drug be long continued. Ward (quoted hy T. M. Lloyd, *Therap. Gazette*, February, 1888) has seen "no untoward result of any nature whatever" follow its use during an experience of fifteen years among the insane, and doubts the existence of such a thing as the "chloral habit." There are others who are inclined to adopt the same view; but those who are sceptical as to the deleterious effect which may follow the continued administration of chloral may find a mass of convincing evidence in the able article by Rehm, in the *Archiv für Psychiatrie*, 1886, Bd. xvii. 36. Although, then, chloral is an invaluable remedy, whose place in some cases cannot be taken by any other drug, the possible dangers attending its use, particularly in a condition of cardiac weakness, render it advisable first to make trial of some substitute for it, if such a substance can be found.

Paraldehyde was recommended by Cervello, in 1882, and has since been used extensively as a hypnotic. It does not affect the heart or respiration in any ordinary dose, and may be given with impunity even when cardiac lesions exist. It is not, however, so powerful as chloral, and possesses certain serious disadvantages. Its dose, mainly, is large, and it has a very unpleasant taste, which remains in the mouth long after the medicine has been swallowed. It may cause vomiting when the stomach is irritable, and in any case it is apt to produce unpleasant eructations, while its disagreeable odor remains on the breath sometimes for days. It is also said to cause great excitement at times, and a recent writer reports two cases where its continued use in large doses induced symptoms resembling those of chronic alcoholism; but this must be a very unusual occurrence. Sommer (quoted in *Therap. Gazette*, August, 1886) reports a case of scarlet injection of the skin, twice occurring after the ingestion of the drug; and Eickholdt (*Ibid.*) has observed cerebral congestion and vasoparalytic symptoms after its prolonged use.

Various other hypnotics have been more recently proposed, such as urethan, amyl hydrate, hypnone, and methylal.

The first two mentioned are receiving the most attention, and we desire here to report our experience with them in a number of cases.

URETHAN.

Urethan, or ethyl carbamide, was first used by Schmiedeberg on animals, and by Jolly on men. It is an ethylic ether of carbaminic acid, with the chemical formula $NH_2CO_2C_2H_2$, and consists of white crystals freely soluble in water, and with no odor and but little taste. It was brought into prominence in 1885, by von Jaksch (*Wiener med. Blatter*, 1885, Nos. 33 and 34), who administered it 110 times in 20 cases. In doses of 7 grains it was an uncertain hypnotic, but when 30 grains were employed he never failed to obtain the desired effect. The amount usually given was 15 grains, which was found sufficient to produce a natural sleep. The drug appeared to be entirely harmless in any medicinal dose, and produced no unpleasant after-effects.

Since von Jaksch's publication urethan has been tried quite extensively. Among the published reports of it may be noticed that of Kräpelin (*Neurolog. Centralbl.*, March 1, 1886), who gave it in doses of 15–45 grains 200 times in 34 cases. He considers it a pure hypnotic, but far inferior to paraldehyde if there has been much excitement, and worthless in delirium tremens. Usually more than 15 grains is required in any case.

Eloy (*L' Union Méd.*, Nos. 36 and 37, 1886) thinks it a powerful agent in doses of 30–60 grains. He has used it in 90 cases.

Scharschmidt (*Therap. Monatsh.*, Sept. 1887) considers it useless in doses of less than 75 grains.

Savage (*Practitioner*, 33, 1887) administered it in doses of 60–120 grains, and says that sleep often comes in one-quarter of an hour. He does not, however, appear to consider the drug at all reliable.

Myrtle (*Brit. Med. Journ.*, February 20, 1886) has seen its good effects in more than 50 cases of insomnia and restlessness from various causes.

Sticker (*Deutsch. med. Wochensch.*, No. 48, 1885) has also obtained favorable results with it, and says the dose may be increased to 60 grains without danger. He further states that too large a dose will sometimes have no effect, when a smaller one will bring sleep.

Bigelow (*Amer. Journ. of Obstet.*, 708, 1887) writes that 15–20 grains give a long, pleasant sleep, and claims that the drug is also an analgesic.

Langovoi (quoted in *Therap. Gazette*, 1887, p. 337) states that the drug is not a powerful hypnotic, and in some cases is ineffectual. It is unreliable but harmless. It may be useful in nervous insomnia and in sleeplessness in the acute fevers.

Ughi (quoted in *Wien. med. Wochensch.*, August 27, 1887) says that doses of even 30–60 grains are inconstant in their hypnotic effects.

Andrews (*Weekly Med. Rev.*, July 30, 1887) has used it in doses of 30 grains in 18 cases of insanity of different forms. About 80 doses in all were given. It produced sleep in about an hour, which lasted through the night. He considers that it has marked hypnotic power, and that it is accompanied by no unpleasant secondary effects.

Sansom (*Valvular Diseases of the Heart*, 1886, 102) considers urethan the most satisfactory agent he has employed as a simple hypnotic in heart diseases. He has found 15 to 20 grains at bedtime induce calm, natural sleep, lasting 5 hours or more, and producing no adverse symptoms.

Carriel (*Therap. Gaz.*, 1888, 101) says of its use in the insane, that it has not produced sleep in 30 grain doses.

Finally, Rottenbiller (*Centralbl. f. Nervenkrankh.*, 1886, No. 10) has given urethan hypodermatically 240 times in 14 cases of mental disorder, and found it ineffectual in amounts less than 30 to 60 grains, while it is not well borne in quantities larger than this. Its action is not very certain. In 8 cases it produced tranquil sleep for 6 to 8 hours, and in 4 others for only 2 to 4 hours. In 1 instance it failed utterly, and paraldehyde was given with success.

In the latter part of 1886 one of us began some trials of the hypnotic power of urethan, and continued them at intervals up to the present time. These cases have now reached 19, and the number of single administrations, certainly over 60. Briefly reported, the cases are as follows:

CASE I.—M., male. Phthisis. Wakeful at night. On October 11th given 15 grains urethan at 9 P. M. Slept from 10.45 to 12. Soon slept again until 4.

CASE II.—H. McN., aged torty, male. Severe bronchitis. Sleeps badly on account of restlessness and cough. Given 15 grains urethan at 9 P. M., on October 8th. Slept better than usual. 10th. 15 grains at 9 last night with no effect. Repeated at 10.20. Soon slept uninterruptedly until 2.30; then with frequent wakings. For 5 nights more a dose of 15 grains was given at about 9, but with no marked result. The patient was unable to say that he slept better than when none was taken.

CASE III.—McG., male, aged thirty. Incipient tuberculosis. Troubled by insomnia, for which morphia has been given. 15 grains urethan administered on night of October 9th, and on succeeding night at 9 P. M. Slept well both times until morning. The patient, however, had slept well on the night of the 8th without any medicine.

CASE IV.—John L., aged thirty-two. Pyopneumothorax. Often sleeps badly. 15 grains urethan at about 9 P. M. every night for 5 nights, beginning October 10th. Slept well through the nights. Urethan then stopped, and patient seemed to sleep just as well.

CASE V.—G., male. Nephritis. Has difficulty in going to sleep; often lies awake until morning. October 9th. 15 grains urethan at 9, no effect. Second dose at 10.30 and slept soon after until 3. 10th. Slept well without medicine, but did not fall asleep so soon.

CASE VI.—T., male. Nephritis; great dyspnœa; orthopnœa. Sleeps but little, and morphia and chloral compound procures but a few hours rest. October 11th. Given 15 grains urethan at 9 last night, and again at 10.50. Slept shortly after until 12.

CASE VII.—Mr. S., aged seventy-two. Emphysema; great dyspnœa. October 14th. 2 doses of urethan, each 15 grains, 2 to 3 hours apart. Thinks it kept him awake. On several other occasions took the drug, sometimes using as much as 60 grains during the night. It sometimes caused nausea, seemed to increase the dyspnœa, and never exercised any hypnotic action.

CASE VIII.—Mrs. C., aged sixty-five. Hemiplegia. Usually very restless at night, and sleeps but little. October 14th. Gave 15 grains urethan at 10. In 20 minutes she was sleeping quietly until 3 A. M. On the next night slept in less than an hour after a similar dose.

CASE IX.—Lizzie P., aged forty-six. Disseminated sclerosis. Always sleeps very poorly. 15 grains urethan at 10 on night of October 13th, produced no effect at all, except some nausea.

CASE X.—Mrs. D., aged sixty-six. Intra-capsular fracture of femur. Tendency to insomnia. October 14th, 15 grains urethan at 10 P. M., had no hypnotic action.

CASE XI.—Mrs. R., aged sixty-nine. Hemiplegia. Usually sleeps very little. October 16th. Took 15 grains urethan at 10 last night. Slept soon and soundly. Woke at 3, but soon slept again. Two days later dose repeated at same hour with equally good results.

CASE XII.—Jacob W., aged eighty-one. Old hernia. Restless at night and sleeps badly. 8 to 10 grains bromide of potash usually helped somewhat. 15 grains urethan twice on the night of October 16th were entirely without hypnotic effect.

CASE XIII.—Dr. B., aged fifty. Herpes zoster. November 12th. Urethan 15 grains b. d. November 13th, 15 grains t. d. Scarcely any effect, while 1/8th grain morphia gave fair hypnotic result.

CASE XIV.—Sadie T., aged twenty-three. Friedreich's ataxia. Usually sleeps well. For several nights has been tossing, restless, "raving." Gave 15 grains urethan on night of November 26th. Little effect. Patient said she would drop asleep and at once wake again.

CASE XV.—Mrs. O., aged seventy. Ulcerative keratitis. Sleep has been restless for some time. 15 grains urethan on night of November 1st had very little effect. Bromide was of little good in this case unless given with morphia.

CASE XVI.—K., aged forty-five. Fracture of ribs. Urethan in doses of 10 or even 20 grains gave no relief to great sleeplessness. Morphia acted like a charm.

CASE XVII.—Miss N., aged forty. Rheumatoid

arthritis. Very restless at night without much actual pain. 15 grains urethan repeated in a few hours and tried on two successive nights had no appreciable effect.

Case XVIII.—Mary S., aged twenty-five. Contraction of lung after pleurisy. Phthisis? Has dyspnœa; troublesome cough; has been sleeping very badly. Took 15 grains urethan at 10 on night of November 10th. Asleep in an hour. Slept an hour. Repeated the dose at 12. Slept soon after, but restlessly. Thinks she slept but little better than usual.

Case XIX.—Walter S., aged thirty-five. Typhoid fever, third week. Very wakeful for some nights. March 7th. 20 grains urethan at 1 A. M. No effect. 30 grains at 4 A. M. Slept after about ½ hour for 2 to 3 hours. 10th. 30 grains urethan at 11 P. M. Slept after about ½ hour all night; but had also shown disposition to sleep during the day. 14th. 30 grains urethan given in the morning were at once vomited.

To sum up, we see that out of 19 cases there have been but 2 (VIII. and XI.) where the hypnotic action was really satisfactory. In a few others the effect was slight, or it was doubtful whether the sleep could be attributed to the action of the medicine, and would not probably have been obtained without it. In 3 cases (VII., IX., XIX.) there were unpleasant secondary effects, though in the last case the stomach was irritable to other drugs usually well borne. It may be objected that the amount generally employed (15 grains) was two small. This may possibly be true, though it is that usually recommended by the earlier writers, and which we therefore adopted. Moreover, the dose was frequently repeated in 2 hours or less, and in one case (VII.) as much as 60 grains were given during the night without hypnotic effect. It is also true that a few cases constituted too severe a test for a simple hypnotic, as pain or persistent cough was present. We must, nevertheless, conclude that, as far as our experience goes, urethan is an uncertain and unreliable hypnotic, though in large doses it will at times prove useful, and has advantages which at least recommend it for trial in some cases.

AMYL HYDRATE.

Amyl hydrate or dimethylethylcarbinol, which promises to become a valuable therapeutic agent, was first studied by von Mering (*Therap. Monatsh.*, July, 1887). It is one of the tertiary alcohols, its formula being $(CH_3)_2.C(C_2H_5)OH$. It is a colorless fluid soluble in 8 parts of water, and with a smell somewhat like camphor and peppermint. The taste is pungent and unpleasant, though less disagreeable than that of paraldehyde; and the medicine leaves no odor upon the breath. V. Mering administered it to 60 cases of insomnia from various causes, and in only 4 did it prove inefficacious. 2 cases of whooping-cough were relieved by it. The total number of doses given was 350, of 45 to 75 minims by the mouth or by rectum. Its principal action is on the cerebrum, and it is unreliable in producing sleep if pain be present. The author claims that it does not cause headache, nausea, or disturbance of digestion. It may be used with impunity in heart disease, since even with doses sufficient to produce profound narcosis in animals scarcely any effect on the circulation could be perceived. On this account it is greatly to be preferred to chloral; while its smaller dose and less disagreeable taste render it superior to paraldehyde. As regards its relative strength, v. Mering calculates that 1 part of chloral equals 2 of amyl-hydrate and 3 of paraldehyde.

Scharschmidt (*Therap. Monatsh.*, September, 1887) gives the drug by enema or by the mouth, freshly mixed with red wine or sugar, or in brandy. He gave it to 80 cases of mental disorders, with 1051 single administrations. The results were good in 869, medium in 138, and there was no effect in 44. The average dose was 30 to 60 minims. By comparative tests he found it superior to chloral, paraldehyde, and urethan, and considers it 3 times as strong as paraldehyde.

Lehmann (*Therap. Monatsh.*, December, 1887) reports 149 observations in 26 insane patients. The dose employed was 15 to 75 minims, and in 1 case 90 minims. The hypnotic results were good in 83.2 per cent. of cases. In mania large doses were required. Paralysis of the insane was benefited, but the insomnia of melancholia was aided to a less degree. It is a pure hypnotic, sleep lasting 6 to 8 hours. Slight nausea and digestive disturbance were noted in some cases. The author considers it more efficient and less disagreeable than paraldehyde.

Avellis (*Deutsch. med. Wochenschr.*, 1888, No. 1) has treated over 40 cases with more than 300 administrations of amyl-hydrate. It may be given either by enema or by the mouth. Sleep comes on after 15 to 45 minutes, though sometimes there is no effect at all. He considers it, on the whole, a reliable hypnotic, if a sufficient amount be employed, and there are usually no unpleasant secondary effects. Nevertheless, in 1 instance a dose of 37 grains produced a condition like drunkenness in a hysterical woman; and another patient, after the same quantity at 1 A. M., felt as though under the influence of a hypnotic the next day. The medicine rather diminishes the cough of phthisis, could be used with safety in heart disease, and was especially valuable in icteric itching. The author greatly prefers it to chloral in all affections of the circulatory apparatus. Where the stomach is irritable it should be given per anum.

Mason (*Boston Medical and Surgical Journal*, February 16, 1888) has used it successfully in a number of cases of marked insomnia. There were no ill effects at all observed, though mild intoxica-

tion occurred in a few instances. Its action appeared better than that of either paraldehyde or of urethan; and in 1 restless typhoid patient it produced a good night's sleep, when opium, chloral, urethan, and the bromides had no effect.

We have been unable to find any other literature on the use of amyl-hydrate. For the past 3 months we have been testing the virtues of the drug, and are convinced that it is a valuable hypnotic agent. We have given it in 18 cases with 85 administrations. The notes of these are in brief as follows:

CASE I.—Carrie D., aged forty-five. Opium habit. Been resting very badly; going as long as 2 days without any sleep. Has been taking bromide of potash, chloral, hyoscine, Cannabis Indica, and paraldehyde, singly or combined. She often required the following formula to produce sleep: Chloral, grs. xv; potass. bromid., grs. xl; paraldehyde, grs. lx; hyoscine, gr. $\frac{1}{70}$. January 10th. 40 minims of amyl hydrate were given at 9 P. M.; followed in the course of 15 minutes by a slight, happy, singing delirium. After 2 or 3 hours this gave place to quiet sleep lasting the rest of the night. The patient remarked in the morning that she had "not spent such a happy night for many a day." 11th. 25 minims given at 9 P. M. Asleep in 10 minutes, and waked but once during the night. 12th. 25 minims at 9. Same result. 13th. 40 minims at 2 A. M. Slept the balance of the night. The drug was given every night up to February 1st, with equally good results, though the dose had to be increased to 1 drachm. The patient then slept without drugs. On March 24th it was given in capsules and nicely borne.

CASE II.—William N., aged thirty-five. Alcoholic delirium; sixth attack. Very delirious, and could be kept only partially quiet by large doses of hyoscine, bromide, and chloral; but these were stopped as their depressing action was feared. January 10th. Very delirious; screaming and jumping out of bed. 20 minims of hydrate of amyl were given, and the delirium ceased almost immediately, and quiet sleep for 2 hours followed in 10 minutes. Later he was quiet and rational, and slept intermittently. After this date he seemed for a time so much better that amyl was not needed, but later began to show increased signs of mental derangement, and became very maniacal. Large doses of morphia and the bromides were administered with but very little effect. 1 drachm amyl hydrate given, but only quieted him partially.

CASE III.—Robert D., aged fifty-three. Dementia. Constantly talking, mumbling night and day; very often noisy. Has taken morphia, the bromides, chloral, hyoscine, paraldehyde, singly and combined in different ways. Not much effect except from very large doses of bromides, but the depressant action feared. January 15th. 30 minims of amyl hydrate at 9 P. M. Asleep in ½ hour, and slept all night. 16th. Been very talkative during the day. 30 minims at 9. Repeated the dose at 11. Sleep in 15 minutes, which lasted 4 hours; after this did not sleep, but remained very quiet. 17th. 30 minims at 9. Asleep at 11, and slept all night. 18th. 30 minims at 9.50. Did not sleep. 19th. 30 minims at 9.50. Slept very soon until 12. Then awoke and bromides given; after which slept until 4.

CASE IV.—Annie M., aged twenty-three. Rheumatoid arthritis. Occasional exacerbations with rise of temperature, insomnia, and considerable pain. The bromides in moderate doses fail to act. January 28th. 30 minims amyl hydrate at 9 P. M., followed by quiet sleep in 15 minutes, lasting the entire night in spite of the pain. 30th. 40 minims at 9. Sleep in 15 minutes, lasting all night. The drug was used on 4 other occasions with equally good results.

CASE V.—Harry J., aged twenty-five. Advanced phthisis; hectic, great restlessness and excitement at night. January 24th. 30 minims amyl given at 9 P. M., producing, in the words of the patient, "the first quiet sleep I have had for a week." The drug used twice afterward with same effect.

CASE VI.—Henry B., aged seventeen. Typhoid fever, with phlebitis. Great wakefulness. January 25th. 40 minims amyl hydrate at 10. Sound and continued sleep in 15 minutes. On the next 2 nights a similar dose produced each time sound sleep in 15 to 20 minutes.

CASE VII.—Mendenhall B., aged fifty-five. Carcinoma ventriculi. No pain worthy of note, but great insomnia lasting all night. January 28th. 40 minims hydrate of amyl at 9 failed to act. Dose repeated at 10, followed after some time by not very sound sleep. 30th. 40 minims were given at 9. Asleep in ½ hour, and slept until 3. 31st. Same result. February 10th. 40 minims at 9, and again at 10. Slept from 11 until 3. 14th. 40 minims at 9; repeated at 10, but slept only 3 hours. 12th. Slept all night after 40 minims at 9.

CASE VIII.—William D., aged twenty-six. Typhlitis? Was not able to sleep for 3 days before admission to hospital. Pain often severe. January 20th. 25 minims of amyl hydrate at 9 P. M., and again at 9.30, but did not sleep at all. 21st. 40 minims at 9, and again at 11. Slept until 2. After that only short naps. 22d. Pain severe. Had 20 grains bromides and 1 drachm of paraldehyde at 10; and ⅙ grain morphia at 1.30 A. M., but did not sleep at all. 23d. 40 minims amyl at 9. Slept better than on any preceding night, but the pain was less. The same dose was given on 6 other occasions with favorable results.

CASE IX.—Mrs. G., aged twenty-six. Phthisis. Sleep is very poor and cough annoying. February 1st. 40 minims of amyl given at 9 P. M., with very little effect. On 3 other occasions the results were also negative; the constant cough seeming to prevent the action of the drug.

CASE X.—Owen McA., aged forty? Renal and cardiac disease. Dyspnœa; patient often has only a couple of hours sleep during the entire night. January 23d. 30 minims hydrate of amyl at 12.30. Slept all night except during two attacks of dyspnœa. On 8 consecutive nights beginning with February 11th, drachm doses of amyl procured sound sleep lasting all night except during occasional attacks of dyspnœa.

CASE XI.—Miss R., aged twenty-three. Psoriasis.

Insomnia from anxiety. 40 minims of hydrate of amyl were given for 3 nights beginning with February 9th. She slept all night, but later a placebo produced the same effect.

CASE XII.—William J., aged twenty-four. Phthisis. 40 minims of amyl were given once, but he did not sleep on account of the cough.

CASE XIII.—W. C., aged fifty-two. Cancer of the intestine? Has not been sleeping without large doses of morphia. March 2d. 40 minims amyl hydrate at 9 P. M. The patient says he spent one of the happiest nights of his life, being quiet and free from pain, although he did not sleep. 3d. Same dose followed by good sound sleep in 15 minutes.

CASE XIV.—W. D., aged forty-five. Aortic regurgitation. Sleeping very little for three nights, and dreams whenever he is asleep. March 10th. The patient was sound asleep in 15 minutes after 40 minims amyl were taken.

CASE XV.—Charles C., aged twenty. Acute mania, with almost no sleep. Patient is exceedingly noisy. January 20. 25 minims hydrate of amyl given at 9. Slept until 4; and then remained quiet, although he did not sleep. 21st. 25 minims at 9, and dose repeated at 10. Slept all night.

CASE XVI.—Peter T., aged thirty-five. Heart disease. Suffers greatly from cardiac asthma. Wakeful. February 17th. 40 minims amyl at 9. Slept about 2 hours; then awakened with an attack of dyspnœa lasting 10 minutes; then slept until 6 A. M. 24th. 40 minims at 9 failed to act on account of intense dyspnœa. 28th. 40 minims at 9. Slept 2 hours; but after that dyspnœa became almost constant

CASE XVII.—Walter S., aged thirty-five. Typhoid fever; third week. Exceedingly wakeful and longing to sleep. March 8th. 30 minims amyl hydrate last night at 9.15, but no effect. Did not sleep until near morning. 9th. 40 minims last night at 9.15. Slept after about ½ hour until 1; and again from 3 until 9 A. M., and feels greatly refreshed. 12th. 40 minims at 10, but the stomach had been very irritable, and vomited the medicine at once.

CASE XVIII.—Miss H., aged forty. Phthisis. Persistent coughing, not quieted by large doses of morphia, keeps her awake at night. March 19th. 40 minims amyl early in the night procured somewhat better sleep than usual; the patient coughing while asleep. Effect lasted but a few hours.

An analysis of these cases is hardly needed, as the exceedingly favorable results are evident. In only 2 cases were there any unpleasant effects; namely, in Case I., where a temporary delirium occurred with the first dose in a rather hysterical woman; and in Case XIX., where vomiting was produced, though the stomach of this patient was unusually irritable. The taste is often complained of, but we have succeeded in disguising it to some extent with liquorice, as v. Mering suggests.

We have also found it very satisfactory when given in gelatine capsules, each containing 20 minims. The ordinary capsule in two parts will answer nicely for this purpose, and will retain the drug without leaking. A full glass of water should be immediately swallowed after the capsule, in order to avoid offending a possibly irritable stomach. In most cases there is no danger of this occurring.

Our results show that amyl hydrate does not always succeed in producing sleep. Particularly is this the case when pain is present, or when there is very troublesome cough. We believe it nevertheless to be a valuable hypnotic, more powerful than urethan or paraldehyde, and to be preferred to them; and always to be chosen in place of chloral to produce sleep, though it is not so strong as the latter drug.

MEDICAL PROGRESS.

The Treatment of Rectal Pain by Conium.—WHITLA, in the *Practitioner* for April, 1888, describes an ointment of conium and his mode of use as follows:

Two ounces of the pharmacopœial juice are placed in a small evaporating dish, and permitted to evaporate slowly at a heat under 150° F. till the bulk is reduced to about one and a half or two drachms. This can be done by placing the dish on the top of an ordinary domestic hot-water cistern for twenty-four or forty-eight hours. The syrupy liquid is then carefully triturated with as much lanolin as will make the weight up to one ounce; the result is a perfectly smooth adhesive ointment of a light brown or dark fawn color and stable.

Happening to have several rectal cases in which severe pain and torturing pruritus were prominent features the ointment was carefully applied. One was a case of multiple small fissures accompanied with intolerable itching; another was associated with severe tenesmus and excoriations from the pus flowing from an iliac abscess bursting through the *levator ani* muscle and penetrating the rectal walls; another was complicated by a bleeding villous growth. These with two cases of hemorrhoids, one of which had an ulcerated surface, were so markedly and speedily relieved by the conium ointment after nearly every known remedy had failed, that I was surprised at the result.

In a considerable number of cases during the last year the same highly gratifying success was achieved by this remedy, whilst I cannot recollect a single instance where the ointment caused inconvenience. It should be freely smeared *inside* the sphincter, and owing to its adhesive quality can be carried a considerable distance up the rectum by the introduction of the forefinger of the patient.

I have never noticed after its use the serious drawback which follows the prolonged application of every other greasy application to this region, namely a tender, sodden, or raw state of the skin about the margin of the anus.

The ointment appears to me to paralyze the endings of the *motor* nerves distributed to the fine muscular layer under the surface of the mucous membrane; the reflex twitchings of this layer keep up the perpetual pain and uneasiness in diseases of the rectum and anus associated with abrasions, ulcerations, or fissures.

At the same time it undoubtedly paralyzes the sensory filaments. I have obtained relief from its use in vagin-

ismus and some painful conditions of the male urethra, and find it a good lubricant for the sound or catheter.

To the ointment prepared according to the above formula there may be added ten or twelve grains of the persulphate of iron as recommended by Mr. Cripps in fissure. From carefully watching the results of this combination of conium with iron I am certain that it should have a trial before resorting to the knife or cautery. I have seen a fissure heal completely under its use. In acute inflammation of hemorrhoidal growths associated with swelling and painful throbbing some relief may be obtained by the free application of the conium ointment without iron, but it is in those exquisitely painful fissures or conditions where there is a loss of substance in the mucous surface that this remedy will be found to give more relief than any other drug.

Ichthyol Collodion in the Treatment of Erysipelas. — BILIEFF, in the *Revue de Thérapeutique* of April 1, 1888, gives the following formula:

Collodion	15 parts.
Ether,	
Ichthyol	āā 1 part.

For local application.

Chloroform Narcosis and its Treatment.—The *Medical Press* of April 4, 1888, writes as follows on this topic:

It is doubtless a highly inexpedient thing for a medical practitioner to undertake unaided in a private case the administration of the anæsthetic and the operation, whatever it may be, as well. Everything may prove in the end to be satisfactory, but, on the other hand, it is impossible to foresee accidents, and the slightest untoward occurrence, which, perhaps, in itself unavoidable, may precipitate a catastrophe, and lead to lasting regrets, and be productive of other consequences, in themselves scarcely less pleasant. When, however, the surgeon finds himself in the presence of a difficulty under these circumstances, and in peril of losing his patient from the effects of the chloroform, it will mainly depend upon his coolness and power of resource, whether his efforts to bring back the patient to life will be successful or not.

In illustration of this fact we may mention a case which has recently been brought under our notice: A medical practitioner was asked to circumcise a child, eighteen months old. Being an experienced administrator of anæsthetics, he undertook to act the dual part of chloroformist and operator. He put the infant under chloroform, and then handed the lint which was in use for the purpose to the nurse, to hold under his superintendence. Everything seemed to be so far satisfactory, but as soon as had removed the necessary portion of prepuce, he was astounded to find that the wound did not bleed. Quickly turning his attention to the child, he discovered it to be pulseless, and not breathing. He put in practice at once all the ordinary methods of bringing the patient to life, but without avail; and, at this time, the father of the child, who was in the room, seeing the condition of affairs, added to the difficulty of the situation by rushing madly up and down, lamenting his loss. The surgeon, having directed the parent to go downstairs, set to work anew, by getting the nurse to draw out the patient's tongue as far as possible, then with his fingers grasping the nostrils, he blew with all his force into the patient's mouth and fully inflated the lungs. This having been done, he compressed the chest, and then inflated again. This process was carried on for some moments, and suddenly the child gave an involuntary gasp. In the course of time, the process being continued, the child began to breathe of itself, and as soon as respiration was properly established, the surgeon completed the operation in the usual way. Such a near escape from what would have been a terrible misfortune, deserves being recorded, and especially on account of the adoption of the means by which the successful result was mainly brought about.

The Action of Antipyrin upon the Heat Centres of the Cerebrum.—GIRARD has experimented upon rabbits by puncturing the corpus striatum, and giving antipyrin for the resulting rise in temperature. His results showed that antipyrin acts directly upon the nervous centres, producing, after such lesions, a considerable fall of temperature.—*Gazette Hebdomadaire*, April 20, 1888.

Borofuchsin, a New Stain for Tubercle Bacilli.—PROFESSOR LUBIMOFF describes in the *Meditsinskoe Obozrênie* a new stain for tubercle bacilli, which he calls borofuchsin. It consists of: fuchsin, 8 grains; boric acid, 8 grains; absolute alcohol, 3¾ drachms; distilled water, 5 drachms. Prepared thus, it has a slightly acid reaction; it is quite clear and not liable to spoil by being kept, consequently it is always ready for use. The sputum is dried on a cover glass, and stained by being heated in contact with the borofuchsin for one or two minutes. The stain is then washed out by treatment with dilute sulphuric acid. The specimen is then washed with alcohol, and subsequently immersed for half a minute in a saturated alcoholic solution of methylene blue. After being washed in distilled water and dried, the examination of the specimen is made in oil of cedar or in a solution of Canada balsam. In exactly the same way sections of tuberculous organs may be stained after hardening in spirit, only in such cases the steps of the operation must be somewhat more prolonged. The main difference between this and other staining processes for Koch's bacilli is that, when borofuchsin is used, the process of washing it out with sulphuric acid is an almost instantaneous one. All other bacilli are, as when other stains are used, rendered colorless and invisible, the tubercle bacilli being alone seen.—*Lancet*, April 21, 1888.

The Treatment of Violent Colic.—CAPITAN prescribes as follows:

Naphthalin	¾ gr.
Iodoform	⅓ gr.
Tannin	1½ grs.
Antipyrin	1½ grs.

In pill form: these amounts may be doubled, and the pills taken as needed.—*Revue de Thérapeutique*, April 1, 1888.

Cocaine Poisoning after Injection for Hydrocele.—In the *Vratch*, No. 4, 1888, p. 64, DR. NIKOLAI M. UNKOVSKY, of Moscow, relates the case of a strong man, aged fifty-six, suffering from hydrocele, in whom the hypodermatic injection of two Pravaz syringefuls of a four per cent. solution of hydrochlorate of cocaine was followed in a

few minutes by intense excitement, agonizing pain along the spine (especially in the lumbar region), giddiness, blanching of the skin and mucous membranes, dryness of the mouth and throat, weakness of the pulse and voice, paroxysmal dyspnœa, failure of sight, prostration, and complete inability to move the limbs. The patient's state rapidly growing worse, Dr. Unkovsky resorted to free inhalations of amyl nitrite (recommended as the best antidote to cocaine by Professor W. F. Grube, of Kharkov, and Dr. Schilling—see *Journal*, 1887, vol. i. pp. 695 and 1401), and subcutaneous injections of ether. The symptoms gradually disappeared in about an hour and a half. The total quantity of amyl nitrite inhaled (from a piece of cotton-wool) in the course of an hour amounted to nearly 15 minims, while three syringefuls of ether were injected. The operation for hydrocele (injections of a four per cent. carbolic solution, etc.) was absolutely painless. Dr. Unkovsky also saw a case in which mental disturbance occurred an hour after the injection of half a syringeful of a twenty per cent. solution of the alkaloid into the gum. In another patient, an injection of a syringeful of a four per cent. cocaine solution under the skin of the leg gave rise in about six hours to giddiness, suffocation, slowness of the pulse, pallor, and faintness. —*British Medical Journal*, April 7, 1888.

The Treatment of Albuminuric Dyspnœa.—The *Medical Press* states that the administration of two or three drops of nitrite of amyl in a teaspoonful of brandy is said to afford instantaneous and lasting relief in the dyspnœa of albuminuric patients.

The Treatment of Dysmenorrhœa.—GOUBERT prescribes for young girls:

Iodoform	gr. ½.
Ext. belladonn.	gr. ⅙.
Asafœtidæ	gr. 1⅕.

In pill form.

Beginning six or eight days before the time of menstruation, six pills should be taken daily.

For adult women he prescribes:

Potass. iodid.	℥ 1.
Tinct. croci	℥ 2.
Tinct. belladonn.	℥ 2.
Syrup. aurant. cort. . . .	ad ℥ 6.

Dose a tablespoonful morning and evening, in any convenient liquid, for a week preceding menstruation.—*Gazette de Gynécologie*, March 1, 1888.

The Value of Potassium Permanganate as an Emmenagogue.—DR. L'VOFF, writing in a Moscow medical journal on the emmenagogue action of permanganate of potash as described by Drs. Ringer and Murrell in 1883, states that during the four years which have elapsed since the publication of the English physicians' paper he has treated some 200 cases with permanganate. His results are thus summarized in five classes of cases: 1. Thirty-two cases of otherwise healthy girls who suffered from dysmenorrhœa with diminished flux, no assignable cause being made out. Here pills containing permanganate and extract of pulsatilla were ordered for a week or ten days before the period, with excellent results. 2. Seventeen cases where the involution of the uterus after childbirth had been excessive, or where atrophy of the uterus and the ovaries had occurred during lengthened puerperal affections, especially during parametritis. These patients took the pills regularly for from three to six months. Improvement in the quantity of the flux generally commenced in from four to six weeks in young women, and in from three to four months in older subjects. 3. Sixty-two cases where pelvic peritonitis occurred after labor. Here a good result was obtained in the majority of the cases, but in a few no effect was observed. 4. Sixty-five cases of young married barren women, in whom gonorrhœal gonococci were mostly to be found, and many of whom suffered from affections of the tubes or ovaries. In this group of cases the results obtained from permanganate were not very striking—indeed, in many of them it was useless. 5. Eleven cases of early appearance of the change of life (from thirty-five to forty years of age), an atrophic condition of the uterus being always recognizable. Here the permanganate proved useless.—*Lancet*, March 31, 1888.

Cocaine in Tracheotomy.—LENNOX BROWNE writes to the *British Medical Journal* of April 7, 1888, as follows on this point:

Since the introduction of cocaine, neither I nor my colleagues at the Central London Throat and Ear Hospital have employed chloroform when performing tracheotomy, but have in substitution injected five minims of a ten per cent. solution of cocaine on each side of the immediate region at which the trachea is to be opened. Ten to twelve minutes have been allowed to elapse before commencing an operation, and in the majority of instances pain has not been felt even from the first incision through the skin. Local anæsthesia has been maintained sufficiently long to allow of a careful and leisurely performance of the operation, without, however, encouraging that undue tediousness against which Mr. Christopher Heath has recently spoken so opportunely, as a besetting fault of modern surgeons who operate under chloroform.

My experience with cocaine in tracheotomy would be represented by about forty cases; we have had twenty in the hospital and in my private practice during the last year. I have witnessed its good effect especially in the last fortnight, during which time I have had occasion to perform the operation four times, all the cases being on account of cancer, and occurring in patients aged seventy-five, fifty-eight, seventy-seven, and fifty-four respectively.

Beyond the advantages of cocaine as a local anæsthetic, this remedy so applied has the effect of depriving the part of blood, and thereby diminishing hemorrhage during the operation, whereas with chloroform and ether the contrary effect is often produced. It also quiets the breathing and steadies the larynx in cases in which respiration is seriously hurried. In only one case have I seen any toxic action, and that was at once remedied, when the trachea was opened and a full flow of air admitted into the lungs.

The Injection of Sterilized Air in the Treatment of Phthisis.—At a recent meeting of the Academy of Medicine, of Paris, POTAIN reported a case of phthisis complicated by pneumothorax which had been greatly improved by the injection of sterilized air into the pleural cavity. The pneumothorax was cured, and the tuberculous process seemed checked.—*L'Union Médicale*, April 26, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,

PHILADELPHIA.

SATURDAY, MAY 19, 1888.

THE POISONOUS EFFECTS OF PETROLEUM.

THE general and local effects of the action of petroleum have been carefully studied by LEWIN, who took the opportunity while in this country last year to visit the oil regions of Pennsylvania and the refineries at Point Breeze in this city. The results of these observations appear in the current number of Virchow's *Archiv*.

In response to the question, Is petroleum a poison? Lewin has collected seventeen cases in which it was swallowed by mistake, in amounts ranging from two and a half ounces to two pounds. In the majority of cases symptoms followed, either gastro-intestinal or cerebral. Among the former were a sense of heat in the mouth and throat, distress in the stomach, and colic; there was never vomiting, but often diarrhœa. Jaundice has been noted, and occasionally painful urination. In the cerebral form of poisoning, the patient complains of headache, dizziness, somnolence, and even loss of consciousness, symptoms closely resembling alcoholic intoxication. In three instances there were convulsions. In several cases the urine is stated to have had a strong odor of petroleum, and even to have had drops of the oil floating on the surface. Experiments made upon animals demonstrated the poisonous action of the heavy oils, but in no instance did the urine either smell of petroleum, or contain it in the free state.

The vapor of the oil does not appear to be in the slightest degree poisonous to plant life in the oil regions, nor are there any evident injurious effects upon the inhabitants; but, on the other hand, workers at the pumps, and those who clean the large tanks, are often severely affected. Loss of consciousness, cyanosis, staring eyes with contracted pupils, and lowering of the pulse and temperature have been observed. One fatal case has occurred. In the early stage of this condition the workers may be very excited, and in high spirits, so that at times force must be used to remove them from their dangerous position. These symptoms are probably due to benzine; the asphyxia, doubtless, to the deficiency of oxygen. Instances have occurred in which symptoms of intoxication have followed the spilling of petroleum in a room.

That workers in petroleum are very liable to boils and acne was observed long ago in the Crimean, the Caucasian, and the Roumanian oil regions, and a similar observation on the subject was made by Harrison Allen in this country more than twenty years ago. The most interesting part of Lewin's paper relates to this condition in the workers at Washington, Pa., and at the Point Breeze refinery. The affection is in reality a disseminated acne, in all stages of progressive and regressive change, distributed chiefly on the extensor and flexor surfaces of the arms and thighs. The trunk is less involved, and the genitals are not affected. The cases occur both at the wells and in the refineries; persons of all ages are attacked, the essential condition being direct contact for some time with the crude oil. Some individuals are exempt, and careful attention to cleanliness lessens the susceptibility. At the refinery the workers in the light oils escape, but those are attacked who work in the heavy oils and residue. It is an affection of the sebaceous glands and hair follicles, due to the direct imbibition of the petroleum, and runs a protracted course, yielding slowly to remedial measures so long as the patient remains exposed to the action of the oil.

At a recent meeting of the College of Physicians, Dr. S. Weir Mitchell showed for Dr. J. K. Mitchell a very typical case of the disease in a Point Breeze worker.

SUDDEN DEATH IN PLEURISY AND ASCITES.

ALTHOUGH the experiments of Lichtenstern throw doubt on the truthfulness of the view, many clinicians still hold with Bartel that the most probable cause of this untoward accident is nipping of the inferior vena cava as it enters the heart, a condition which Fräntzel is said to have confirmed by autopsy

in three cases. In Virchow's *Archiv*, Bd. cxi., Heft 3, HAGEN-TORN reports two cases in support of the theory which Lichtenstern has so ably advanced, that the danger arises from an increase of the negative pressure within the thorax, and the consequent engorgement of the right heart and normal lung. In the first case, a woman with cirrhosis and ascites, alarming symptoms followed the removal of seventeen quarts of fluid. The bandage became loose, and serious collapse immediately supervened. Pressure on the epigastrium gave relief; a cushion was at once placed beneath the bandage, and the patient revived in a few minutes. In the second case, chronic empyema with great depression of the diaphragm, difficulty of breathing, and failure of the heart came on during the removal of the fluid. These symptoms disappeared when the diaphragm was supported by means of a pad of cotton-wool bandaged on the abdomen. The condition is one of insufficiency of the diaphragm, and the practical measure resorted to in these cases is worth noting. In the great majority of cases of sudden death in pleurisy no cause has been found at the autopsy; in a few instances, thrombi have existed in the right heart and veins, and in a still smaller number other causes of death, such as abscess of the brain, have been found. Heart failure in consequence of altered conditions of pressure within the chest, certainly seems the most reasonable view to take of these cases.

PREVENTIVE INOCULATION.

IN previous numbers of THE NEWS we have called attention to experiments in preventive inoculation by means of sterilized cultures of pathogenic bacteria, especially to experiments in typhoid fever by Beumer and Peiper, and by Chantemesse and Widal. The latter, in the paper cited, had endeavored to depreciate the value of certain experiments of Salmon and Smith, but as it was foreign to the topic then considered, we made no allusions to that attack. In a recent sitting of the Académie des Sciences, Pasteur, in characteristic language, claimed for his own laboratory priority in the discovery of such inoculations. This has called forth a rejoinder from Hueppe, who gives in the last *Fortschritte der Medicin*, a sketch of the development of our knowledge of the action of bacteria through soluble chemical substances—ptomaines or toxines—and of the efforts made to secure immunity by inoculations of these substances.

Hueppe shows clearly that the first successful experiments of this kind were made by D. E. Salmon and Theobald Smith, of Washington, in the spring of 1886, the virus used being that of hog-cholera (*Proc. of Biological Society of Washington*, viii., Feb. 22, 1886). That the American investigators were fully aware of the immense practical bearing of their results is shown by the quotations by Hueppe, and the latter was so impressed by the facts adduced that he used them in illustration of his remarks before the "Naturforscher-Versammlung" in 1887, on the "genesis of pathogenic action."

Though the full value of these experiments cannot yet be realized, we consider them as marking one of the greatest advances in bacteriology, and destined to do the same for medicine, and it cannot be other than a matter of pride that American investigators have taken such a prominent part in the work, and that the credit, which is their due, is publicly conceded to them by one of the most eminent living authorities in bacteriology.

SMALLPOX has been impartially strewed on both sides of the Atlantic by that pestiferous steamer, the "Circassia." One of the latest cases to come to light is that of a Scottish immigrant, who arrived at New York early in March, and thence found his way to Goldsboro, North Carolina. He states that there was a case of the disease on shipboard that died. They were detained at quarantine only about nine hours; all on board were vaccinated, and were then "let loose on the country," as Dr. M. E. Robinson expresses himself, in his report of the case, dated April 21, in the last *Bulletin of the North Carolina State Board of Health*. At that date, the patient had nearly recovered. Prompt and thorough measures for the prevention of the spread of the pest were employed at Goldsboro, and no second case has arisen. Five of the crew of the "Circassia" were taken down with the disease on the return voyage.

AT the recent Congress of German Surgeons von Bergmann announced a plan for the erection, in a central location in Berlin, of a memorial building to von Langenbeck. The building is to contain an auditorium seating 700 or 800 persons, and accommodations for a large library. The building will cost about $100,000, half of which is pledged by individuals or by the Society; the rest will be raised by a loan on the building. The German Society for Surgery will be the virtual possessor of the building,

but the Berlin Medical Society will also make its headquarters there. A committee composed of von Bergmann, Bardeleben, Hahn, and Langenbuch, was appointed to further the plan.

THERE have been a number of deaths by electricity within the past month, chiefly in consequence of defective management of the wires used in electrical lighting. The powerful current carried along the wires that are strung overhead in nearly all our cities requires a completeness of insulation that taxes severely the ingenuity of experts. Much of the danger will be obviated by compelling the companies that supply the lights to run their street wires in underground conduits, as is done in Europe. Fatal accidents are comparatively infrequent in foreign cities, but it is said of the underground system that "it has hindered the development of electrical interests" in London and elsewhere.

In the case of a death recently occurring in New York City, the verdict of the Coroner's jury found that one of the illuminating companies was chargeable with the death, and that the overhead system is a standing menace to health and life, and that it is the duty of the authorities to take immediate steps to have the wires conducted underground. The interests of the public health and safety far outweigh the interests of the corporations; and as the Coroner said on the occasion of this inquest, "it matters not how difficult or expensive it may be to meet the dangers incident to electrical illumination, it must be done; public health and life must be protected."

A NEW ophthalmic hospital is projected in New York City, to be known as the New Amsterdam Eye and Ear Dispensary. It will have for its chief medical officer Dr. Thomas R. Pooley, who for fifteen years has been the colleague of Dr. Herman Knapp, at the New York Institute. If this project shall prove a success, it will make the fourth of the kind in that city, and the ground pertaining to this specialty will have been very thoroughly covered. In the three institutions now in successful operation there are treated annually over thirty thousand cases, and at a cost of not less than fifty thousand dollars. There will be associated with Dr. Pooley as medical staff Drs. L. Bolton Bangs, J. W. Barstow, and C. S. Ward.

THE Thirty-ninth Annual Session of the Medical Society of the State of Pennsylvania will be held in Philadelphia, on June 5th, 6th, 7th, and 8th, at Association Hall, Fifteenth and Chestnut Streets, under the Presidency of Dr. R. J. Levis, of Philadelphia.

A CREMATION SOCIETY has been recently organized in Chicago, and a stock company will be formed, and a crematory erected as soon as possible.

THE College of Physicians and Surgeons of New York graduated a class of 120 at its recent Commencement.

THE College of State Medicine was incorporated in London in 1887, and is presided over by Sir Joseph Fayrer. The course of lectures during the summer session will be given in rooms of the Chemical Society, Burlington House. Among the lecturers will be Professors Klein, Fleming, Fayrer, Brudenell Carter, Seely, and Sir Robert Rawlinson. The regular professor of hygiene and public health is Dr. Wm. Robert Smith. The Public Health Laboratory connected with the College will be open throughout the session, which opens early in May.

DR. C. S. MUSCROFT, of Cincinnati, died at his home on May 8, 1888. He was a surgeon of large experience and wide culture, and had been for many years a member of the staffs of St. Mary's and the Cincinnati Hospitals.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Thirty-ninth Annual Meeting, held at Cincinnati, May 8, 9, 10, and 11, 1888.

(Specially reported for THE MEDICAL NEWS.)

GENERAL SESSION.

FRIDAY, MAY 11TH.—FOURTH DAY.

The Association was called to order by the President at 10.30 A.M.

DR. H. P. WALCOTT, of Boston, delivered

THE ADDRESS IN STATE MEDICINE.

(See THE MEDICAL NEWS of May 12th, page 510.)

DR. N. S. DAVIS then presented the

REPORT OF THE COMMITTEE ON METEOROLOGICAL CONDITIONS.

It embodied: 1. A summary of facts gathered concerning all appreciable meteorological conditions coincidentally observed and recorded in different parts of the country. 2. The efforts made to determine how far these facts show any constant relation of one series of facts to

another. 3. A summary concerning the prevalence of a number of the acute general diseases, more particularly typhoid fever. 4. Critical examination instituted to determine what uniform coincidence, if any, can be traced between the more immediate meteorological conditions and the prevalence of disease.

The following questions were propounded: 1. Is it probable that the free albuminate of ammonia when existing in the atmosphere, compared with the amount of ozone and hydrogen protoxide, can constitute the pabulum for the rapid development of either pathogenic germs or ptomaines, and thereby afford an explanation of the apparently simultaneous attacks of some epidemic diseases in several persons in the same city or district, yet without any other traceable connection with each other? 2. Do the well-established facts attending the development or propagation of typhoid fever and cholera justify the inference that the specific causes acquire active propagating pathogenic forces only exterior to the body, and in connection with soil water? 3. May such specific causes continue to propagate and retain their pathogenic force indefinitely exterior to the body, or do they pass one stage of development in the body and another exterior to it?

On motion, the Committee was continued.

DR. I. N. QUIMBY, of Jersey City, presented the report of the special committee on

THE CRIMINALITY OF FŒTICIDE, AND EFFORTS FOR ITS PREVENTION.

Objections to the report were raised by several members, and it was finally tabled. Subsequently, however, on motion of Dr. I. N. Love, of St. Louis, it was taken from the table and referred to the Section on State Medicine.

DR. H. O. MARCY, of Boston, presented a report of the special committee on

THE DUTIES COMMONLY EXERCISED BY CORONERS,

which was adopted as read.

On motion a resolution was adopted urging upon Congress the importance of the immediate passage of Senate Bill No. 2493 to perfect

THE QUARANTINE SERVICE OF THE UNITED STATES,

which bill has passed the Senate and is now pending the action of the House of Representatives, in order to make provision against the introduction of contagious diseases before the approaching summer.

A motion was made and carried to take from the table the amendment proposed to the by-laws of the Association at the last meeting by Dr. Carl Seiler, of Philadelphia, providing for the

DIVISION OF THE SECTION ON OPHTHALMOLOGY, OTOLOGY, AND LARYNGOLOGY,

so as to make one section on ophthalmology, and another on otology and laryngology. The amendment was adopted.

HIGHER MEDICAL EDUCATION.

DR. I. N. QUIMBY presented a resolution recommending the appointment of a committee, to consist of one member from each State, whose duty it shall be to devise the best means to secure adequate legislation to provide for the examination of the charters of colleges, and provide for higher medical education.

The motion was tabled.

400TH ANNIVERSARY OF THE DISCOVERY OF AMERICA.

The following resolution was adopted:

Resolved, That the American Medical Association approves the movement looking to the celebration in Washington, in 1892, of the 400th anniversary of the discovery of America by Columbus, and the establishment there of a museum of arts, industries, and antiquities of the three Americas; and the Association hereby requests Congress to pass the necessary legislation preparatory to this end. Carried.

The Secretary then read the reports of work done by the various Sections, as transmitted by the several secretaries.

The following members were appointed

DELEGATES TO FOREIGN MEDICAL SOCIETIES:

R. A. Plummer, M.D., of San Francisco; H. A. Kelly, M.D., of Philadelphia; N. S. Davis, M.D., of Chicago; W. H. Myers, M.D., of Fort Wayne, Indiana; A. E. Hoadly, M.D., of Chicago; I. E. Waxham, M.D., of Chicago; Alex. McAllister, M.D., of Camden, N. J.; J. J. Chisholm, M.D., of Baltimore; D. A. K. Steele, M.D., of Chicago; J. V. Shoemaker, M.D., of Philadelphia; S. J. Jones, M.D., of Chicago; J. E. Owens, M.D., of Chicago; Ephraim Cutter, M.D., of New York; L. A. Sayre, M.D., of New York; V. C. Vaughan, M.D., of Ann Arbor, Michigan.

THANKS.

The following resolution was adopted:

Resolved, That the heartfelt acknowledgment of this meeting be tendered to the physicians of this city, to the Apollo Club, and to all who have contributed toward the great success of the session, and especially are our thanks due, and we take pleasure in this manner to express them, to the fair coterie of ladies who have given brilliancy to the social entertainments by their charming presence. They are the best jewels in the crown of this metropolis, which is destined to be the Queen City of the East as well as of the West.

The Association then adjourned to meet in Newport, R. I., on the first Tuesday in June, 1889.

SECTIONS.

OBSTETRICS.

TUESDAY, MAY 8TH.

DR. ELY VAN DE WARKER, of Syracuse, opened the meeting with some remarks on

HOW GYNECOLOGY IS TAUGHT.

In which he dwelt upon the imperfect way in which this branch is taught in the colleges of the United States. The introduction of the graded system, with its methods of text-book study is the adoption of a method already discarded by progressive educators. It is a method detrimental to both student and teacher. Of 109 medical colleges in the United States, and only those are selected which are approved by the Illinois Board of Health—in only 56 is the subject announced in their catalogues as taught. In 14 the chairs of the diseases of women and children are united. In 32 there are professors or lecturers on gynecology. In 10 no mention is made of the subject. One announces 44 lectures on gynecology. In

66 of the 109 the diseases of women are taught by the professor of obstetrics or not at all.

Dr. Joseph Price, of Philadelphia, next presented a brief paper upon

THE SYSTEM OF VISITING NURSES AS ORGANIZED IN PHILADELPHIA.

Dr. W. W. Jaggard, of Chicago, then presented a

NOTE ON THE OCCASIONAL RELATION OF ENDOMETRITIS GRAVIDARUM TO THE PERNICIOUS VOMITING OF PREGNANCY.

He reported a case with a careful analysis, calling attention to the occurrence of these cases, with a plea for more careful diagnosis, (1) as to the existence of pregnancy, (2) as to the factor causing the vomiting, (3) as to the causes of vomiting independent of the vomiting. To the care taken in making the diagnosis he attributes the infrequency of cases of pernicious vomiting reported in German literature as compared with French and American. In the case reported all remedies for checking the vomiting, including dilatation of the cervix, were unavailing, and the patient's condition becoming critical abortion was induced at the fifth month. Examination of the membranes showed pathological conditions identical with Herger's description of the conditions in hydrorrhœa gravidarum. Cessation of nausea and vomiting immediately followed the abortion and the patient made a good recovery.

Dr. DeLaskie Miller said these cases are not infrequently met with in practice, and he was glad attention had been drawn to the subject. The plan of delaying too long the induction of abortion, too often resulted in the death of the mother. Since having departed from this rule he has obtained better results.

Dr. Nelson, of Chicago, stated that in his experience the pernicious vomiting is usually associated with displacements of uterus or appendages.

Dr. Marcy, of Boston, referred to the views of Ercolani as to placental development. These cases are not cases of inflammation of the decidua, but the secretory and absorptive organs of the placenta are not in proper relation, there is a lack of proper placental development.

In the cases of vomiting due to this cause, it is useless to trust to medication, and abortion should be induced early, since there is certain to be one of two results if they are let alone—the death of the fœtus and its spontaneous extrusion, or the death of both mother and fœtus.

Dr. Wm. Goodell, of Philadelphia, then read a paper upon

NEUROSES OF THE RECTUM.

In hysterical affections of the muscles, the circular muscles—sphincters—are most liable to be attacked. Rectal neuroses are not infrequent. There are usually present some of the symptoms of general nervous prostration; but often the rectal trouble is the chief symptom, and so prominent that the physician is led to believe some grave affection of the part is present. There will, however, be noticed an irregularity in the pain; an affectation of suffering; a lack of consistency in the symptoms. One class of cases closely simulates the symptoms of fissure. In another, a throbbing pain when the bowel becomes loaded, and a burning pain in defecation are present. These cases are often cured by over-stretching the sphincter. Disease of the coccyx must be carefully excluded. Sometimes stricture is so completely counterfeited that the feces are passed in ribbons or pellets. In some cases, defecation is followed by great exhaustion. Cases were cited showing the strange pranks played by the hysterical rectum.

Another class of cases are those known as follicular enteritis. He has found these cases always to be hypochondriacal or hysterical. In the treatment the general nervous prostration must first be cured by the Weir Mitchell plan of treatment. When the evacuations are followed by great exhaustion, it is important to secure a passage at bedtime. Suppositories of iodoform or antipyrin may be used as in fissure, or over-stretching may be resorted to, and repeated if there is a relapse. In follicular enteritis he has found injections of broths, flaxseed tea, witch-hazel, undiluted lime water, etc., useful; opium is to be avoided. The compound sumbul pill he has found of advantage. The bromides are often needed. When patients are so situated that the Weir Mitchell treatment cannot be employed, an hour or two of absolute rest daily in bed, in a darkened room, should be insisted upon.

Dr. Gordon, of Boston, spoke on

HYSTERECTOMY FOR CANCER.

Cancer of the uterus should not be an exception to the surgical rule now generally adopted, to remove as soon as possible. He reported three cases with one death, two are living and doing well.

Dr. Goodell expressed himself as "on the fence," being yet undecided, from the number of cases reported, and the length of time elapsed after operation, as to the justifiability of the operation. He had operated twice, one died from septicæmia; the other lived six months, and died from recurrence.

Dr. Cushing, of Boston, had seen the operation so successful in Berlin that he favored it.

Dr. Howard A. Kelly, of Philadelphia, considered that there was no question as to the legitimacy of the operation.

Wednesday, May 9th.

Dr. L. H. Dunning, of South Bend, Indiana, read an exhaustive paper upon

DOUBLE UTERUS AND VAGINA.

After reporting an interesting case, he gave an analysis of 97 cases whose histories he had collected. In the 97, there were

Uterus bipartitus	7 cases.
" unicornis	3 "
" bicornis	52 "
" bilocularis	23 "
" single, neck and vagina double	2 "
Not clearly stated	10 "
Atresia of vagina	6 "

Of the 97, 47 were married, 3 unmarried bore children, making 50 mothers.

No. women pregnant	42
" of pregnancies	76
" " natural labors	42
" " difficult labors	13

Means of relief in these:

Forceps in	7
Turning	1
Septum cut	4
Rupture of uterus	1

Of the 42 pregnant women, 14 miscarried eighteen times. 23.6 per cent. of pregnancies resulted in abortion or miscarriage. No instance of a pregnant uterus bipartitus is found in the 97.

There were—pregnancies in

Uterus unicornis	3
" bicornis	21
" bilocularis	12
Single uterus with double vagina	4
Unknown form	2

He concludes that the malformation is more common than generally supposed.

Dr. W. H. Taylor, of Cincinnati, reported two cases which had occurred in his practice.

Dr. Howard A. Kelly, of Philadelphia, mentioned several cases which he had seen, and stated that he believed the malformation to be more common than is usually stated.

Dr. Goodell reported a case in which diagnosis of extrauterine pregnancy was made and a contemplated operation only avoided by the timely discovery of the mistake.

Dr. Franklin H. Martin, of Chicago, read a paper upon

THE VALUE OF GALVANISM, AS APPLIED BY APOSTOLI IN THE TREATMENT OF FIBROID TUMORS OF THE UTERUS.

1. A means of generating a continuous current of electricity of steady and uniform character, that can give an actual current strength through a resistance of two hundred ohms, of 500 milliampères, is necessary in order to obtain all the benefits of this treatment.

2. Fibroid tumors of small size can be completely absorbed by the proper application of strong currents of galvanism.

3. Hemorrhages from hemorrhagic fibroid tumors can be promptly cured by the local coagulating effect of the positive pole by intrauterine application. Severe neuralgias, so often accompanying these troubles, can invariably be relieved by three or four applications of this treatment.

4. When the cervical canal cannot be entered by any form of intrauterine electrode, flexible or otherwise, after repeated trials, a negative galvano-puncture should be made into the presenting part of the obstructing mass of the tumor and an artificial canal opened, which is to take the place of the impenetrable uterine canal in all subsequent treatments.

5. The intrauterine electrode should in all cases be negative, unless there is hemorrhage or excessive leucorrhœa, when the positive pole is always required. The same patient may, however, present symptoms demanding the use of both poles at successive operations.

6. The strength of the current should depend entirely upon the amount of active surface of the internal electrode, and should be twenty-five milliampères for each square centimetre of active surface in actual contact with the endometrium. If more is used, the concentration of the current will be sufficient to cause troublesome cauterization; if less is used, the concentration at any one point will not be sufficient to cause the necessary coagulation for checking hemorrhage.

7. The duration of the treatment should be five minutes of the maximum current required.

8. The number of operations is necessarily dependent upon and influenced by the result to be accomplished. A severe hemorrhage can be checked, and symptomatic relief can often be accomplished by four or five séances, while a general reduction of the tumor necessitates many operations, varied, of course, according to the size and location. In some cases of large multiple tumors a relief of symptoms, or symptomatic cures, must be accepted as a substitute for an actual cure.

9. The operation should be intermenstrual, if possible; if hemorrhage is continuous, however, operate during flow. The séances can occur as often as every day, with the system of concentration adopted that enables one to attack different portions of the canal at succeeding treatments, or treatment can be given with advantage as seldom as once a week.

10. Since the adoption of the flexible intrauterine electrodes and Dr. Apostoli's vaginal galvano-puncture, extrauterine puncture should be regarded, if at all, only as a last resort.

11. Galvano-puncture needles and the internal electrodes, should be constructed of material that is not injured by coming in contact with strong carbolic acid, or 1:1000 bichloride of mercury solution. All internal electrodes should be thoroughly scrubbed with a nail brush and soap and water after each application, and allowed to remain in one or the other of these standard antiseptic solutions until they are to be employed again, when they should be washed in a weaker solution of the same before using. Before a vaginal puncture is made, the vagina should be thoroughly wiped out with a 1 to 3000 bichloride solution.

12. There is no excuse for any percentage of mortality in the proper application of this treatment. While Dr. Apostoli has had two deaths in 275 cases, he candidly admits they were due to avoidable accidents, rather than to any legitimate result of the operation.

13. In experienced hands, and by the adoption of the present means of concentration, the most delicate and sensitive patient can receive, without experiencing any severe discomfort, all the benefits to be derived from this valuable treatment.

Thursday, May 10th.

Dr. Wathen, of Louisville, read a paper upon

ABDOMINAL SECTION IN EXTRAUTERINE PREGNANCY,

in which he favored operation as soon as the diagnosis could be made. In most cases the sac can be removed, and hemorrhage controlled, by proper application of ligatures. The objection to operation on the ground of the difficulty of separating the sac, is more theoretical than practical. If it cannot be removed, it may be left.

Dr. A. W. Johnston, of Danville, Ky., followed with a paper upon the same subject. He claimed that the treatment by electricity at any period was wrong in principle, dangerous in practice, and disastrous in its results, and that it would soon be entirely discarded by the profession. To destroy the life of the fœtus is not sufficient,

the growth of the placenta must also be stopped. To do this requires such a shock to the pelvic nervous supply as to be dangerous. It is now established that the early cramping pains, attended with prostration of the patient, are really due to slight ruptures of the tube. When electricity succeeds in destroying the life of the fœtus, and checking the growth of the placenta, the danger is not over, the mother is still liable to septic infection from the remaining mass; and the subsequent history of these cases is often one of chronic invalidism. Operation should be made as soon as the condition is discovered.

Dr. Rufus B. Hall, of Cincinnati, made

A PLEA FOR EARLY OPERATIVE INTERFERENCE IN CASES OF OBSCURE PELVIC PAIN.

It is now known that recurrent attacks of pelvic peritonitis are very often due to disease of the Fallopian tubes. He would recommend the operation before the patient's general condition is too bad for recovery, and after careful treatment by other means had failed. By operation very many cases, doomed otherwise to life-long invalidism or to death, may be saved. By modern methods and in experienced hands the mortality from operation is not more than from two to six per cent. He cited Lawson Tait's experience, and the intense opposition he had encountered. The general profession being opposed to operation allow these cases to die which ought to be relieved by operation. He reported one case, which having refused operative interference, died under "expectant" treatment, and two cases in which removal of the tubes and ovaries was followed by complete relief, and the restoration of the patients to complete health.

Dr. C. R. Reed, of Middleport, Ohio, read a paper upon

THE EARLY REMOVAL OF ABDOMINAL CYSTIC TUMORS.

He condemned tapping, and favored the removal of the growths as early as possible.

Dr. Marcy, of Boston, presented a paper upon

EXPLORATORY LAPAROTOMY.

He advocated the more frequent resort to the operation in obscure cases, and reported illustrative cases from his own practice.

Dr. Wm. H. Myers, of Fort Wayne, Ind., next read a paper on

TREATMENT OF ACUTE PERITONITIS.

The old plan of treatment by opium should be abandoned. The best results are to be obtained by the early and free use of saline cathartics. Peritonitis is never idiopathic. Its treatment belongs to the surgeon rather than the physician. Antiseptic precautions and drainage were prophylactics to be employed in operations. Patients should not be allowed to die of peritonitis without the benefits of operation. Free irrigation was commended.

Dr. Goodell opened the discussion upon the papers read by stating that in the main the views expressed were in accord with his own; yet some of them were rather too sweeping. He agreed with Dr. Meyers that free purgation should be employed at the beginning of an attack of peritonitis; uses opium as little as possible, but in cases attended by severe pain it would be cruel to withhold it. He would not remove a small stationary ovarian growth which was giving no trouble, and such cases he had had under observation for years.

Dr. Hall's paper he thought too sweeping. Many cases may be cured by the Weir Mitchell plan of treatment, and without operation. If the truth were known, a larger per cent. of cases operated upon die than has been stated.

Dr. Robert Battey wished to make some corrections as to history in the paper of Dr. Hall. Lawson Tait says that he does not operate with the design of producing the change of life, but he removes ovaries and tubes to cure pain as the dentist pulls an aching tooth. An American surgeon, as long ago as 1872, did operate with this object—*i. e.*, to produce the change of life—distinctly in view.

Dr. Hall had referred to Tait's great opposition from the profession in England, but the fight on this question was all over in this country before Tait's voice had ever been heard on the subject. It was not until seven years after the first operation in this country that Tait made a claim to have operated in a case one month earlier than Battey. In 1879 he came forward and stated that in a private conversation with Dr. Chadwick, of Boston, he had told of this operation. Dr. Chadwick has no recollection of such a conversation. Why did he remain silent for these seven long years, while the warfare was going on in this country? Why had he made no mention of the subject in his book on the ovaries published in the meantime? "When the fox-chase was all over he came forward and wanted to cut off the fox's tail."

Dr. Howard A. Kelly stated that a large portion of the profession were ignorant of the truth in regard to Dr. Battey's claim to priority, that he himself was for a long time; but having investigated the subject he had found that Dr. Battey was undoubtedly entitled to the credit of having originated it.

Dr. Hall, in reply to Dr. Battey, stated that his paper was not concerned with the question of the priority of the claimants to oöphorectomy.

Adjourned.

Medicine.

Tuesday, May 8th.

Dr. N. S. Davis, of Chicago, opened the meeting by announcing the death of Dr. A. B. Palmer, of Ann Arbor, the Chairman-elect, and the unavoidable absence of the Secretary, Dr. N. S. Davis, Jr., of Chicago. An election of officers was then held with the following result:

Chairman.—Dr. W. C. Van Bibber of Baltimore.

Secretary.—Dr. G. A. Fackler, of Cincinnati.

Dr. Van Bibber opened the discussion

ON PNEUMONIA, ITS ETIOLOGY, PATHOLOGY, AND TREATMENT,

with a consideration of the mechanism of pneumonia and its treatment. His remarks covered two points: 1st, an inquiry into the initial causes of pneumonia; and secondly, the treatment of pneumonia.

He recognized among the predisposing causes of pneumonia four, which are quite different from each other, and each one of them must produce the same effect, viz., congestion in the capillaries, by a different mode of action. The causes are age, cold, malaria, and alcohol. He stated the following conclusions: The predisposing

causes, as the name implies, do not produce pneumonia, *de ipso facto*, but they have already worked such structural changes in the body that upon further disturbance of the system a congestion of the numerous pulmonary capillaries is more likely to occur than any other diseased condition.

A study of these structural changes, brought about by the predisposing causes, gives advantages, both in advisory prophylaxis, as well as in treatment.

He introduced the discussion of the treatment of pneumonia with the statement from Fothergill, that "every new remedy almost is tried in turn in pneumonia. It is a disease particularly suitable to speculative medicine." He had determined to present the subject by means of four hypothetical cases: one a child of eighteen months, one a youth of twenty-five years, one sixty-five years of age, complicated with malaria, and one case seventy years old, complicated with old age, malaria, and alcohol. In the discussion of these cases much stress is laid on cupping over the roots of the lungs, between the shoulders, or, more particularly still, between the third and eighth dorsal vertebræ, in order that by the laws of counter-irritation over affected parts, the circulation through the roots of the lungs may be kept entirely free and open. It is also a means of controlling, or, at least, of moderating, the effects of high arterial action during fever. It is valuable for the relief of pain and oppression it affords.

The medicines recommended are five in number: muriate and carbonate of ammonium, the former acting upon the circulation in the capillaries, assisting to unload them when they become engorged, as a resolvent, a general expectorant, and a diaphoretic; the latter as a stimulant, a resolvent, as a remedy which prevents the coagulating or engorging of blood in the capillaries. It may also be used as a vehicle in inhalations. Antipyrin and antifebrin seem to control the fever, by diminishing the heat of the blood. Digitalis, veratrum viride, strychnia, strophanthus, and other remedies, are valuable.

Dr. J. T. Whittaker, of Cincinnati, said that it is no exaggeration to say that the past two years have been more eventful in the history of pneumonia than any period in the past two thousand, for in this short space of time pneumonia, a disease which causes 6.6 per cent. of the total mortality, and 12.7 per cent. of the mortality of internal affections, has been definitely placed among the acute infections.

Pneumonia is now known to be an acute infection with the symptoms, course, and lesions characteristic of this class of diseases. With this knowledge came the correction of many errors which like the envelopes of a veiled statue obscured the figure so that only its rough outlines could be seen. The first intimation in this direction came from a recognition of the fact that pneumonia sometimes assumes epidemic proportions, but the deathblow came to the old conception of the nature of the disease in the establishment of the fact that it does not result from taking cold. Over 80 per cent. of cases can recall no possible exposure to cold in explanation of the origin of the disease. Another error perpetuated from time immemorial, that pneumonia picks by preference upon the healthy and robust, was corrected in the observation that the disease has a predilection for enfeebled conditions. Dietl declares that but 18 per cent. of cases were previously healthy. The subjects of rickets, tuberculosis, syphilis, alcoholism, malaria, anæmia, previous infections, etc., furnish the victims of pneumonia. Then it was discovered that while wounds may cause an inflammation of the lungs they can in no way produce a croupous pneumonia. Not the out-door but the in-door life is especially liable to attack. Soldiers are attacked in garrison and barracks, not in active campaign. Sailors who are exposed to the cruelest inclemencies and vicissitudes of weather are almost never attacked on the open sea, and but rarely, though more frequently, when near shore. 17.02 is the appalling percentage of deaths among the nuns in Paris, while that of washerwomen is but 3 per cent. Among 674 individuals engaged in unloading vessels, standing often waist-deep in water, Parent du-Chantilet found but one case of congestion of the lungs. On the other hand, prisons, factories, and tenement-houses furnish a large contingent of cases of this disease. The proportion of cases in cities to country is as 5 : 2.

But while it is acknowledged that cold and trauma are not the real causes of the disease, it may be admitted that they do, in exceptional cases, act as exciting agents where the cause preëxists in the body, just as injury to the brain and spine may excite abscess of the brain or caries of the spine, or measles excite tuberculosis.

It was the observation of these facts that gradually led advanced thinkers in clinical medicine, notably Oppolzer, of Vienna, and Andrew Clark, of London, to the belief that pneumonia was not the type of the acute inflammations produced by cold, but was probably due to some peculiar condition of the atmosphere. It was reserved, however, for Juergensen, of Kiel, in 1872, to formulate this view more precisely in the declaration, as the result of his observations, that pneumonia was an infection, and thus to stimulate the bacteriologists to discover its cause. Juergensen saw, 1, that the disease had different temporal and causal relations from the affection commonly ascribed to cold; 2, that the general symptoms, —fever, nervous symptoms, prostration—by no means always correspond with the extent of invasion of the lung; 3, that the disease runs a typical course with a definite termination in five to nine days; 4, that its lesions and complications on the part of the heart, lungs, kidneys, and spleen were the same as the other infections, and was thus able to declare the character of the affection in the absence of any distinct proof. When this proof should be furnished seemed only a matter of time. Klebs first appeared with his monadines found in bronchial secretions, cultivatable in proper soils, and inoculable to produce the disease in rabbits. There is little doubt now that Klebs was able to produce the disease by inoculation but not with pure cultures. Eberth and Koch next each observed ellipsoid micrococci in the lungs, meninges, and blood, though not with sufficient evidence of pathogenic properties. The memorable disclosures of Friedländer, in 1883, of capsule cocci constantly present in the exudation into the lungs, lymph vessels, and pleural effusions furnished the first evidence of satisfactory character that this microörganism could be successfully isolated, cultivated, and inoculated to produce the disease in certain animals. But it was soon seen that Friedländer's microörganism was present in but the smallest contingent of cases, according to the observations of Weichselbaum in but 5.5 per cent. Fränkel next, in 1886, isolated a pneumococcus quite similar to, but not identical with that of Friedländer,

which a number of subsequent observers find present in nearly all the typical cases of the disease. This organism which Weichselbaum distinguishes as a diplococcus with candle-light or lancet-shaped elements, and which seems to be identical with Sternberg's sputum septicæmia bacterium, can be detected in over 90 per cent. of cases. Though often confounded with that of Friedländer, its different manner of growth quite easily distinguishes it, and the great frequency with which it is found gives it, at the present time, supreme importance. Artigalas and Pane have each since advanced a special microörganism as the cause of the affection, and Weichselbaum admits that the lesions of pneumonia may be produced by the introduction into the lungs of the streptococcus and staphylococcus of pus. There is reason to believe that the typhoid bacillus may also produce hepatization of the lung.

Thus, there is no poverty of material in the etiology; on the contrary, an *embarass des richesse*. What are we to conclude from this abundant and apparently conflicting testimony? It is safe to conclude, in the first place, that lobar pneumonia has not yet been finally resolved; that there are various forms of the disease, undistinguishable as yet by physical signs. Clinical medicine has long since separated primary and secondary pneumonia. The pneumonia incident to typhoid fever, scarlatina, smallpox, dysentery, and other infections, shows a character and course quite different from the primary acute croupous disease. That secondary pneumonias may be readily explained by invasions of the lungs with the microörganisms of these diseases, is quite certainly established at least for typhoid fever. Other cases admit of explanation on the ground of mixed infection. Thus, suppuration is not a natural termination of acute croupous pneumonia. Suppuration means a coincident or subsequent invasion of the lungs by the organisms of pus. Omitting all these cases, we have left pneumonia proper, which can certainly be produced by the diplococci of both Friedländer and Fränkel. Whether these pneumonias differ in their character, or what fine differences they present, we know not as yet, but we do know, clinically, that acute croupous pneumonia has a classically typical course. Few other infections, Baumgartner declares, present a course so uniform and so regular. It is, therefore, safe to assume, as in the case of other infections of uniform course, typhoid fever and erysipelas, for instance, a single sole cause in the production of pneumonia. Whether or not this cause has been discovered in Fränkel's microörganism cannot be declared as yet, but the bulk of recent testimony lies certainly in this direction.

Then, to speak only from a clinical standpoint, this organism is most uniformly found in the sputum of perfectly recent cases, or in the first days of the disease, a fact which gives it supreme value from the point of view of differential diagnosis. Thus, in the examination of seventy successive cases, Wolff found Fränkel's diplococcus 66 times—*i. e.*, 94 per cent., and Friedländer's but 3 times—*i. e.*, 4 per cent. The examination was negative in but a single case. Verification was established by cultures in more than half the cases.

The diagnosis of pneumonia is generally easy, but difficulties are often presented in the separation of tuberculosis and pleurisy, and still more frequently in the first days of the disease. Illustrative cases of the value of the pneumococcus in this direction, are reported by Russian physicians. Thus Ignatieff, of Moscow, details four cases of tuberculosis complicated by pneumonia as recognized by the discovery of both forms of bacteria, and maintains that the presence of the diplococcus renders much more grave the prognosis of tuberculosis. The coincidence of the affections was verified on autopsy. Kotovshtchikoff, of Kazan, describes five cases in which the diagnosis of pneumonia could only be made in this way. In two cases a central lesion ran its course without physical signs up to the fifth and seventh day; in the other three the signs were those of pleurisy. Khomiakoff declares that he was able thus to diagnosticate the disease twenty-four hours, and Lubimoff seventy-two hours, before the appearance of any physical signs.

A most interesting clinical contribution was offered in the report of Ampugnani, at the Italian Congress of Physicians, September, 1877. Ampugnani had made hourly observations of the temperature in one hundred cases of pneumonia, revealing the fact that the temperature underwent oscillations of ¾° to 1° in successive hours of the same day. These fluctuations, which in extreme cases ranged over three degrees, were characteristic rather of mild cases. Severe cases showed a more continuous and sustained elevation. But the fatal cases were not characterized by the very high temperatures. Death does not occur from fever, but from heart complications.

Now it is known of Fränkel's bacteria that a high temperature attenuates and a higher destroys its virulence. A temperature of 107° destroys virulence in twenty-four to forty-eight hours; of 105°, in four days; and of 103.5°, in seven days. We may not say of it that a high temperature is an effort of nature to destroy the cause of the disease—assuming these bacteria to be the cause—but that it is the nature of certain bacteria to develop in the body a high temperature which is fatal to their virulent properties.

The disease probably enters the body through the avenue of the lungs—diplococci have been found by Emmerich and Uffelman under floors and on the walls of houses—and is always local at first. Subsequent disseminations from the lungs may invade the meninges, endocardium, spleen, and kidneys, favorite localizations of the disease. Thus pneumonia is an acute infection—not in the sense of Juergensen, as a general disease with a local expression in the lungs—but as a local disease which may undergo resolution at any stage, or may become general in its later course.

But aside from all questions of etiology, clinicians had already come to the conclusion that a high temperature in pneumonia is not serious because the duration of the disease is so short. Perhaps we are justified in administering antipyretics only to secure comfort to the patient. The pulse is the main indication of gravity. A pulse over 120 in an adult is always of grave import. Fräntzel goes so far as to abandon all antipyretics, because they all affect the heart in greater or less degree. He advises hot water rather than cold in the relief of pleuritic pain, but gives alcohol regularly from the fifth day on. The true treatment of pneumonia at the present time consists in sustentation of the heart, by alcohol and digitalis, for seven to ten days, or until the disease process has run its course.

DR. N. S. DAVIS thought it a curious fact that the mortality in pneumonia of to-day is undoubtedly greater than that of forty-five years ago. If anything is established,

this very fact has so been by statistics gathered not in the hospitals only but among the population of the United States—city and country, in private and in general practice. As to the question of cold, it has been indubitably demonstrated that the disease prevails more during the winter than during the summer months. He referred to the statements made by a prominent Canadian physician in one of the early meetings of the Association of that Dominion, to the effect that during a practice of thirty years he had adopted three plans of treatment. During the first of the three decades the treatment consisted of bloodletting; the second decade constituted the transmission period from the bloodletting, antiphlogistic treatment to the expectant plan; and the third, the stimulant method. He found, in footing up the records, that the mortality was least during the first decade and greatest during the last. The speaker dwelt at some length upon the benefits derived from bloodletting during the first stage, followed by cardiac depressants during the subsequent twenty-four to thirty-six hours. He cited cases in illustration.

DR. VON KLEIN, of Dayton, Ohio, had, during service in the Russian army, found that pneumonia prevailed to a less extent in a climate in which the temperature averaged 50° below zero, than in our moderate climate. He believed in the judicious use of the lancet. He ascribed the increase in mortality to the fact that the people are not as robust as those of fifty years ago. They have changed as to the surroundings, habits, clothing, etc., and our treatment ought to be guided by the peculiarities of each case.

DR. OCTERLONY, of Louisville, took issue with Dr. Davis in regard to the increased mortality. During the time of bloodletting the mortality was one in five. During the time of mixed treatment, according to the statements of Skoda and Austin Flint, the results improved fifty per cent. J. H. Bennet, of Edinburgh, introduced the method of furthering the natural progress of the disease, with the result that the mortality was reduced to one in thirty-six. He had on former occasions defended the theory that pneumonia depended upon local causes, that the changes were local and that they were amenable to local treatment. But, impelled by more extended observations, he has become a convert to the theory of pneumonia being an essential, specific fever, due to a specific cause, probably the pneumococcus. He thought that a physician was rarely called to a patient during the first stage, but generally when exudation had already commenced.

DR. JENKINS, of Iowa, attributed the apparent increase in mortality to the improved facilities of diagnosis and the advances in our knowledge of pathology.

DR. BAILEY, of Louisville, advocated decidedly the use of stimulants, especially during the last stage.

Dr. F. C. SHATTUCK, of Boston, stated that although it is doubtful whether the increased temperature is a salutary and curative process, yet he thought that more attention should be paid to the condition of the pulse than that of the fever. During the past the influence of temperature in pneumonia has been overrated. He had discarded the systematic use of antipyretics in this disease. It is a febrile affection of short duration, and he believed that the use of antipyretics, especially at the approach of the crisis, is dangerous when the heart's action is enfeebled, and this plan of medication may cause dangerous collapse.

DR. VAN BIBBER, in conclusion, stated that he had received a letter from Dr. W. L. Welch, in which the following statement was made: "It is apparent that the evidence is not conclusive that either of the organisms is the infectious agent of croupous pneumonia, certainly no such evidence has been presented as that which leads us to accept the tubercle bacillus, the typhoid bacillus, or the cholera spirillum as the cause of the respective diseases."

DR. MORRIS H. HENRY, of New York, read a paper entiled

CLINICAL EXPERIENCE IN THE ADMINISTRATION OF IODIDE OF POTASSIUM IN THE TREATMENT OF SYPHILIS.

He prefaced his remarks with a few words on the value of mercury in the early, or what is termed the middle period of the evolution of syphilis. In the discussion of the subject proper he stated that the iodide may be administered in doses varying from 5 to 50 grains every four hours; 20 to 200 every twenty-four hours. He spoke of the value of the remedy in syphilitic rheumatism. The remainder of the paper dwelt upon the claims of various authors to the priority of the adoption of the treatment of late and inveterate lesions of syphilis by the administration of *large* doses of iodide of potassium.

NEWS ITEMS.

The Hygienic Protection of Railway Passengers during the Coming Summer.—Dr. Rauch, Secretary of the Illinois State Board of Health, addresses the following admirable circular, which should apply throughout the country, to the railway managers of Illinois:

The Board directs me to advise you that it is deemed desirable before the advent of warm weather to secure such care of railway stations and grounds and of railway travel, as may tend to improve the sanitary condition and comfort of passengers generally, and specifically to limit the danger of any epidemic contagious disease.

Although there seems to be no immediate cause for alarm as to Asiatic cholera, the germs of that disease still exist in some parts of Europe whence large numbers of immigrants are constantly arriving in this country; and it now prevails as an epidemic in Chili, Brazil, and probably elsewhere in South America. Until it has died out in the countries with which the United States has direct commercial intercourse, it will not be prudent to relax vigilance, nor to omit proper precautions.

We had a narrow escape last fall from the introduction of this disease, and there is no telling what may happen during the summer.

The cleanly condition of water-closets on cars and at stations, also of privies, and the purity of drinking-water supplies for passengers and employés are matters of the first importance in this connection. At many of the small stations the conditions which obtain in these respects are far from satisfactory. Where privies are used they should be kept clean by constant attention. Vaults should be emptied at proper intervals, the contents disposed of so as to prevent further nuisance, and efficient disinfectants should be freely and continually used. Explicit instructions on these points will be furnished by the Board whenever requested.

Interruption of railway travel and traffic may be prevented, and the comfort and welfare of the travelling public will be promoted by good sanitary conditions, and the Board will cheerfully coöperate with you to secure these ends.—*Sanitary News*, April 21, 1888.

The Berlin Exposition of Appliances for the Prevention of Accidents.—Minister Pendleton sends to the State Department from Berlin the translation of a letter which he has received from the Board of Directors of the German Universal Exposition for the Prevention of Accidents. The Exposition, which will be held from April to July, 1889, is to contain apparatus and appliances meant to protect workingmen against the dangers which threaten them in the industrial occupations, from the knowledge and introduction of which a reduction in the number of industrial accidents may be expected. It is added that the humanitarian views which prompt this exposition have won the full sympathy and support not only of the principal representatives of industry and agriculture in Germany, but also of the German Imperial and Royal Prussian State officials. The Exposition aims not only to promote a knowledge of the apparatus and appliances calculated to prevent accidents, but also to stimulate an interest in their further development and to furnish the inventors of similar protective contrivances an opportunity to demonstrate their practical utility. The Exposition will, therefore, have much of the character of an industrial exposition, differing only from the purely industrial expositions in that such articles only will be admitted whose whole aim or make has a demonstrable relation to the prevention of accidents. Such articles and appliances shall also be admitted which tend to the workingmen's protection and general welfare, and are, therefore, adapted to lead indirectly to a diminution of industrial accidents.

As the workmen and handicraftsmen of all lands have an equal concern in the decrease of accidents in the industrial occupations, there can be no doubt that this Exposition will also be of interest for other countries, especially as foreigners are allowed to enter exhibits. The Board of Directors respectfully beg Mr. Pendleton to make this projected undertaking known, in the manner that may seem most fit, among those whom it may concern, but especially among the makers and inventors of safety apparatus in the States whose government he represents.—*Sanitary News*, April 21, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM MAY 8 TO MAY 14, 1888.

MCKEE, JAMES, *Lieutenant-Colonel and Surgeon.*—Granted leave of absence for one month.—*S. O. 107, A. G. O.*, May 9, 1888.

GREENLEAF, CHARLES R., *Major and Surgeon.*—Detailed as a member of a Board of Medical Officers, to assemble at the U. S. Military Academy, West Point, N. Y., on June 1, 1888, to examine into the physical qualifications of members of the graduating class, and of the candidates for admission to the Academy.—*S. O 104, A. G. O.*, May 5, 1888.

O'REILLY, ROBERT M., *Major and Surgeon.*—Detailed as a member of a Board of Medical Officers, to assemble at the U. S. Military Academy, West Point, N. Y., on June 1, 1888, to examine into the physical qualifications of members of the graduating class, and of the candidates for admission to the Academy.—*S. O. 104, A. G. O.*, May 5, 1888.

SKINNER, JOHN O., *Captain and Assistant Surgeon.*—Detailed as a member of a Board of Medical Officers, to assemble at the U. S. Military Academy, West Point, N. Y., on June 1, 1888, to examine into the physical qualifications of members of the graduating class, and of the candidates for admission to the Academy.—*S. O. 104, A. G. O*, May 5, 1888.

Par. 11, S. O. 104, A. G. O., May 5, is amended by par. 4, S. O. 108, A. G. O., May 10, 1888: CHARLES R. GREENLEAF, *Major and Surgeon*, ROBERT M. O'REILLY, *Major and Surgeon*, and JOHN O. SKINNER, *Captain and Assistant Surgeon*, are detailed as a Board of Medical Officers, to assemble at the U. S. Military Academy, West Point, N. Y., on June 1, 1888, to examine into the physical qualifications of the candidates for admission to the Academy, and, in connection with the Superintendent of the Academy and Commandant of Cadets, of the members of the graduating class.

BROWN, HARVEY C., *Major and Surgeon.*—The leave of absence for seven days, granted by Orders No. 68, Fort Barrancas, Florida, May 2, 1888, is extended twelve days.—*S. O. 90, Division of the Atlantic*, May 8, 1888.

LORING, LEONARD V., *Captain and Assistant Surgeon.*—Granted leave of absence for three months, on surgeon's certificate of disability.—*S. O. 105, A. G. O.*, May 7, 1888.

BROWN, PAUL R., *Captain and Assistant Surgeon.*—Granted leave of absence for six months, on surgeon's certificate of disability, with permission to leave the Division of the Atlantic.—*S. O. 107, A. G. O.*, May 9, 1888.

BENHAM, ROBERT B., *Captain and Assistant Surgeon.*—To proceed from Fort DuChesne to Fort Douglas, Utah, and report to the commanding officer of that post, not later than the 26th inst., to accompany the battalion of the Sixth Infantry to Fort Lewis, Colorado. Upon completion of this duty, he will return to his station, Fort DuChesne, Utah.—*S. O. 33, Department of the Platte*, May 5, 1888.

APPEL, D. M., *Captain and Assistant Surgeon.*—Will be relieved from duty at Fort Davis, upon the arrival of Captain and Assistant Surgeon J. V. Lauderdale, and proceed to Fort Hancock, and report to the commanding officer of that post for duty.—*S. O. 49, Department of Texas*, May 5, 1888.

EDIE, GUY L., *First Lieutenant and Assistant Surgeon.*—Will proceed, not later than the 25th inst., to Fort Concho, and report to the commanding officer of the Eighth Cavalry for duty as Medical Officer, in compliance with par. 13, S. O. 99, c. s., Headquarters of the Army.—*S. O. 49, Department of Texas*, May 5, 1888.

CLENDENIN, PAUL, *First Lieutenant and Assistant Surgeon.*—Will be relieved from duty at Fort McIntosh, and proceed with the battalion of the Sixteenth Infantry from that post to San Antonio; from the latter point he will accompany the companies of the Sixteenth Infantry to their destination.—*S. O. 49, Department of Texas*, May 5, 1888.

WALKER, F. V., *First Lieutenant and Assistant Surgeon.*—Will be relieved from duty at Fort Ringgold, and proceed with Company "D," Sixteenth Infantry, to San Antonio; he will then report for duty to the commanding officer of the Post of San Antonio.—*S. O. 49, Department of Texas*, May 5, 1888.

HARRIS, H. S. T., *First Lieutenant and Assistant Surgeon.*—Will be relieved from duty at Camp Pena, Colorado, and proceed to Fort Davis, where, upon arrival, he will report to the commanding officer of the Eighth Cavalry for duty as Medical Officer with that regiment on its march to the Department of Dakota.—*S. O. 49, Department of Texas*, May 5, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING MAY 12, 1888.

CABELL, A. G., *Passed Assistant Surgeon.*—Detached from the U. S. Steamer "Adams," to proceed home, and wait orders.

SIMONS, M. H., *Surgeon.*—Detached from the Naval Academy, and ordered to the Practice Ship "Constellation."

HORWITZ, P. J., *Medical Director.*—Granted leave of absence for six months, with permission to leave the United States.

A Naval Medical Examining Board is now in session at the Naval Hospital, Philadelphia, for the examination of candidates for admission to the Medical Corps of the Navy. There are eleven vacancies in the list of Assistant Surgeons. Permits for examination can be obtained on application to the Secretary of the Navy.

THE CARTWRIGHT LECTURES.

ON THE GENERAL PATHOLOGY OF FEVER.

Delivered before the Association of the Alumni of the College of Physicians and Surgeons, New York, April 12, 1888.

BY WILLIAM H. WELCH, M.D.,

PROFESSOR OF PATHOLOGY, JOHNS HOPKINS UNIVERSITY, BALTIMORE.

LECTURE III.

THE ETIOLOGY OF FEVER.

(Concluded from page 544.)

We come now to the third and most important group of fever-producing agents, the pathogenic microörganisms. So overshadowing is their importance that it has been claimed that they are the sole causes of fever. In contrast with former times it is no longer the symptomatic fevers whose etiology is clearest. We have much more definite ideas as to the mode of production of some of the essential fevers which were once the most obscure, than we have of symptomatic fevers. It does not seem to me worth while to go over the chain of evidence which establishes the doctrine that the infectious fevers are caused by microörganisms. There is probably no one who has thoroughly investigated the subject, and is competent to form an opinion on it, who does not to-day admit that a number of infectious diseases have been proven to depend upon specific microörganisms, and that it is a logical inference that all infectious diseases are caused by parasitic organisms.

It is not germane to our subject to enter into a morphological or biological description of the different species of pathogenic organisms which are causes of febrile diseases. The only question which concerns us in this consideration of the general etiology of fever is how the microörganisms produce fever. Are they themselves the pyrogenic agents, or do they produce chemical substances which are pyrogenic? A number of other possibilities might be mentioned. These and similar questions have suggested themselves to investigators since the beginning of any knowledge of parasitic microorganisms. Our information is far from sufficient to enable us to answer these questions in a positive manner, and still we are not left wholly to vague surmises in attempting to form some sort of an opinion.

That bacteria can produce mechanical effects by plugging up capillaries and in other ways is certain, but the wide differences presented by the various infectious diseases cannot be reconciled with the idea that pathogenic bacteria act chiefly by mere mechanical interference with the fluid and the solid constituents of the body. Notwithstanding the fact that Stricker and Albert succeeded in producing fever by the injection of starch granules into the blood, probably no one will be inclined to attribute the pyrogenic activity of bacteria in any considerable extent to occlusion of bloodvessels.

In a certain number of infectious diseases, particularly of animals, bacteria are present in such enormous number in the blood and tissues that some are inclined to refer the disastrous effects of the organisms to the withdrawal of oxygen and other nutritive pabulum from the cells of the body. So far as the appropriation of oxygen is concerned, this idea is not supported by the results of most of the examinations of the blood in cases of anthrax. This explanation was more popular in the early days of bacteriology than it is at present, and at the best its value is limited, for it cannot be applied to a large number of infectious diseases, such as cholera or typhoid fever where the circulating blood is not largely invaded by the parasites. Furthermore, it is not clear how the appropriation by bacteria of nutriment intended for the tissues would help us to explain the production of fever.

It has been suggested that the increased temperature in infectious fevers may be explained by the heat produced by oxidation or other chemical changes in the microörganisms themselves. But this is not at all a satisfactory explanation. Not only is the quantity of heat which can come from this source in all probability very small compared with that constantly produced in the body, but such an explanation of febrile rise of temperature is not in harmony with what we know concerning the mode of production of fever (see Lecture I.).

The failure to explain the pathogenic power of bacteria in these and similar ways led to the supposition that the morbid activity of pathogenic bacteria is exerted chiefly by means of injurious chemical products. The demonstration of such products leaves no room for doubt as to the correctness of this supposition for some infectious diseases. This explanation is probable for most such diseases, but experience has shown that it is particularly dangerous to indulge in hasty generalizations in this department of medical science.

Sterilized and filtered cultures, particularly old cultures, of various pathogenic bacteria are capable of producing fever and other symptoms when injected into the blood or tissues. This, of course, makes it evident that the bacteria in question give rise to poisonous substances. It is necessary to distinguish between the intoxication produced by the injurious products of bacteria and the infection caused by multiplication of the microörganisms within the body. That this distinction may be readily overlooked is shown by the recent experiments with the inoculation into animals of pure cultures of the typhoid bacillus. Small quantities of these cultures may be inoculated without any apparent effect; if, however, larger quantities are injected into the veins or the peritoneal cavity of a rabbit, the animal dies in a short time

and the characteristic bacilli are found in the blood, spleen, and elsewhere. It was supposed by Fränkel and Simmonds,[1] to whom we owe this latter observation, that actual infection took place, but it has been demonstrated by Sirotinin and by Beumer and Peiper[2] that under these circumstances no multiplication of the injected bacilli occurs, and that the same results may be obtained by the injection of sterilized typhoid cultures.

The isolation in a chemically pure state of the poisonous products of pathogenic bacteria encounters great difficulties, and we owe to Brieger[3] nearly all that has been accomplished in this direction. Two substances which he has obtained from cultures of pathogenic bacteria are of great interest. Brieger isolated from pure cultures of the typhoid bacillus a very poisonous ptomaine or toxine, as he prefers to call this group of substances. He has given to it the name typhotoxine. It may be somewhat significant that he failed to find typhotoxine in a culture which had stood for twenty-four hours at a temperature of 102.2° F. (39° C.). The injection of typhotoxine into guinea-pigs produced great muscular weakness, diarrhœa, increased frequency of pulse and of respiration, and death. Nothing is said as to the effect upon the temperature of the animal.

A toxine has been isolated by Brieger in a crystalline form from an impure culture of the tetanus bacillus. This substance, called tetanin, produces, when injected into animals, the characteristic symptoms of tetanus.

It is evident that these important discoveries render far more definite than was formerly possible, the belief that bacteria produce fever by means of their chemical products.

A dangerous influence exerted by poisonous ptomaines is that under their agency the power of the body of resisting the invasion of various microörganisms may be impaired or overcome. Thus, Wyssokowitsch has shown that the immunity of some animals against certain species of bacteria may be destroyed by ptomaine poisoning.

In order to observe the effects upon the temperature, I have injected into rabbits sterilized cultures of the typhoid bacillus. Injections of very small quantities of these cultures produce no effects, somewhat larger amounts cause a rise of temperature without other marked symptoms, still larger quantities produce increased temperature, diarrhœa, weakness, and other manifest symptoms of severe illness, but the animal may recover; relatively large amounts are followed by fall of temperature, grave illness, and death. I have also obtained results similar to those of Sirotinin, who inoculated two rabbits with the same amount of a typhoid culture. In one rabbit fever developed and the animal recovered; in the other, the temperature fell after the injection, and the animal died. This certainly does not indicate that the rise of temperature in itself is an unwelcome attendant of intoxication with the poisonous products of bacteria. My experiments certainly showed that the animals were more likely to die after injection of typhoid cultures when the temperature fell than when it rose, independently of the quantity of material injected. One is reminded here of the very malignant cases of typhoid fever reported by Fräntzel, and others, in which the temperature throughout a great part of the disease was subfebrile, or even at times subnormal.

In no disease is the dependence of the febrile paroxysm upon the presence of bacteria so apparent as in relapsing fever, where, according to the statements of most, although not of all, observers the spirilla appear in the blood at the beginning of a paroxysm and disappear at the end. Whether or not, here and in malaria, the pyrogenic agent is a chemical product of the microörganisms causing the disease, we do not know.

I must content myself with having brought before you evidence showing that at least in some of the infectious fevers the specific bacteria produce pyrogenic substances. We have no right to say that this is the only way in which pathogenic bacteria can cause fever.

We have considered now three groups of agents concerned in the production of fever, viz.: first, unorganized ferments and other relatively homologous substances; second, ptomaines and other chemical products of saprophytic microörganisms; third, pathogenic microörganisms and their chemical products.

It is not to be understood that these groups correspond to sharply defined classes of fever-producing agents. The same substance may be produced by the action of unorganized ferments, as well as by saprophytic bacteria or by parasitic bacteria; hence, we may find the same fever-producing agent in each of the three groups. As has already been mentioned, our knowledge does not justify us in regarding these various substances as the immediate and direct pyrogenic agents. The epithet pyrogenic is applied to them only by a certain latitude of signification. It is possible that these various substances, which we are in the habit of describing as pyrogenic, may produce in the body some common change which gives rise to the real fever-producing agent. This is the view of von Bergmann and Angerer, who believe that this common change is a liberation of fibrin ferment by destruction of leucocytes. While we cannot consider this view as more than an hypothesis, it is, nevertheless, well to remember that apparently heterogeneous substances, which are usually designated as pyrogenic, may produce similar changes which are to be regarded as the real source of the febrile disorder of animal heat. But, notwithstanding these limitations and these elements of uncertainty, it seems to me that some such classification as that suggested of the agents producing fever is more useful than that usually employed in the discussions of the etiology of symptomatic and of essential fevers.

There is one point which must be impressed upon every one who makes many experiments with pyrexial agents. This is, that once in a while a substance of undoubted pyrogenic power causes a fall instead of a rise of temperature. This occurs frequently when the substance is injected in large quantity and under these circumstances there is usually produced a condition of collapse. But in exceptional cases the same dose which will cause in one animal a rise of temperature may give rise in another animal of the same species to a distinct reduction of temperature. In these latter cases there must be some idiosyncrasy on the part of the animal. Aronsohn[1] refers this unusual phenomenon to some peculiarity of

[1] Fränkel and Simmonds: Die Ætiologische Bedeutung des Typhus-bacillus, Hamburg und Leipzig, 1886.

[2] Sirotinin: Zeitschrift f. Hygiene, Bd. i. 465.

[3] Brieger: Untersuchungen über Ptomaine, Berlin, 1886.

[1] Aronsohn: Deutsche med. Wochenschrift, 1888.

the heat centres in the brain, and he draws an interesting parallel between this contrary effect of pyrogenic substances and the exceptional cases in which antipyretic drugs give rise to elevation instead of lowering of temperature.

The causes of fever which we have thus far discussed, have been substances which exert a pyrogenic effect when introduced into the circulation. We suppose that these substances act in some way upon the nervous system, but whether or not this action is a primary one it is impossible to say. Even if we assume, as is often done, that these substances incite directly in the blood and tissues chemical changes which lead to increased production of heat, we must still have recourse to some action upon the nervous system, as has already been sufficiently set forth in the previous lectures.

It cannot be doubted that fever may be caused by other agencies than pyrogenic substances present in the blood or tissues. The effects of exposure to external heat have already been considered. We found experimental evidence in support of the view ably advocated by H. C. Wood, that in typical cases of thermic fever or sunstroke, the strain placed upon the heat-regulating centres by exposure to excessive heat results in paralysis of these centres with rapid elevation of the internal temperature.

The cause of the elevation of temperature in tetanus is not altogether clear. In this disease the temperature may vary but little from the normal, but it is not uncommon to find excessive elevations of temperature toward the termination. Temperatures of 113° F. (45° C.), or more, have been recorded. The idea would naturally suggest itself that the rise of temperature is due to the tetanic muscular spasms, which we know to be accompanied by production of heat. Leyden was led to adopt this explanation by the results of experiments made upon animals. He succeeded by producing violent tetanic contractions of the muscles of a dog, in raising the internal temperature in the course of one hour and a half from 103.3° F. (39.6° C.) to 112.6° F. (44.8° C.). Clinical observations, however, do not support the supposition that the hyperpyretic temperatures of tetanus are dependent upon the muscular contractions. In spite of violent and prolonged tetanic spasms, the internal temperature may remain normal or be but slightly elevated. There is a decided similarity between the hyperpyrexia of tetanus and that which occurs in rheumatism and some other diseases, particularly in affections of the central nervous system, and it certainly seems probable that in all of these cases there is a profound disturbance of the heat-regulating centres. As the elimination of urea in tetanus is not excessive, we find additional reason to separate tetanic hyperpyrexia from ordinary febrile conditions. Recent investigations of the etiology of tetanus, have rendered it certain that at least some forms of this disease are caused by infection with a special microorganism. This has been demonstrated not only in the tetanus of animals but also in that of human beings. The tetanus bacillus has been found wide-spread in the ground in Germany, and I find it abundant in the ground in Baltimore and its neighborhood. In experimental tetanus, the bacillus, which has not yet been obtained in perfectly pure cultures, develops chiefly in the tissues near the seat of inoculation, and does not invade other parts of the body and the blood to any great extent. This indicates that the symptoms are referable chiefly to poisoning by some chemical products of the specific microörganism. As has already been mentioned, this view is sustained by Brieger's discovery in cultures containing the tetanus bacillus of a peculiar ptomaine which he has called tetanin, and which produces tonic spasms of the muscles. It is, therefore, reasonable to believe that the hyperpyrexia of tetanus is caused by the action of poisonous products of the tetanus bacillus on the nervous centres concerned in temperature regulation. Our present knowledge, however, does not warrant us in asserting that all forms of tetanus in human beings are of an infectious nature.

In the first lecture of this course, evidence was presented to show that pyrexia may be caused by affections of the nervous system without the agency of any pyrogenic substance. It may jar upon the sensibilities of some to call this form of pyrexia fever; but this hesitation can be due only to the idea that symptoms which are referable to infection or intoxication are essential to the conception of fever. In my judgment, we shall be led into confusion if we attempt to incorporate into our definition of fever, more than properly belongs to the febrile disorder of animal heat, and from this point of view there can be no impropriety in designating as fever, the pyrexia dependent directly upon affections of the nervous system.

It is not necessary to repeat here the conclusive experimental evidence for the existence in the nervous system of centres or regions which control the dissipation of heat and the chemical processes concerned in the production of heat. Those who are not much impressed by experiments upon animals, can hardly fail to be convinced by the clinical evidence which demonstrates that lesions of the nervous system may cause elevation of temperature, which cannot be referred to the action of any pyrogenic substance. Such evidence must, of course, be collected from cases where the fever cannot be explained by inflammation, bed-sores, or other lesions which can give rise to absorption fever. W. Hale White,[1] in the interesting article already referred to, has collected a number of cases of tumor, hemorrhage, softening, sclerosis, injury and functional disturbance of the spinal cord and brain, in which the pyrexia or hyperpyrexia is to be explained only by the lesion of the nervous system. The number of such cases might be considerably increased. These cases show that lesions of the cervical part of the cord, of the pons, of the corpus striatum, and of the neighboring white matter, are most likely to be associated with high temperature, but the cases hitherto reported hardly justify positive statements as to the exact situation in man of thermically active nerves or regions in the brain and spinal cord. As might be expected, not only focal lesions, but also diffuse diseases such as occur in general paralysis of the insane, locomotor ataxia, multiple sclerosis may give rise to pyrexia which sometimes assumes the form of temperature crises. It is in harmony with what we know of other disorders of the nervous system, to find that not only demonstrable anatomical lesions, but also functional disturbances may produce nervous pyrexia. Such functional disturbance furnishes the most probable explanation of the singular

[1] W. Hale White: The Theory of a Heat Centre from a Clinical Point of View. Guy's Hospital Reports, vol. 42, 1884.

and erratic elevations of temperature which have been occasionally observed in hysteria.

A question which merits more consideration than it is possible to give to it on the present occasion, relates to the possibility of the occurrence of fever as a reflex neurosis. The advance in our knowledge of the etiology of traumatic and inflammatory fevers, has pushed aside almost wholly the old doctrine of irritative fever. There are, however, cases of fever where still the simplest, and apparently most rational, explanation of the causation, is peripheral nerve irritation. As examples may be mentioned, the fever resulting from teething in children, that sometimes accompanying the passage of gall-stones or urinary calculi, and that occasionally following the insertion of a catheter into the urethra. It must be admitted that the evidence on this point is not conclusive. Especially is there lack of satisfactory experimental evidence. Electrical irritation of the exposed sciatic nerve is, under ordinary circumstances, followed by a moderate fall of temperature, although Ott[1] finds that in atropinized cats such irritation is followed by a decided rise of temperature. But these experiments cannot be held to weigh for or against the doctrine of irritative fever. Observations on human beings indicate that peripheral nerve irritation, if ever a cause of fever, is so only in certain situations and under certain forms of stimulation, and in certain individuals. In infants temperature regulation is more labile than in adults, so that it may be that nerve irritation can more readily disturb the temperature in the former than in the latter. The chief controversy as to the question now before us, has been as to the explanation of certain forms of urethral or catheter fever. It cannot be doubted that a large number, probably most, of the cases of so-called urethral fever, are instances of genuine absorption fever. Even if we exclude all cases with diseased kidneys, or with cystitis or other inflammatory disease of the urinary passages, there remains a certain number of cases in which the gentle insertion of a disinfected catheter is followed by distinct febrile reaction. It seems unwarrantable to assume that in all of these cases the catheter has caused a laceration of the urethra through which pyrogenic substances are absorbed. What is the nature and whence the source of these substances? In the cases now under consideration, they can be sought only in the normal urine, and of their existence there no proof has been afforded. In these cases it is certainly very difficult to understand how the fever can be interpreted as due to the absorption of some pyrogenic agent, and failing this explanation, the idea that the fever is dependent upon nerve irritation is most plausible.

I have now presented to you an imperfect survey of the general etiology of fever. The attempt has been made to classify the leading causes of fever, but it cannot be claimed that every variety of fever can be assigned to one of these groups of causes. Our knowledge of the etiology of special fevers is still too imperfect to warrant any such generalization. This is an attractive field for much patient investigation. I need only remind you of the uncertainty which still pertains to the causation of many of the fevers of warm countries. There is reason to believe that there remain yet to be differentiated etiologically, specific types of fever which occur among us, and particularly in our Southern States. It may be, that increasing knowledge will necessitate the recognition of varieties of pyrogenic agents entirely distinct from any with which we are now familiar. It is certain that future investigations will add clearness and precision to our ideas of the nature and mode of action of causes of fever which, at the best, we can now understand only imperfectly.

I cannot conclude this course of lectures without saying a few words on a subject which must engage the attention of every one who gives much thought to the nature of fever. What is the significance of fever, is a question which thrusts itself upon us no less than it has upon physicians in all ages. Unfortunately, we cannot to-day, any more than could our predecessors, give other than a speculative answer to this question. There have been in all ages enlightened physicians who have held the opinion that fever is a process which aids in the elimination or destruction of injurious substances which gain access to the body. Under the influence of ideas which sought in increased temperature the origin of the grave symptoms of fever, we have in recent times in great part lost sight of the doctrine once prevalent, that there may be in fever a conservative element. There is much which speaks in favor of this doctrine. The real enemy in most fevers, is the noxious substance which invades the body, and there is nothing to prevent us from believing that fever is a weapon employed by nature to combat the assaults of this enemy. The doctrine of evolution indicates that a process which characterizes the reaction of all warm-blooded animals against the invasion of a host of harmful substances, has not been developed to so wide an extent, and is not retained with such pertinacity without subserving some useful purpose. This is a point of view from which many pathological processes can be regarded with advantage. Even suppuration, which one does not generally look upon as a beneficent provision, is a most important instrument of nature in forming a barrier against general infection of the body with certain microörganisms. It is impossible with our present knowledge, to say in exactly what way fever accomplishes a useful purpose. There are facts which suggest that in some cases of fever the increased temperature as such may impair the vitality or check the virulence of pathogenic microörganisms, but there are many circumstances which make it difficult to suppose that this is the agency by which fever usually exerts a favorable action.

The supposition seems to me more probable that the increased oxidation of fever aids in the destruction of injurious substances. According to this view, the fever-producing agents light the fire which consumes them. It is not incompatible with this conception of fever, to suppose that the fire may prove injurious also to the patient and may require the controlling hand of the physician. Time will not permit me to elaborate further the ideas here suggested. In the course of these lectures some facts have been presented and others might be drawn from clinical and experimental observations which favor the hypothesis that fever is in a certain sense a conservative process. Unproven and intangible as the hypothesis may seem to some, no apology is needed for bringing to your attention a conception of fever in favor of which much can be adduced, and which, if true, is of fundamental importance, both theoretically and practically.

RECTAL INSUFFLATION OF HYDROGEN GAS AS AN INFALLIBLE TEST IN THE DIAGNOSIS OF VISCERAL INJURY OF THE GASTRO-INTESTINAL CANAL IN PENETRATING WOUNDS OF THE ABDOMEN WITHOUT LAPAROTOMY.[1]

BY N. SENN, M.D.,
OF MILWAUKEE,
PROFESSOR OF SURGERY IN RUSH MEDICAL COLLEGE, CHICAGO.

THE operative treatment of penetrating wounds of the abdomen complicated by visceral injury of the gastro-intestinal canal is now sanctioned by the best surgical authorities and may be considered as a well-established procedure based, as it is, upon experimentation and clinical experience. A visceral wound of the stomach or any part of the intestinal canal sufficient in size to give rise to extravasation into the peritoneal cavity must be looked upon as a mortal injury, unless promptly treated by abdominal section. A number of well-authenticated cases are on record where a wound in the stomach, or large intestine, healed, and the patients recovered without the intervention of surgery, but these instances are so few that practically the force of the preceding statement remains unimpaired.

Visceral injury of the stomach or intestines rarely gives rise to symptoms upon which the surgeon could rely in making a positive diagnosis. In the treatment of penetrating wounds laparotomy is resorted to either for the purpose of, 1, arresting dangerous hemorrhage, or, 2, detection and treatment of a wound or wounds of its hollow viscera. The first indication is readily recognized, and the diagnosis not only justifies the operation, but imposes it as a stern duty upon the surgeon, from which he should never shrink. The recognition of the second indication offers greater difficulties, and the uncertainty of diagnosis which surrounds such cases is used as a sufficient argument by many in opposing the adoption of timely and efficient surgical treatment, and is responsible for the loss of many lives which might otherwise have been saved. The uncertainty of diagnosis must remain in the way of a more general adoption of laparotomy in the treatment of penetrating wounds of the abdomen treated by timid surgeons, and may lead to important medico-legal complications in the practice of bolder and more aggressive operators.

It is apparent that if some infallible diagnostic test could be applied in cases of penetrating wounds of the abdomen which would indicate to the surgeon the presence or absence of visceral lesions of the gastro-intestinal canal, the indications for aggressive treatment would become clear, and the medico-legal responsibility of the operator would be reduced to a minimum. As we can never expect by the study of symptoms, or by the ordinary physical examination, to fill this gap, I was induced to search for some reliable test which in such cases should prove that the penetrating bullet or instrument had injured the gastro-intestinal canal. It occurred to me that a wound in the stomach or intestine should be sought for in some such way as the plumber locates a leak in a gas-pipe. The first object to be accomplished was to prove the permeability of the entire gastro-intestinal canal to inflation of air, and the next step was to find some innocuous gas, which when inflated would escape from the intestinal wound into the peritoneal cavity, and from that through the external wound, where its presence could be proved by some infallible test. Numerous investigators of this question have come to different conclusions, particularly as to the permeability of the ileo-cæcal valve. We should *à priori* expect that air and gases, on account of their lesser weight and greater elesticity than water, could be forced along the intestinal canal with less force, and for that reason alone, if for no other, should be preferred to water in cases where it appears desirable to distend the intestine above the ileo-cæcal valve.

I made a set of experiments, twenty-six in number, to demonstrate the permeability of this orifice to gases without rupture or injury of any of the coats of the intestine. I next demonstrated the safety of the procedure as a diagnostic and therapeutic measure, by showing that the resistance of different portions of the gastro-intestinal canal was about the same, and everywhere greater than was necessary for the forcing of the gas into all portions of the tract. This was established by a large number of experiments, using the manometer or mercury gauge to determine the exact degree of pressure. A number of experiments were also made to demonstrate the ability to distend the gastro-intestinal canal by rectal insufflation of hydrogen gas, preliminary to the practical application of the hydrogen-gas test as a diagnostic measure in penetrating wounds of the abdomen. These furnished only so many more demonstrations of the permeability of the ileo-cæcal valve and the entire alimentary canal to rectal inflation of hydrogen gas. Many of these experiments were practised upon the human being.

Experiment LI. is particularly interesting. "I was desirous of experiencing myself the sensations which would be caused by inflation of hydrogen gas, and therefore submitted myself to experimentation. Under a pressure of one-half pound, nearly one and a half gallons of gas were inflated per rectum. The distention of the colon caused simply a feeling of distention along its course; but as soon as the gas escaped into the ileum, colicky pains were experienced, which increased as insufflation advanced, and

[1] An abstract of a paper read before the Surgical Section of the American Medical Association, May 9, 1888.

only ceased after all the gas had escaped, which was only the case after an hour and a half. When the intestines and stomach had become fully distended, the feeling of distention was distressing, and was attended by a sensation of faintness which caused a profuse, clammy perspiration. A great deal of the gas escaped by eructation, which was followed by great relief."

The colicky pains which attend inflation of the small intestine by air or gas are always caused by the peristaltic action of the bowels in their attempt to expel their contents, as they always assume an intermittent type, and subside promptly after the escape of the gas. In none of the experiments did the pressure exceed a pound. The escape of the gas through the ileo-cæcal valve, after distention of the colon, was easily recognized in every instance by a reduction of the pressure as well as by the auscultatory signs heard most distinctly over the ileo-cæcal region.

The experiments also demonstrated the fact that inflation of the intestinal tract, in order to be safe and effective, must be done *very slowly*, under a low, steady pressure, which will accomplish a great deal more than a higher pressure continued for a short time, and is attended by no risks whatever of causing rupture of a healthy intestine; and when cautiously practised can be resorted to, even in cases where the resisting power of the intestinal wall has been diminished by antecedent pathological processes.

The experiments further demonstrate the innocuous character of pure hydrogen gas upon the tissues of the body, since in none of them were any immediate or remote toxic effects produced. A number of experiments were made for the purpose of demonstrating the innocence of this gas, as well as its non-irritating character when brought in contact with living tissues, and also that the gas is promptly removed by absorption.

A set of experiments were finally made for the purpose of demonstrating the applicability of the rectal insufflation of hydrogen gas as a diagnostic measure in perforation of the intestine by gunshot wounds of the abdomen. They proved an infallible test in every instance. Contrary to the experience of other investigators, I found that fecal extravasation does not uniformly take place soon after gunshot wounds of the intestines, and in the cases where I observed it, some part of the colon had been wounded. Intestinal inflation, I therefore conclude, does not tend to increase the liability to this accident, and must, therefore, be looked upon as a harmless measure in this direction. Inflation as a preliminary measure greatly expedites the first step in the operation of abdominal section in cases where the intestine has been perforated or injured, as the gas which escapes into the peritoneal cavity separates the intestine from the anterior abdominal wall, and the incision can be made safely and rapidly without fear of wounding the intestine.

In order to guard against the accidental overlooking of a perforation after one or more openings have been closed, I think it advisable again to practise insufflation.

After a careful study of the subject of rectal insufflation of hydrogen gas in its various aspects, I do not hesitate to recommend its adoption in practice as an infallible diagnostic test in demonstrating the existence of a wound of the gastro-intestinal canal in penetrating wounds of the abdomen without resorting to an exploratory laparotomy.

In conclusion, I submit for discussion the following propositions:

1. The entire alimentary canal is permeable to rectal insufflation of air or gas.

2. Inflation of the entire alimentary canal from above downward, through a stomach tube, rarely succeeds, and should, therefore, be resorted to only in demonstrating the presence of a perforation or wound of the stomach, and for locating other lesions in the organ or its immediate vicinity.

3. The ileo-cæcal valve is rendered incompetent and permeable by rectal insufflation of air or gas under a pressure varying from one-fourth of a pound to two pounds.

4. Air or gas can be forced through the whole alimentary canal, from anus to mouth, under a pressure varying from one-third of a pound to two and a half pounds.

5. Rectal insufflation of air or gas, to be both safe and effective, must be done *very slowly and continuously*.

6. The safest and most effective rectal insufflator is a rubber balloon large enough to hold four gallons of air or gas.

7. Hydrogen gas should be preferred to atmospheric air or other gas for purposes of inflation in all cases where the procedure is indicated.

8. The resisting power of the intestinal wall is nearly the same throughout the entire length of the canal, and in a normal condition yields to a diastaltic force of from eight to twelve pounds. When rupture takes place, it either occurs as a longitudinal laceration of the peritoneum on the visceral surface of the bowel, or as multiple ruptures from within outward at the mesenteric attachment.

9. Hydrogen gas is devoid of toxic properties, non-irritating when brought in contact with living tissues, and is rapidly absorbed from the connective-tissue spaces and all of the large serous cavities.

10. The escape of air or gas through the ileo-cæcal valve from below upward is always attended by a blowing or gurgling sound heard most distinctly over the ileo-cæcal region, and by a sudden diminution of pressure.

11. The incompetency of the ileo-cæcal valve is caused by a lateral and longitudinal distention of the cæcum, which mechanically separates the margins of the valves.

12. In gunshot or punctured wounds of the gastro-intestinal canal, insufflation of hydrogen gas enables the surgeon to determine positively the existence of a visceral injury without the risks and medico-legal responsibilities incident to exploratory laparotomy.

ILLUSTRATIONS OF BLOODY DISCHARGES FROM THE UTERUS OTHER THAN NORMAL MENSTRUAL, AND THE IMPORTANCE OF PHYSICAL EXAMINATION IN THEIR DIFFERENTIATION.[1]

BY W. P. MANTON, M.D. (HARV.),
VISITING PHYSICIAN TO THE WOMAN'S HOSPITAL, DETROIT, ETC.

IF we glance over the long list of uterine disorders which we find recorded in the text-books, we will notice that there are few of these which are not, at some period in their course, associated with a bloody discharge. Now, an escape of blood from the uterus, whether of greater or less intensity, a sudden gush, or the *stillicidium uteri*, which gives rise to a reddish-brown leucorrhœa, should, as we know, always be looked upon with suspicion; for while in some cases it may have no particular significance as regards local disease, in the majority of instances it is indicative of pathological changes taking place in the uterine tissue or mucosa. The tendency of most patients is to ignore or underestimate the importance of an inter-periodic loss of blood, and particularly if the hemorrhage seems to be only a prolongation of the normal menstrual flow, or appears as a dull, rusty leucorrhœa. Such patients are more likely to appeal to the physician on account of the effects of the blood loss—diminished strength, loss of color, etc.—than because of the condition itself. The bleeding is, however, a signal of danger, which, in most instances, may be averted by timely aid: but if the patient neglects the warning, and awaits a more positive demonstration of actual disease, the advent of the latter may be but the assurance that the disease has accomplished its work, and all efforts on the part of the physician thereby rendered futile. It is, therefore, incumbent upon the practitioner that no case of bloody discharge from the uterus be passed over lightly, but that in every instance active measures be undertaken to find out the cause, and relieve the condition.

Except in the case of very young girls, uterine hemorrhage demands a physical examination, and this should always be insisted upon. Nothing is more harmful to the patient than dosing with astringents to stop the bleeding, when we are in total ignorance of the cause. A hemorrhage which has been going on for months or years, the sufferer meantime ruining digestion and the secretory functions by the internal remedies taken, may frequently be almost instantaneously stopped by a simple operative procedure, demanding perhaps no longer than five minutes in its execution.

Although a bloody discharge may take place from the uterus at any time between the periods of puberty and the complete cessation of the menstrual function, and even after, a goodly proportion of these cases are seen at or about the time of the menopause. This time of life being characterized by degenerative or retrograde metamorphoses in the sexual organs, it is particularly liable to morbid changes in those organs, which may either tend to the destruction of life or to great future suffering and annoyance of the individual. Possibly these conditions, occurring as they are apt to at a definite period of life, may be classed with other obstacles, which, in the struggle for existence, serve as a check on over-population.

If we group a number of typical cases, occurring at the climacteric, and presenting symptoms not dissimilar, we can appreciate better the importance of a bloody discharge at this time, and the necessity of careful and thorough physical examination.

CASE I.—Mrs. B., aged fifty-one, a large, well-nourished, American woman, and the mother of several children. Menstruated last five months since. Excepting a slight bronchial affection of recent date, she has always enjoyed good health. During the morning of the day on which I was called, she expressed herself as feeling nervous, and having a fulness of the head, associated with dizziness. I found the patient on her back in bed, with the knees drawn up over the abdomen, cold, pale, and perspiring freely; the breathing short and quick, the countenance indicating great suffering. There was a profuse flow of blood from the genitals.

CASE II.—Mrs. H., German, aged fifty-two, mother of four children. For the past six months patient has had a "starchwater" discharge, which, on drying, leaves the napkins worn stiff. This discharge is followed each day by a slight loss of blood. There is more or less pain.

CASE III.—Mrs. C., American, aged fifty-two. Seen in consultation with Dr. Hamilton, of Tecumseh. Menopause two years since. Family history of cancer. One year ago the flow returned and was put down to "change of life." Three months later hemorrhage again occurred, and there was a regular loss of blood for two months. Following this the flow appeared every three or four weeks, and then every two or three weeks, such being the condition when I saw her. Pain is present, but is not a prominent symptom.

CASE IV.—Mrs. C., French, aged fifty-one. Kindly referred to me by Dr. S. P. Duffield. Patient has had two children; no abortions. For two or three years past there has been an irregular bloody

[1] Read by invitation before the Pere Marquette Medical Society, Michigan, May 8, 1888.

discharge from the uterus, which of late has been associated with a thick white discharge in which occasional pieces of a "skin-like material" were found. Patient is confined to bed, is weak and exsanguinated. There is considerable pain and soreness across lower portion of abdomen.

Case V.—Mrs. McG., Irish-American, aged thirty-eight. Seen in consultation with Dr. H. A. Cleland. Patient has been married for thirteen years, but has remained unfruitful. Menstruation, which has of late been very profuse, has recently been almost a continuous flow, only a week or ten days intervening between the periods. Patient is much debilitated. Pain, very severe at times, over lower portion of abdomen.

Case VI.—Mrs. B., American, aged fifty-seven. Seen in consultation with Dr. George P. Andrews. Menopause four or five years ago. For several years she has suffered from metrorrhagia, and watery discharge. At the date of my first visit, the patient was very pale, weak, and confined to bed the greater part of the time. There is a sense of uneasiness and discomfort, but not much pain, referable to the pelvis.

Here we have a series of cases occurring in women at about the same period of life, and presenting analogous symptoms, viz., loss of blood from the genitals, and pelvic pain or discomfort. From a careful history of these cases, experience may enable us to make a provisional diagnosis, but the symptoms of all are so similar that nothing but a careful physical examination will reveal the true conditions present, and if we give the menopause credit for the conditions, and attempt to cure, or even alleviate the patient's sufferings by the administration of internal remedies, we are worse than blind leaders of the blind, and certainly deserve to meet the reward of falling into the ditch.

In Case I. we have one of those explosions which sometimes occur during the climacteric. There is an attempt on the part of nature to rid the system of a certain amount of blood, which might otherwise prove a source of real danger, and like a nose-bleed at certain ages, possibly prevents so untoward an accident as cerebral hemorrhage. Barnes explains this condition very aptly when he says: "It is remarkable, that, as a result, probably, of the disposition which the uterus has acquired of acting as a periodical evacuant, long after the cessation of menstruation proper, it still continues to be the safety valve by which vascular repletion or tension is relieved."

It is a curious fact that this condition is sometimes seen in old women after ovariotomy. In one of my patients, sixty-three years old, from whom I removed a large double ovarian multilocular cyst, and who had not menstruated for ten years, quite a profuse bloody discharge from the uterus set in on the twenty-fourth day after the operation, and continued several days.

Case II. proved to be a simple pedunculated fibroid about the size of a hen's egg, readily removed, and with the resulting speedy cure of the patient.

Case III., an epithelioma of the cervix, presented on physical examination the usual characteristics of these growths at an early stage, and was probably at that time curable.

In Case IV., a positive diagnosis between sloughing fibroid and carcinoma or sarcoma could only be made after microscopical examination. It proved to be sarcoma.

Case V., in many respects similar to that just mentioned, turned out to be a fibroid involving the whole fundus uteri; while Case VI. was a double ovarian tumor, which I afterward removed. In this case there was also a small intra-mural fibroid, which almost disappeared under treatment, so that at the operation the uterus only appeared considerably thickened in its posterior wall.

Small fibroids of the submucous variety often exist without the patient's knowledge, as no symptoms are present.

In a case recently seen with Dr. C. G. Jennings, a tumor the size of a goose's egg, situated on the right horn of the uterus, was not discovered until the five months' pregnant womb made it apparent as a lump in the side. In another case which I delivered two years ago, three of these small fibroids were present on different portions of the womb, but had never caused the slightest inconvenience.

Illustrations of this class of bloody discharges from the uterus might be multiplied, but without further discussion of these, I desire to call attention to another group of cases in younger women, the symptoms of which are also similar.

Case VII.—Miss R., a pale, anæmic girl, aged twenty-three, with a family history of phthisis; has had a bloody discharge midway between the menstrual periods for two years past, which at present leaves her only for a few days during the month. There is no particular pain, but the constant drain on the system is exhausting her.

Case VIII.—Miss C., American, aged sixteen; referred to me by Dr. Cleland, began to menstruate a little over a year ago, and has continued to lose blood at irregular intervals since, the flow varying greatly in amount. Three weeks before my visit she had flowed continuously for over two weeks, and as a result was looking pale and pasty. There was no pain attending the flow.

Case IX.—Mrs. H., American, thirty-two years old. The mother of two children; suffers from extreme menorrhagia, as a result of which she is very weak, and unable to walk or assist herself. There is no pain.

Case X.—Miss F., American, aged thirty-one; began two months ago to have considerable spasmodic pain in lower portion of abdomen, running down to the feet, and attended by backache, nausea,

vomiting, and general malaise. She has had eight of these attacks, but is now feeling fairly well. For six weeks there has been a slight bloody discharge from the uterus, the amount lost increasing with the advent of the distressing symptoms noted.

Here, again, we have four cases presenting much the same symptoms, but differing widely in their physical conditions.

Case VII. was diagnosed as *endometritis fungosa hemorrhagica*, and two curettings during the year removed a considerable quantity of granulations from the cavum uteri. The family history gave rise to the suspicion of tuberculosis, but careful microscopical examination of the granular material removed, failed to reveal the familiar bacillus. I am quite certain that in this case the climate had much to do in the causation of the uterine congestion, for after a summer at the seaside, with change of diet (sea food), and salt-water bathing, the young lady has had no further return of the old trouble.

The hemorrhage in Case VIII. was due to the presence of a small varicose tumor in the left labium major, which, by keeping up a continuous irritation, determined a larger quantity of blood than normal to the parts. Removal of the dilated vessels caused a disappearance of the symptoms, and menstruation became regular and normal in amount.

In Case IX. we have a condition which, I believe, is very frequently overlooked by the practitioner, namely, a menorrhagia resulting from an old and deep cervical laceration. The relief to the patient following the operation for the restoration of the uterine neck was immediate and gratifying.

Case X. differed slightly from the other in having a history of previous pain. It was one of those obscure cases of retro-uterine hæmatocele which are often so puzzling to the diagnostician.

In the foregoing remarks I have briefly attempted to show the close similarity in symptoms manifested by very different conditions affecting the uterus. Many other causes of hemorrhage more familiar, as metritis, subinvolution, etc., might have been added, but sufficient has been said to indicate the great importance of physical examination in the diagnosis of those conditions before treatment can be intelligently inaugurated.

83 Lafayette Avenue, Detroit.

MEDICAL PROGRESS.

The Administration of Medicines to Children.—Jacobi writes as follows, on this point, in the *Archives of Pediatrics* for May, 1888: In the administration of medicines excitement on the part of the patient must be avoided; the nervous system of infants and children loses its equilibrium very easily. Fear, pain, screaming, and self-defence lead to disturbances of circulation and waste of strength. Preparations for local treatment or the administration of a drug must be made out of sight, and the latter ought not to have an unnecessarily offensive taste. The absence of proper attention to this requirement has been one of the principal commendations of "homœopathy," whatever that may have been the last twenty-five years. Still, the final termination of the case and the welfare of the patient are the main objects in view, and the choice between a badly tasting medicine and a fine-looking funeral ought not to be difficult. In every case the digestive organs must be treated with proper respect; inanition is easily produced, and vomiting and diarrhœa must be avoided. The most correct indications and most appropriate medicines fail when they disturb digestion; it is useless to lose the patient while his disease is being cured.

The administration of a medicament is not always easily accomplished. Indeed, it is a difficult task sometimes, but one in which the tact or clumsiness of the attendants has ample opportunities to become manifest. For "when two do the same thing, it is by no means the same thing." Always teach a nurse that a child cannot swallow as long as the spoon is between the teeth; that it is advisable to depress the tongue a brief moment, and withdraw the spoon at once, and that now and then a momentary compression of the nose is a good adjuvant. That it is necessary to improve the taste as much as possible need not be repeated. Syrup will turn sour in warm weather, glycerine and saccharin keep; the taste of quinine is corrected by coffee (infusion or syrup), chocolate, and "elixir simplex," a teaspoonful of which, when mixed each time before use, suffices to disguise one decigramme —one and a half grains—of sulphate of quinia. Powders must be thoroughly moistened; unless they be so, the powder adhering to the fauces is apt to produce vomiting. Capsules and wafers are out of the question, because of their sizes; pills, when gelatine-coated, or otherwise pleasant and small, are taken by many. The rectum and nose can be utilized for the purpose of administering medicines in cases of trismus, cicatricial contraction, or obstreperousness. Both of these accessories it may become necessary to resort to for weeks in succession.

Oertel's Treatment of Heart Disease.—The *British Medical Journal* of April 21, 1888, reports the discussion on this subject at the recent German Medical Congress as follows: Professor Oertel (Munich), whose method has attracted so much attention, both at home and abroad, since the cure of Prince Bismark by Dr. Schweninger (hence falsely "Schweningercur"), opened the discussion on the treatment of chronic diseases of the heart-muscle. After stating that, in his opinion, Stokes, who first introduced this method, had not found any followers, he said that it had first been employed in Germany by himself, with great success on a relative of his own, who suffered severely from weakness of the heart-muscle in 1875. During the following nine years he endeavored to give a scientific basis to this mode of treatment by experiments on animals and observations on men, which are to be found in his book *Therapie der Kreislauf Störungen*. He had, however, reconsidered his position, and recognizing that his treatment was not equally suitable for all cases, he would exclude from it advanced atheroma and grave incompetence of the heart-muscle. By a combination of an appropriate diet (animal food containing little water) and exercise obtained by the gradual ascent of

mountains (Terraincur), he obtained the following results: 1, diminution of the quantity of fluid in the body, and removal of the condition which he had termed "serous plethora;" 2, oxidation of the fat; 3, compensation between the arterial and venous system; 4, strengthening of the heart-muscle. This method, he said, ought not to be employed when the dyspnœa was increased by it and the flow of urine diminished.

PROFESSOR LICHTHEIM (Berne), his opponent in the discussion denied the existence of a serous plethora, and cited the recent publications of Bamberger, and one of his own pupils, showing that the relative amount of red corpuscles and serum was a constant quantity. He considered the method only suited (although then very effectual) for cases of fatty heart in persons of sedentary habit who lived high, and for the removal of dropsical swellings. The chief danger lay in acute dilatation of the ventricles; several of the cases of sudden death recorded were thus brought about.

DR. KISCH (Prague) mentioned that in cases of general obesity, with or without dropsical swellings, he had found that the proportion of red corpuscles was always constant.

Formulæ for Anthrarobin, a New Remedy in Dermatology.—BEHREND, in the *Therapeutische Monatshefte* for March, 1888, gives the following formulæ:

In ointments,

Anthrarobini	10 parts.
Ol. oliv.	30 "
Lanolini	60 "

A 10 per cent. ointment.

Also,

Anthrarobini	20 parts.
Ol. olivar., Lanolini	āā 40 "

A 20 per cent. ointment.

And,

Anthrarobini	10 parts.
Ol. olivar.	15 "
Adipis	75 "

A 10 per cent. ointment.

Also,

Anthrarobini, Ol. olivar.	āā 20 parts.
Adipis	60 "

A 20 per cent. ointment.

Alcoholic tinctures may be prescribed as follows:

Anthrarobini	10 parts.
Alcohol	90 "

A 10 per cent. tincture.

Also,

Anthrarobini	20 parts.
Alcohol	80 "

Dissolve by boiling.

A 20 per cent. tincture.

A glycerine solution is thus ordered:

Anthrarobini	10 parts.
Glycerin.	80 "

Solutions with borax, in water or glycerine:

Anthrarobini	10 parts.
Boracis	8 "
Aq. dest.	80 "

And,

Anthrarobini	20 parts.
Boracis	35 "
Glycerin., Spiritus	āā 90 "

Anthrarobin may be used where chrysarobin is indicated. (See THE MEDICAL NEWS of April 14, 1888, p. 412.)

A Loose Body in the Elbow-joint.—In the *Gazette Médicale de Strasbourg*, of April 1st, DR. G. BŒCKEL relates a case which is of some interest in connection with views which have recently been expressed as to the nature and mode of origin of loose bodies in joints. The patient, a strong, healthy man, aged forty-five, fell from a ladder on his left elbow. Immediately after the accident he lost all power of movement in the forearm. When he came under Dr. Bœckel's care some two months later, movement was found to be very limited and painful, both pronation and supination being accompanied by grating in the joint. Between the olecranon and the external condyle of the humerus a hard body was felt projecting slightly, which could be moved laterally to the extent of some millimetres. Dr. Bœckel was under the impression that he had to do with a case of old arthritis deformans, which the injury had started into renewed activity by displacing an osteophyte. He cut down on the loose body, and with considerable difficulty removed it, when he was surprised to find that it consisted of half the head, with a small piece of the neck, of the radius. The patient made an excellent recovery, and in three weeks from the date of the operation had so far regained the use of his limb that he was able to do light work with it. Dr. Bœckel said that this was the first case he had met with in which the loose body was a fragment of articular surface broken off by violence, and he took the opportunity of formally recanting a different opinion to which he had recently committed himself on the subject. In fact, less than a year ago (*Gaz. Méd. de Strasbourg*, 1887, No. 11, p. 121) he had maintained that such a mode of origin was inadmissible, the loose body being in all cases formed by vegetations springing from the synovial membrane or the articular cartilage.—*British Medical Journal*, April 14, 1888.

Stab Wound of the Left Ventricle; Recovery.—KIAWKOFF, in *Russkaja Medizina*, No. 42, reports the case of a Cossack who in a quarrel with a fellow soldier received a stab wound in the fourth intercostal space of the left side, in the mammillary line and parallel to the ribs, which bled profusely. The wound was cleansed, a compress applied, and restoratives were given. The area of dulness was greatly extended over the cardiac region, but the patient gradually recovered, and was discharged from the hospital in four weeks' time. Five days afterward, in attempting to lift a heavy weight, the patient expired suddenly. Post-mortem examination showed the integument wound closed; the pericardium was adherent to the wound. The cavity of the pericardium was filled with dark blood; a small punctured wound of the left ventricle was present, whose edges showed beginning fatty

degeneration of the heart muscle; subacute endocarditis was diagnosticated. The wound in the ventricle had probably closed, but the sudden strain had ruptured the cicatrix; the endocarditis resulting from the wound had not yet been recovered from. The reporter writes that seven per cent. of heart wounds are stated to have healed.—*Centralblatt für Chirurgie*, March 24, 1888.

Antipyrin and Saccharin in Diabetes.—*Les Nouveaux Remèdes* of April 8, 1888, gives the following formula:

R.—Antipyrin . . . . . ℥ 2½.
Saccharin. . . . . grs. 3.
Sodii bicarb. . . . . grs. 1½.
Infus. caffeæ . . . . ℥ 4½.—M.
Sig.—Teaspoonful to dessertspoonful three times daily.

An Explanation of the Action of Antipyrin.—In the *Practitioner* for April, 1888, BOKENHAM, after reporting various cases treated by antipyrin, explains the action of large and small doses as follows:

It appears to me that a reasonable explanation of the fact that small doses, given for the relief of migraine, seem quite as serviceable as much larger ones, may be found by considering the rate of excretion of the drug. It will be observed that diuresis was produced in some of the cases just narrated, and this is probably a key to the path taken by antipyrin in its elimination from the body. My own opinion is, that it is only the first portions that are absorbed which give relief, and that the surplus dose only throws unnecessary work on the kidneys. If these organs are not acting efficiently, the drug may accumulate in the system and produce poisonous symptoms. It is difficult to see, too, how such small doses can possibly produce that tolerance which has been found to follow the use of large doses with the same object, and which has rendered subsequent relief by the drug impossible.

Early Vaccination.—The *Lancet* of April 14, 1888, writes as follows on this point:

An infant, aged four weeks, who died from suffocation, was the subject of a coroner's inquest at East Greenwich last week. That the death was due to suffocation only was perfectly obvious; but the baby had been vaccinated when six days old, and the jury added to their verdict that this was too young an age to vaccinate a child, and desired the coroner to make a representation to the authorities "with a view to the prevention of similar cases in the future." Whether the jury hope to prevent the suffocation of children by this means is not quite clear, but we are led to assume this is their object; they appear, however, to have been informed by the practitioner who made the post-mortem examination that it was certainly not safe to vaccinate a child at so early an age, and on this point we may say a word. The child had been born in the Greenwich Union Infirmary, and children born in such institutions would, unless vaccinated before leaving, go out into the world and remain unprotected against smallpox, for these cases cannot often be traced by vaccination officers. There was, therefore, much reason for the vaccination of the child if it could be done without undue risk. Experience has amply shown that children at this very early period of life bear vaccination well, and we have no hesitation in saying that this operation is as nothing compared with the remaining susceptible to smallpox. We trust, therefore, the Greenwich guardians will not be moved to prevent the early vaccination of children born in their institutions.

The Treatment of Meningitis in Children.—The *Journal de Médecine* of March 18, 1888, in a detailed description of the treatment of meningitis in children, advises cold applications to the head and counter-irritation, also prompt purgation, if need be, by croton oil. If convulsions occur:

Ether . . . . . 20 parts.
Syrup. . . . . 30 "
Aquæ . . . . . 100 "

of this fifteen minims may be given as needed.

Epileptiform convulsions may be treated by

Zinc. oxid.,
Calomel.,
Valerian. pulv. . . . āā gr. 8.

In ten powders. One every four hours.

Photograms of the Eye.—The *British Medical Journal* writes that in the recent (sixtieth) Naturforscherversammlung in Wiesbaden both Dr. Claude du Bois-Reymond and Professor Cohn exhibited photograms of the eye obtained by means of the "lightning" illumination (discovered by Herren J. Goedicke and A. Miethe, Berlin, S. W., Ritterstrasse 74). The illumination is so sudden and fleeting that when it occurs in a chamber in previous absolute darkness, the pupil has not time to contract, and thus the maximal dilatation can be represented on photograms. It is hoped that by appropriate arrangements the retina can be thus photographed during life.

Morphinic and True Tetanus.—BROCK, of Richmond, in the *Virginia Medical Monthly* for April, 1888, concludes from cases under his observation, and from his study of the subject, that the disease may occur as:

(1st) *True tetanus*, established by the use of a foul syringe, or a filthy solution of morphine—either or both of them being contaminated by the presence of the pathogenic germ on which tetanus depends.

Or (2d) to the effects produced by the continued use of an impure article of morphine, rendered impure by the presence of one or more of the tetanous group of alkaloids, the action of which on the spinal cord produces a set of symptoms that are scarcely—if at all—distinguishable from true tetanus.

The Bacillus of Dysentery.—At a meeting of the Academy of Medicine of Paris on April 17th, CHANTEMESSE and VIDAL reported that they had found and cultivated a specific bacillus, in patients suffering from dysentery contracted in hot climates. The bacilli were found in the intestines and their contents, and in the spleen and mesenteric glands. The microbe develops rapidly on gelatine, in bouillon, and in water; it is colored with anilin only with difficulty. Rabbits inoculated with cultures of the bacillus, and by intra-peritoneal inoculation developed the lesions characteristic of dysentery. Peritonitis, pericarditis, and fibrinous pleurisy, were developed after intra-peritoneal inoculation with the bacilli.—*Revue de Clin. et de Thér.*, April 19, 1888.

A Liniment for Use in Neuralgias.—*L'Union Médicale* of March 22, 1888, gives the following formula:

Alcohol. camphor.	parts 90.
Ether. sulf.	parts 30.
Tinct. opii	parts 6.
Chloroform.	parts 20.

Flannel may be saturated with this fluid and laid upon a painful region of the body; over this an impervious material should be placed.

Is Chloroform a Safe Anæsthetic for Children?—The *Lancet* of April 14, 1888, writes that one of the many points of interest connected with the medico-legal aspects of anæsthetics was introduced at a recent inquest, held by Mr. A. Braxton Hicks, upon the body of an infant who died under chloroform at one of our large hospitals. The child, aged five months, was operated upon for the removal of a nævus, and died from the effects of the chloroform after the operation had been completed. The report states that the "coroner elicited that children very rarely die under chloroform; they take it readily, and easily recover." Children, it is true, take this anæsthetic fairly well, but it is hardly consonant with our present state of knowledge to allege that fatalities among infants and children under fifteen are less frequent than among adults, always providing the individual in either category is not the subject of disease. The ill-fed and poorly nourished children who come to our hospitals are not favorable subjects for chloroform administration, and the belief, which we fear is only too prevalent, that the young rarely die under its influence is likely to aid in increasing the number of victims who are yearly sacrificed to chloroform. It is highly probable that, when healthy members of the community are compared, no decennial period of life can be selected as being less obnoxious to chloroform than any other. Snow's tables, although faulty in some points, show, and we believe truly, that the maximum of deaths occur from chloroform between the ages of fifteen and forty-five; but such deaths are not to be attributed simply to an age liability, but to many intercurrent circumstances conditioning life during that busiest period of existence. When children are too small to render the exhibition of nitrous oxide gas and ether advisable, it is wiser to employ chloroform diluted with ether, as in the A.-C.-E. or one of the many kindred mixtures.

Antipyrin versus Insufflation in Whooping-cough.—GENSER, at a recent meeting of the Vienna Medical Society, reported thirty-six cases of whooping-cough treated by insufflation of various remedies, the average duration of the disease having been forty-three days. Insufflations possess this disadvantage, that they often cause attacks of coughing and vomiting, which greatly distress and weaken the patient. In marked contrast were the results obtained by the use of antipyrin. Taking one and one-half grains as his unit, Genser gave to children as many times this unit in twenty-four hours as the child was years old; for example, when ten years old fifteen grains. He often increased the doses to one and one-half times the original dose. Antipyrin was willingly taken in solution, and had only good effects. In 120 cases so treated, the average duration of illness was twenty-four and one-half days.—*Deutsche medicinische Wochenschrift*, April 19, 1888.

The Communicability of Tubercle by Milk.—PARKES, of London, in the *British Medical Journal* of April 21, 1888, writes as follows on this point: Whilst not denying that the tubercular virus may find other means of reaching the digestive tract than through unboiled cow's milk it appears to me that there are no sufficient safeguards in the management of town dairies to warrant us in assuming that milk from cows in an advanced stage of tuberculosis has no chance of being mixed with the milk of other healthy cows. In every dairy of any size there will probably be tubercular cows, some of them, perhaps, with tubercular deposits in the udders; and as it is the common custom with dairymen to mix together the milk yielded by different cows, it is not too much to assume that tubercle bacilli may be widely distributed in the milk supply of any town. It has been said that the tuberculosis of cattle is not the same disease as the tuberculosis of man, and that the absence of any proof of the human variety having ever been dependent upon ingestion or inoculation of the virus of the bovine variety tends to strengthen such a belief. To this it may be replied that the bacilli of bovine tuberculosis are identical—according to all bacteriological methods at present known—with those found in tubercular formations in the organs of man, and that although the disease presents anatomical differences in man and cattle, these differences may be explained as being due to differences of soil in the human and bovine tissues, the bacilli ingrafting themselves in those tissues which present conditions most favorable to their growth and development; secondly, absence of proof may only mean want of observation or recorded data, and cannot be held to imply that at no future time will satisfactory evidence of the dependence of the human disease upon a bovine source be brought to light.

Having regard to all those considerations, surely, the time has arrived when a radical change in the present methods of milk production and milk consumption is urgently needed. In the first place it should be rendered illegal for cows known to be suffering from tuberculosis to be kept in stock by dairymen and farmers for milking purposes; and, secondly, in no household should unboiled milk be consumed, more especially by children. No other animal food is consumed by civilized nations in an uncooked state; and by the light of our recently acquired knowledge it would appear that there is as much, or more, danger connected with the practice of drinking unboiled milk as of eating raw flesh.

Exposure to the heat of boiling water for five minutes destroys the life and action of the tubercular virus (Klein); and the same is true of the other specific disease poisons. By such simple means, then, is it possible to guard against an ever-present source of danger, as well as to obtain protection from those possibilities of the introduction into our bodies of the viruses of enteric fever, scarlet fever, and the like, which the experience of past epidemics has taught us to be latent possibilities in milk, with powers of development at the most unexpected periods. If medical practitioners generally recognized the importance of these views, and were careful to enforce them upon those entrusted with the care of delicate children of scrofulous diathesis, or with hereditary tendencies to tubercle, a commencement would be made in the right direction, which would gradually extend itself through all classes of society.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

PHILADELPHIA.

SATURDAY, MAY 26, 1888.

SULPHONAL, A NEW HYPNOTIC.

THE restless life of modern civilization has so far murdered sleep that poppies and mandragora and the drowsy syrups of the East no longer serve us. They have lost their old charm and grow delusive and uncanny. On the one hand, we dare not use ourselves to them lest they make us their slaves for life; on the other, they fail us because they have become feeble and uncertain of effect. Too often these ancient drowsy drugs, whether they bring sleep or not, play sad pranks with our nerves and stomachs on the morrow. Thus it has come to pass that the quest for some new sleeping draught that has no drawbacks, either for to-night or to-morrow, has busied the modern therapeutist alike in field and laboratory. It is not probable that the ideal hypnotic, invariably certain, safe, and prompt alike for the well and the ill, will ever be found. The true nepenthe, like the fountain of youth and the philosopher's stone, exists not in nature but in the imaginations of men. Sleep and forgetfulness for a while, however, we can and often must have. The sleep-inducing properties of the modern, as of the older hypnotics, have, as a rule, been discovered by chance, and usually in the course of experimental studies of the effects of new-found substances upon animals.

KAST, of Freiburg, in the *Berliner klinische Wochenschrift* of April 16, 1888, in the course of investigations conducted in association with Baumann, in regard to the sulphur combinations in animal tissues, has brought to light a hypnotic of great importance. This substance is an oxidation product of a combination of æthylmercaptans with acetone. It crystallizes in large, colorless, tasteless, and odorless plates, soluble in one hundred parts of water at ordinary temperatures, and readily soluble in alcohol and in mixtures of alcohol and ether. It resists alike the action of acids and alkalies.

Administered to dogs, this substance produced ataxic phenomena, followed by muscular resolution, and finally by light slumber, passing into deep sleep lasting several hours. Upon waking, the animals were at first unsteady upon their feet, but soon came right again, eating with appetite and showing no trace of disturbance from the drug. Sleep by no means invariably resulted, the effects of the drug being occasionally, and especially in strong animals, limited to the above-mentioned motor disturbances. It was then seen that the drug in question possessed powerful physiological activities, affecting primarily the gray matter of the cerebral cortex.

Its effects in healthy human adults, in doses of from 45 to 60 grains, were somewhat analogous, the muscular phenomena being, however, absent, while the tendency to deep and prolonged sleep was, under circumstances favorable to repose, very great. Thus the customary short after-dinner nap of surgical convalescents in a quiet ward, was prolonged into a sleep of several hours, so deep that the patients were aroused with difficulty. The sleep thus induced was followed by no trace of derangement of the nervous system or digestion.

The hypnotic influence of the preparation in the insomnia of pathological conditions was next extensively studied. The sleeplessness of "neurotic" persons, of those suffering from organic disease of the brain, of old age, of the acute febrile affections, of the stadium ultimum of heart disease, of senile dementia attended by active delirium, yielded more or less promptly and completely to the influence of this remarkable drug.

The average single dose in these investigations was 30 grains. In females, as a rule, 15 grains only were required to produce full results; while in robust men as much as 45 grains were frequently given, without unpleasant after-effects. These doses had little or no effect upon the circulation or respiration. Spectroscopic and microscopic investigations showed that the drug exerts no unfavorable influence upon the composition of the blood. It is, also, without unfavorable local action upon the gastro-intes-

tinal mucous membrane. Kast has observed no indication of diminished effect from the continued use of the drug, notwithstanding the fact that some of his patients had taken it regularly for several weeks.

Kast concludes that sulphonal favors the usual periodical need of sleep, and when the normal tendency is lacking, calls it into existence. It is free from the dangers of opium and chloral, much more efficacious than the bromides, and of wider applicability than methylal, acetophenon (hypnone), urethan, paraldehyde, or amylen hydrate.

To this substance, which belongs to the group of the disulphons, Baumann has given the name diæthylsulphondimethylmethan, a designation against the scientific propriety of which nothing can be urged, but which is inconvenient for everyday use in practical medicine. The term "sulphonal," appears to meet the requirements of commerce,

Sulphonal may be administered in powder in water, or mixed with any convenient menstruum, or, being without taste or odor, in milk, soup, or tea. As to its fate in the organism, but little is as yet known: it is eliminated in great part with the urine in the form of other organic sulphur combinations.

We may look for further reports in regard to sulphonal. Already Rabbas, Assistant Physician in the Irrenanstalt in Marburg, has published in the *Berliner klinische Wochenschrift* of April 23, 1888, the results of his observations in twenty-seven insane patients, to whom the drug was administered on two hundred and twenty-five different occasions. These patients had been under observation for varying periods, and their previous use of various narcotics constituted control experiments which invest his researches with peculiar value. His conclusions are as follows: Sulphonal is a hypnotic which in moderate doses (30 to 45 grains) produces a more certain and better effect than amylen hydrate and paraldehyde in maximum doses. Its results are satisfactory, even in patients accustomed to the use of narcotics. It possesses decided advantages over these drugs in respect of taste and odor. While chloral hydrate induces sleep more rapidly than sulphonal, its effects are decidedly less lasting. Doses of sulphonal of 30 to 45 grains are followed, as a rule, by good results, even in conditions of great excitement. Prolonged use does not necessitate increased doses. Sleep follows usually in half an hour; occasionally, not for an hour or even two hours, and continues without interruption six or eight hours or longer, the effect being gradual and continuous, and the sleep in all respects like normal sleep. Large doses (60 grains) followed, after a short interval, by the usual dose (30 to 45 grains), produced no evil effect. Unpleasant after-effects do not occur. The appetite, digestion, respiration, and heart's action were in no way unfavorably affected.

Rabbas, while strongly advocating the use of sulphonal as a hypnotic, especially in insane patients, ends his report with the remark that it sometimes fails—there is no such thing as an absolutely certain hypnotic.

THE CARTWRIGHT LECTURES ON FEVER.

In Dr. Welch's lectures we not only have an able summary of our existing knowledge of fever, but a masterly presentment which will prove invaluable to the student as a starting-point for fresh investigations, and to the practitioner as offering suggestions on many points in etiology and treatment. One who has groped in the dim light of the theories of the past twenty-five years feels encouraged to hope, on rising from the perusal of these lectures, that a solution of the problem is not very far off, and that we shall ere long reach the heart of the mystery which for so many centuries has occupied the minds of the great thinkers of our profession. In the first lecture the conclusion is reached that fever-producing agents act in some way upon the nervous mechanism controlling the production and discharge of heat. The question of heat centres so carefully studied experimentally by Ott should engage the attention of clinicians, as the results of Hale White's observations indicate that we have here an important field for observation.

In the second lecture on the effects of increased temperature, questions of the highest clinical interest are discussed, such as the relation of the various symptoms associated in the febrile process to the elevation of temperature. High fever is not the only danger nor is it always, as Liebermeister held, the chief indication for treatment. Of the experimental evidence brought forward in this connection that relating to the action of high temperature on the heart muscle is of special interest. Dr. Welch thinks that we have been too hasty in assigning to degeneration of the heart muscle so large a share in the production of heart failure in fever. The symptoms may be present during life without extensive corresponding post-mortem changes, and, on the other hand, there may be extreme degeneration

without symptoms.. That fatty degeneration does not necessarily impair the functional activity of muscle seems proven by the fact that the blood pressure in animals with hearts demonstrated to be fatty is not lower than the normal. This entire section is worthy of the most careful study. There is no more important question offered for solution than the definite determination of the respective action on the one hand of the high temperature, and on the other of the infective agent.

In the final discussion on the etiology of fever, Dr. Welch has marshalled a long series of valuable facts in a most suggestive and instructive manner. Of special interest just now are his remarks on the group of pyrogenic agents which have no necessary connection with microörganisms, and which are either not foreign to the healthy organism, or are readily formed by unorganized ferments from normal or abnormal constituents of the body. The influence of non-pathogenic and pathogenic organisms in the production of fever is presented in a forcible and attractive way.

It is no disparagement to former holders of the lectureship to say that the value of the Cartwright foundation has never been better illustrated than in the course just completed, and to the Alumni Society of the College of Physicians and Surgeons of New York are due the thanks as well as the congratulations of the profession.

It is pleasing to note in these valuable lectures the repeated references to the work of American investigators on this most complex of all physiological problems—to Wood, Ott, Martin, and others; and it is also gratifying to have so able and comprehensive study from a member of the Johns Hopkins University, an institution, the medical department of which may, we trust, give a stimulus to advanced study in medicine and surgery in this country, such as the sister faculties have already given to literature, history, and science.

A TEST FOR INTESTINAL PERFORATIONS.

While it is very generally admitted that perforations of the gastro-intestinal tract should be closed by sutures, one need only read the discussions during the past year at the American Surgical Association and the Congress of French Surgeons, as well as the views expressed by recorders of individual examples of shot wounds of the belly, to be convinced that surgeons do not agree as to the propriety of exploratory laparotomy in doubtful cases. This hesitation is due, partly, to the obscurity of the early symptoms, and partly to the legal complications that may arise, but more to the fact that, up to the present time, there has been no accurate test in diagnosticating the existence of perforations of the gut, without a resort to exploratory laparotomy.

In the current number of The Medical News may be found an abstract of a remarkable paper read by Senn before the Surgical Section of the American Medical Association at its recent meeting, in which rectal insufflation of hydrogen gas is recommended as an infallible test for intestinal perforations. We had the pleasure of witnessing the author's experiments at Cincinnati, on three dogs, which conclusively proved the truth of his assertions as to the safety and absolute reliability of the measure.

It is scarcely to be expected that every surgeon will have a bag of hydrogen gas ready for emergencies, but there is no reason why every hospital should not be equipped with such a contrivance, to be used not only by its staff, but also to be available to other practitioners whenever it may be required.

At a meeting of the Trustees and Faculty of the Medical College of the State of South Carolina, held last week, the chair of surgery was divided into clinical and didactic surgery. Prof. R. A. Kinloch, who has long held the chair of surgery, was assigned to the chair of clinical surgery, and Dr. Manning Simons elected to that of didactic surgery.

Dr. P. Gourdin de Saussure was elected to the chair of obstetrics and gynecology made vacant by the death of Prof. J. Ford Prioleau.

Prof. Kinloch was made Dean of the Faculty.

Dr. Charles McBurney has been appointed Visiting Surgeon to Roosevelt Hospital, New York, in place of Dr. Sands, recently resigned. Dr. R. J. Hall has been appointed Attending Surgeon to Bellevue Hospital, and Dr. George L. Peabody Attending Physician.

It is announced that Succi, the faster, has begun a fast of thirty days in Florence, under the supervision of Italian physicians, who seek to ascertain from his fast how long the digestive organs may be safely left at absolute rest, as such knowledge would be valuable in abdominal surgery, in hemorrhage from perforation, and other conditions. Succi is allowed a saline laxative, an alkaline beverage water to drink and to use in cleansing the mouth, and a little olive oil to use by inunction.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Thirty-ninth Annual Meeting, held at Cincinnati, May 8, 9, 10, and 11, 1888.

(Specially reported for THE MEDICAL NEWS.)

SECTIONS.

MEDICINE.

(Concluded from page 563.)

WEDNESDAY, MAY 9TH.

The Section went into an

ELECTION OF OFFICERS FOR THE ENSUING YEAR

which resulted as follows:

Chairman.—Dr. F. C. Shattuck, of Boston.

Secretary.—Dr. G. A. Fackler, of Cincinnati.

DR. WILLIAM PEPPER, of Philadelphia, opened the discussion

ON THE DIAGNOSIS AND TREATMENT OF DISEASES OF THE STOMACH.

He illustrated his remarks with the following case: A man had been losing two pounds in weight per week for a period of sixteen weeks. No disease could be detected. Blood and urine normal. No affection of heart and lungs. No enlargement of the spleen or glands. Eye ground presented no data of significance. No pain, vomiting, or constipation. Teeth had failed, and hence there was an element of imperfect mastication. Careful diet with small doses of arsenic brought about a temporary cessation of loss of flesh; but emaciation in time resumed its progress. Only by excluding every affection demonstrable did he arrive at a diagnosis of developing cancer in the walls of the stomach.

The case resulted fatally three to four months after it first came under his observation, and the walls of the stomach were found to be the seat of general carcinomatous infiltration. Such cases demonstrate the want of some additional more delicate means of diagnosis to insure accuracy. Not only is this true in rare cases like this, where all symptoms are absent, but many cases will be met with in which one or two symptoms may be present, and yet the group is too inadequate to make a definite diagnosis. He had but recently seen a business man, sixty-four years of age, who had previously enjoyed good health, but was suddenly attacked with severe pain in the pit of the stomach, coming on when that organ was empty and at night. It occurred every night, and extended from the pit of the stomach to the back. His bowels were quiet or a little costive. He had lost from thirty to forty pounds, was pale but not cachectic. Most careful search of the epigastrium revealed nothing. His radials were hard, and arcus senilis was present, the abdominal aorta appeared somewhat enlarged; no evidence of pancreatic disease. Under the use of careful diet, hydrocyanic acid, the application of the thermocautery to the region over the stomach and back, a most remarkable improvement was noted. But it was only transient. Months passed and emaciation advanced, and a hardness could be detected close up to the crura of the diaphragm. Patient died, and an autopsy revealed a fungus epithelioma in the superior posterior wall of the stomach, doubtless involving nervous filaments in the dense adhesions.

We recognize then the need of something outside of such clinical data as pain, vomiting, emaciation, etc., which, although they usually suffice to establish a diagnosis, still fail when they are most needed for differential diagnostic points.

He then alluded to a field which seemed to offer us assistance in this regard, viz., the application of organic chemistry in the examination of the contents of the stomach removed in a systematic manner. Vomiting usually occurs so soon after eating, and the vomited matter is so mixed with portions of the previous meals, or with mucus, etc., that the study of the substance is inadequate. The contents of the stomach should be removed by aspiration. It should be done at a definite time after the ingestion of a definite meal, which shall consist of a certain amount of mixed food, starchy and nitrogenous. The matter obtained should be tested for free hydrochloric acid, lactic acid, and peptic strength—that is, the power it possesses still further to digest albumen.

The methyl-violet is one of the best tests for hydrochloric acid. It is asserted by Riegel that, in thousands of investigations he has found that when cancer is present, no free hydrochloric acid will be found in the contents of the stomach six hours after a test meal. Here, then, we have a point of enormous importance if it be confirmed.

The secretion of the stomach is just as accessible as urine, though, of course, it cannot be collected with equal facility. The statements have been confirmed by most excellent observers. The ability to diagnose accurately has distinct limitations. In our efforts to diagnose a certain case, some or all the classical symptoms may be absent. Here, then, a field has been opened that appears to promise large results. What has been presented to us may be accepted as possessing confirmed value, although not regarded as infallible.

DR. F. C. SHATTUCK endorsed the conservative position of Dr. Pepper with regard to the test for cancer. The modern methods are very promising. At present our position must be a waiting one. In many cases the free hydrochloric acid is absent, and persistently absent. We should be careful not to draw our conclusions from one examination. Free hydrochloric acid has been found in undoubted cases of cancer, and has been absent in atrophy of the gastric tubules, in chronic gastric catarrh, and even in the normal state. Another question to consider is the quantity of the acid present. While the test for the acid is satisfactory and easy of application, yet, unfortunately, we possess no test which can be put to much clinical use to determine accurately the amount. We know that in cases of gastric ulcer there is a condition of undue gastric acidity. A method has been suggested by Ewald to gain some light as to the motor power of the stomach. He has taken advantage of the new remedy, salol, which is a combination of carbolic acid and salicylic acid, and is not broken up into these constituent parts in acid media. It passes, hence, through the stomach as a whole; when it comes in contact with the alkaline secretions in the duodenum, it is there broken up into carbolic and salicylic acids, and the latter, or its salts, are absorbed and may be detected in the urine. This experiment is of value especially in cases of supposed gastric dilatation. Ewald's investigations led him to think that

salicylic acid can be detected in the urine one hour after the time of its administration. The speaker had administered the remedy in 50 cases, in 27 of which the reaction was obtained in one hour or less, in 13 in one to one and a half hours, and in 10 in one and a half to three hours.

These were cases in which the stomach was presumably in normal condition. He had also given salol in a few cases of gastric disease. In two cases of chronic catarrh the reaction was obtained in one hour, in one case two hours to three hours and twenty minutes; in a case of gastric dilatation, one and a half hours; in a case of cancer in one and a half hours, and in a second case of cancer in two and a half hours.

The time relation between the digestion of food and the taking of the salol had seemed to make a difference in the interval which elapses before the salicyl reaction is obtained in the urine. We are not as yet, certainly, justified in diagnosticating motor insufficiency whenever the reaction is delayed beyond an hour.

DR. OCTERLONY, of Louisville, had for several years made use of chemical analysis in the diagnosis of gastric disease. In no single case did the examination fail to corroborate the diagnosis. In malignant disease free hydrochloric acid was always absent.

DR. WHITTAKER, of Cincinnati, said: The subject of supreme importance is the question of the presence or absence of free hydrochloric acid as a sign of the presence or absence of cancer. It has been made plain already that the continued absence of this acid nearly always means cancer as distinct from ulcer, in which process the acid is superabundant, not only as a prime cause in the production, but also in the prevention of the healing of an ulcer. It is the hyperacidity of the stomach that makes the gastric ulcer so obstinate. But the main interest centres about cancer, and the first question that arises is this: Is the detection of the presence or absence of the free acid easy? If the fluid furnished for examination must be sent to a chemist for examination on every occasion, the whole subject becomes impracticable. But the truth is, any practitioner may make the examination himself with not much more expenditure of time and trouble than attends the examination of urine for albumen. It is essential to remember, first, that the fluid must be withdrawn seven hours after a meal of bread and meat. A healthy stomach empties itself of its contents in this time. A mere inspection will show any undigested matter left. Then, as has been properly insisted upon, the fluid should be withdrawn through the long, soft stomach-tube, which the patient soon learns to swallow with ease. Depression of the outer end of the tube makes a siphon of it so that sufficient fluid can be collected in a cup. Should the contents not escape with a light pressure over the stomach, the tube may be filled with water and a little suction applied. It is best not to use the stomach-pump, though it may be necessary at times. But the practical value of the test ceases when complications of this kind arise. The patient, properly instructed, furnishes the fluid to the physician on his visit, or brings it to the office, as he would a bottle of urine.

If the fluid be clean, as it is, as a rule, it may be coarsely tested with litmus paper, but far better with congo paper, which will detect the 0.0019 per cent. of free acid. This paper, dipped in the fluid, remains red in the absence of free hydrochloric acid, whereas it becomes, in its presence, lilac or blue in intensity corresponding to the amount of acid present. Lactic acid will also color it, it is true, but lactic acid under one per cent. much less intensely than hydrochloric. A deep blue color is always imparted in a hyperacidity, as from gastric ulcer, and a deep blue nearly always means hydrochloric as distinct from lactic acid. The execution of this test is the work of a minute. The evidence of it may be corroborated by the methyl-violet test, which is also short work. A few drops of the stomach fluid, filtered of course, if turbid, dropped into a test-tube containing a solution of methyl-violet, distinctly colored, changes the color, if free acid be present, distinctly to blue.

To decide absolutely between hydrochloric and lactic acids in a doubtful case, where coloration is not very decided or pronounced, it is necessary to resort to the test of Uffelman; two drops of liq. ferri sesquichloridi added to a four per cent. solution of carbolic acid, give this clear solution a steel-blue color. This solution is decolorized by hydrochloric acid, but is turned yellow by lactic acid. No other acid, acetic, butyric, etc., found in the stomach, has this property.

Now, if examination daily or every other day for a week or ten days shows the persistent absence of free hydrochloric acid, it is safe to conclude the case to be cancer. The evidence is actually more valuable than that furnished by a tumor. It is the most valuable single sign. There are exceptions, of course, but they are about as frequent as the exceptions connected with albuminuria, of which it is known, that while the presence of albumen does not necessarily imply it, and the absence of it necessarily exclude it, yet the persistent presence of albumen in the urine nearly always means Bright's disease.

The main difficulty in the experience of the speaker was to get the patient to furnish the fluid. Patients who come from a distance and want a diagnosis at once, cannot have the benefit of this test. A stay of a week or ten days is necessary for a proper examination. It is the first trial only that is difficult. After the first success with the tube, confidence is established and subsequent attempts are easy.

It is impossible to overestimate the value of this test in doubtful cases, and most cases are doubtful, and correspondingly great are our obligations to the gentleman who has come so far to bring this subject properly before us.

THURSDAY, MAY 10TH.

DR. J. MCFADDEN GASTON, of Atlanta, read a paper on

CEREBRO-SPINAL MENINGITIS.

His object in preparing the paper was to emphasize the great importance of recognizing the gravity of the situation at an early period, by the general symptoms indicative of congestion and not wait for indications of inflammation to determine the nature of the disease. He cited forty-five cases of meningitis, thirty-five of which were cerebro-spinal meningitis and the balance spinal meningitis, with the following results, eighty per cent. of the latter and forty per cent. of the former died. As to treatment, he thought that while the recourse to opiates has, in some cases, seemed to afford relief, it is evident that in most cases it only soothes the passage to the grave. There is an urgent demand for restoring the functions of the vital organs and rousing the nerve cen-

ters to action by revulsive applications externally and revolutionary measures internally.

Relying upon the special properties of a mixture of calomel and quinine, he has employed it for the purpose of jugulating the progressive development of the congestive stage of this disease. Hot mustard baths were applied to the lower extremities and cold to the head.

Mustard plasters may also be placed along the spine assisting in restoring the energy of the nervous system, together with mustard applications to the inner surface of the arms and legs. He cited cases in illustration and proof of the efficacy of this treatment, followed by the administration of salicylate of sodium and fluid extract of jaborandi.

DR. DIDAMA, of Syracuse, gave in detail five very obstinate cases of

HEMATURIA,

which, after resisting ordinary and extraordinary treatment for periods of from six weeks to three months, finally yielded, in the course of a week or so, to large doses of alum—five drachms, three times daily—or smaller quantities every three hours. He called attention to the importance of having the alum dissolved in a large quantity of water, and claimed that when so diluted —twenty grains to a goblet of water—it found ready access to the blood and urinary passages, and never produced constipation. Some of his cases had, under the care of the most eminent physicians, received the best known treatment without the slightest benefit. Alum had been used in some instances, but never in the large doses which he has employed with invariable success up to the present time.

DR. N. S. DAVIS had met with cases of persistent hematuria, so severe as greatly to impoverish the patient and endanger life. He reported a case of such a character, which could not otherwise be explained than upon the theory that there existed a defect in the influence of the vasomotor nerves over the vessels of the kidney. Acting upon this theory, he had used the remedies under which the patient recovered, ergotin on the one hand, in moderately full doses, and at the same time, the fluid extract of hamæmelis Virginicus. It is probable that alum, well diluted, so as not to create gastric disturbance, will pass through the kidneys in sufficient quantity to increase the tonicity of the kidney vessels.

DR. V. C. VAUGHAN, of Ann Arbor, read a paper upon the

ETIOLOGY OF TYPHOID FEVER,

presenting in detail his experiments with the Eberth bacillus obtained from drinking water, and the successful inoculation of dogs with the germ.

SURGERY.

TUESDAY, MAY 8TH.

The Surgical Section convened at 3 P.M., DONALD MCLEAN, M.D., of Detroit, *President*, in the Chair, and B. A. WATSON, M.D., *Secretary*.

DR. MCLEAN, after calling the Section to order, at once proceeded to deliver his address, entitled

SOME THOUGHTS ON RETROSPECTIVE AND PROSPECTIVE SURGERY.

Our generation has witnessed one of the most active and progressive eras in the history of that department of the medical sciences to which the attention of this Section is especially directed. It occurred to him that a concise and candid statement of some of the impressions made upon his own mind, and some of the conclusions at which he had arrived as the result of active experience, extending over a period of at least a quarter of a century, might not be altogether uninteresting.

The marvellous progress of surgery in our time is generally attributed to two great agents, namely, anæsthetics and antiseptics. But, with all due deference to these, it should not be forgotten that they themselves are only part of the fruits of a great general movement all along the line of the natural sciences, and that advances in anatomy, chemistry, physiology, histology, etc., have contributed in innumerable ways to the progress of surgery, and it is no more than just that the great army of able and enthusiastic laborers in these collateral departments should receive adequate recognition for the services which they have rendered, directly or indirectly, to surgery. Nor should the fact be overlooked that, even before the beginning of the present surgical era—that is, before the introduction of anæsthetics, and long before antiseptics were dreamed of, surgery was a great and a brilliant scientific art, and many of the principles and the methods promulgated and taught by our fathers, stand unchallenged and unchanged to this day.

It is a common thing to hear much if not all the credit of the wonderful advances in the surgery of the abdomen, the surgery of the articulations, the surgery of the blood-vessels, etc., given to Listerism, or antiseptic devices. The fact is, that *antiseptics without anæsthetics could have had but a comparatively insignificant field of usefulness:* and before attempting to decide or define the value of antiseptic processes let us try to do justice to some of the other factors in this interesting problem.

The introduction of anæsthetics vastly extended the bounds of modern surgery. It must not be forgotten that this great advance had attained considerable progress before the introduction of antiseptics, as is best illustrated in the history of abdominal surgery. Spencer Wells, Clay, Atlee, Peaslee, Dunlap, and Keith, had achieved world-wide fame as ovariotomists long prior to the advent of antiseptic surgery. It has been customary, or, perhaps, fashionable of late years, when a successful operation of a new or exceptional nature, such as resection of intestine, cholecystectomy, splenectomy, etc., is reported to claim the result as another argument or fact in support of antiseptic surgery.

Is it not just possible that too much importance has been attached to the influence of antiseptics and too little to the numerous other factors which enter into this complex and many-sided problem. All honor to Lister as the great apostle of surgical cleanliness, no matter what the ultimate fate of his theoretical views may be. Whatever the fate of the so-called germicides, like carbolic acid, bichloride of mercury, etc., may be, one thing is certain that anything like a return to the old, loose methods of conducting surgical operations and of dressing surgical patients is absolutely impossible, and for this the world will always feel grateful to Joseph Lister.

With reference to anæsthetics, he found himself irresistibly forced to the conclusion that upon the whole for all general purposes, chloroform possesses superior advantages. His own experience has led him to believe that when carefully administered in suitable cases it is little, if at all, more dangerous than other anæsthetics, and its

advantages in other respects are too well known to require illustration. Fortunately, in the progress of surgery in late years, local anæsthesia by ether spray, cocaine, etc., has been found to constitute an efficient and altogether safe substitute in a large field of minor, though painful operations.

Much was hoped from the microscope as an aid to the diagnosis of different kinds of tumors, and for determining the prognosis in relation to the return, or the danger of general infection of the system. He could not persuade himself that it has added much, if anything, to our resources. In certain departments of practical medicine, as in the examination of the urine, it is invaluable; but to the ordinary practical surgeon its use has not equalled the expectations of its early enthusiastic advocates.

Electricity has, when used for suitable purposes, demonstrated its right to the respect and gratitude of the profession. Much harm has been done and much unfair prejudice has been excited against this useful agent by the absurd and extravagant claims which have, from time to time, been made in its behalf as the result of inaccurate observations or unscientific deductions, and there is reason to fear that this kind of obstruction to the proper recognition of electricity as a surgical agent has not yet entirely ceased.

The applicability of electrolysis to urethral fistulæ of long standing was made a subject of especial consideration, as was also its effect upon the growth and tendencies of uterine fibroids, as supported by Apostoli, Keith, and others.

With regard to the treatment of aneurisms, he believed the revival of the old operation of Antyllus in certain suitable cases, and the restriction of the Hunterian operation to a somewhat more limited field of usefulness, a striking and interesting improvement, for which the credit is mainly due Professor Syme.

The recently promulgated view that an artery may be securely ligatured by a broad animal ligature, without rupture of any of its coats and without the formation and organization of the classical coagulum, was pronounced, if true, the greatest discovery relative to the surgery of the arteries which has been made in our day. Such a revolutionary doctrine, ought, however, to be accepted cautiously, and after careful observations *on the human subject*. A few personal observations favoring this view were reported.

The treatment of diseased joints has made solid progress in recent times. Those intractable cases, to the pathology of which Sir Astley Cooper devoted so much attention and which he unsuccessfully endeavored to cure by different forms of counter-irritation and constitutional treatment, are now successfully managed by rest, pressure-extension, and counter-extension, and especially by the operation of resection or partial resection. The latter operation was especially valued.

In the treatment of fractures, he preferred the Gurdon Buck method now so generally employed. He preferred a splint made of folded newspapers surrounded by a roll of cotton wadding. The treatment of Colles's fracture without splints is an advance. The sprain of the neighboring joint should be considered the important factor in the case, and immobilization is everywhere contra-indicated in sprains. The treatment of non-united fractures was also considered.

He closed with a consideration of the operation for the removal of urinary calculi, expressing preference for the cutting operation as being more certain of success and much less liable to be followed by recurrence.

DR. HENRY H. SMITH, of Philadelphia, read a paper on

THE APPENDIX VERMIFORMIS; ITS FUNCTION, PATHOLOGY, AND TREATMENT.

In writing of intestinal obstructions, he said, Mr. Treves states that "their importance may, in one way, be estimated by the circumstance that over 2000 individuals die every year in Great Britain from obstructions of the bowels, exclusive of hernia." Dr. Senn, of Milwaukee, also considers them of such importance that during the last eighteen months he has reported one hundred and fifty operations performed on animals for the purpose of studying the principal varieties of intestinal obstruction produced artificially. Treves does not state what proportion of the deaths he speaks of were due to disorders of the appendix, and Dr. Senn's experiments have not been extended to this tube. It is, however, widely known that the appendix is sometimes a cause of constriction of the ileum, and that stenosis of its cæcal orifice, from inflammation of its coats, or concretions, or foreign bodies in its canal, frequently induces local and general peritonitis, pericæcal abscess, or perityphlitis. Whether the starting-point of the latter is in the appendix or in the cæcum, is still *sub judice;* but there is much evidence to show that it is in the appendix in the United States.

He next considered the special anatomy of the appendix. In man it varies from two to nine inches in length, about as broad as a goose-quill. It is generally slightly flexed, is sometimes adherent to the left and posterior side of the cæcum, and extending up nearly to the gall-bladder. Its blind extremity points toward the spleen, though it may dip into the pelvis and become adherent to the right broad ligament or ovary. When it occasionally becomes attached to some other organ and wound around the cæcum, it may cause strangulation. At the base, the appendix opens obliquely into the posterior and inner, but not the lowest point of the cæcum. The mucous coat and submucous tissue are well developed; a semilunar fold opposes the passage of solids into the appendix. Such entrance is forced mainly by straining or vomiting. Sometimes there is a second deeper, valve-like projection. Gerlach states that, in elderly persons, these valves are shrunken and atrophied, and this is the reason that perforation from the pressure of concretions is unknown. Perityphlitis is rare after forty; Bauer states that typhlitis is most common between sixteen and thirty-five. Appendicitis is mostly met with before forty-five.

The coats of the appendix are the same as those of the intestine, but the longitudinal fibres predominate, their action tending to force its contents into the cæcum. The follicles of Lieberkühn are abundant; Peyer's agminated follicles are also present; Brunner's glands are not beyond question.

The function of the appendix is yet doubtful, some question its importance, as it is found in but six animals. Morgagni, John Hunter, Meckel, Haller, and others, report cases where the appendix was wanting in man, and attach little importance to it. A recognition of its function in health would, however, be of importance to our treatment

of its diseased conditions. That the appendix exercises some influence on the action of the cæcum in digestion is probable, as its mucous coat differs quite materially from that of the cæcum and colon in the arrangement of its capillaries and crypts. Whatever be its function, the mucous membrane of the appendix is certainly liable to catarrhal inflammation, leading to stenosis, accumulation of secretion, distention, ulceration, and perforation, and finally peritonitis, with accumulation of pus and abscess in the right iliac region, especially in the loose connective tissue around the cæcum, a symptom often spoken of as perityphlitis. As surgeons, should we not strive to overcome the early constipation, and the restoration of the bowels, by emptying the cæcum, and favoring increased peristalsis; or, when this fails, promptly overcome the obstruction by an operation?

He then considered the pathological conditions to which the appendix is liable, malformations, misplacements, occlusion by foreign bodies, ulceration, perforation, inflammations, etc., with the numerous consequences upon itself or other organs. Tuberculosis sometimes attacks the glands of Peyer in the appendix. The stenosis of the canal with retention of the secretion not infrequently results in the formation of a calculus, the nucleus of which may be a speck of hardened feces around which the mucus collects, receiving in addition a deposit of phosphate or carbonate of lime.

The symptoms of appendicitis are in the beginning those which indicate a disturbance of digestion, the disease appearing without premonitory symptoms, with griping, vomiting sometimes severe. The pain may be preceded or followed by vomiting, first mucous then stercoraceous. The right thigh is sometimes flexed. The attack may be a single severe prolonged one or may remit. The belly may be tympanitic with variable flatness in the right side, sometimes more prominent than usual; sometimes a tumor is palpable.

The diagnosis, usually difficult, may, when early sought, be arrived at from due consideration of the history, by palpation, revealing imperfect induration in the right iliac region with pain, when the temperature and pulse permanently rise and there are symptoms of peritonitis. Even a diagnostical laparotomy often leaves the patient in a better condition when an appendicitis is neglected.

The prognosis is always grave and the result uncertain.

Under the head of treatment the speaker insisted upon the importance of an early recognition of the condition and the following out of the preliminary treatment such as would be directed to an intestinal catarrh, the administration of five grain doses of calomel, until twenty or thirty are taken, morphia hypodermatically to relieve pain, and a dose of sulphate of soda or magnesia. This in the early stages before perforation is supposed to have occurred. The patient should be etherized for careful palpation. A delay in operating for appendicitis, as in hernia, decreases the chances of recovery.

DR. THOMAS G. MORTON, of Philadelphia, next read a paper on

THE DIAGNOSIS OF PERI-CÆCAL ABSCESS AND ITS RADICAL TREATMENT BY REMOVAL OF THE APPENDIX VERMIFORMIS.

Abdominal surgery can show many brilliant achievements under modern antiseptic methods, but in scarcely another instance does an operation afford its own justification, or when properly timed present such satisfactory results as laparotomy when performed for suppurative appendicitis.

Under the head of pathology and clinical history, the speaker said that it would greatly simplify the subject under discussion if we can first clear up the nomenclature, which it would seem has been greatly confused by the refinements of pathologists and others. We are accustomed to certain distinct terms to express inflammation of the cæcum, of its peritoneal investment, and of the surrounding structures and cellular tissue.

It would seem reasonable that all the niceties of diagnosis between typhlitis, perityphlitis, paratyphlitis, and pericæcal abscess can properly be set aside as without real practical value; since recent pathological researches have demonstrated that as a rule in cases presenting the well-recognized characters of typhlitis, the symptoms are almost invariably due to appendicitis. Exceedingly rare are the cases in which the cause resides in the cæcum. Pericæcal abscess may then, in most cases, be said to mean disease of the appendix vermiformis.

It seems hardly worth while to consider the conventional division of appendicitis into the catarrhal and the ulcerative; for clinically speaking, although an uncomplicated catarrhal condition may exist, there are ordinarily no signs by which it may be recognized.

Inflammation and perforation of the appendix, in most cases, very probably in all, is due to irritation excited by the presence of a foreign body in the organ. It has been shown that the foreign body is commonly a fecal or a phosphatic concretion, or an aggregation of small bodies which have from time to time gained admittance, or the concretion may be composed of epithelium or other constituents aggregated into a hard mass from the ordinary secretions of the parts.

No complete or fully satisfactory classification of the cases of inflammation, perforation, and abscess of the appendix can probably at this time be made; but for practical purposes, a division according to the onset and history of the disease, into the acute and chronic varieties, will probably fulfil all necessary clinical requirements.

In the acute disease the symptoms come on with suddenness and increase in severity, often very early presenting grave characters. Occasionally the disease progresses from first to last, with frightful rapidity, so much so that the patient rapidly enters a condition bordering on collapse. Possibly the extremely acute cases might afford an opportunity for a still further division into the acute and the supra-acute; the latter cases running their course in a few hours.

The close proximity to the peritoneum of such fetid pus as is found in suppurative appendicitis produces very early unusual depression and exhaustion.

In the chronic forms of appendicitis we have recurring attacks or relapses. These are often followed by deposits of lymph which forms a barrier more or less complete, sufficient when perforation takes place to protect the peritoneal cavity at least for a time. But if operative measures are not undertaken or are unduly delayed, such lymph partitions often yield, and the general peritoneal cavity becomes involved and peritonitis results. In other cases, the abscess walls form a distinct pus cavity which surrounds the organ so that when perforation occurs gas and pus form a tumor, of more or less defined

hardness. Such tumors frequently make their way toward the surface, and the superimposed structures become infiltrated and markedly œdematous. In such cases the perforation of the appendix may remain open and a fistule form between the bowel, the abscess cavity, and the external abdominal surface. Several cases of appendicular disease were reported.

As a provisional classification of the diseases of the appendix the author offered the following:

1. Those cases where the appendix and its surroundings become encysted by deposits of lymph, so that a cavity more or less complete is formed, into which the contents of the appendix are received when perforation occurs, while the walls of the cavity afford possibly a complete separation partition which separates it from the peritoneal cavity. These cases are likely to be chronic in their course.

2. Those cases in which an insufficient limiting partition wall has been formed and where the general peritoneum promptly becomes involved. Appendicular ulceration and perforation has been so rapid that sufficient lymph for the production of a partition wall has not been thrown out. This group furnishes the acute cases.

The symptoms of the disease were much the same as those described by Dr. H. H. Smith.

In the author's opinion many attacks of so-called colic are but contractions of the appendix in its efforts to expel foreign bodies so often present.

Actual perforation of the appendix is generally ushered in by intense, excruciating, agonizing pain, which is sometimes relieved by the occurrence of the accident.

Treatment.—He divided the treatment into that of the pre-purulent and that of the post-purulent or suppurative stage. The treatment of the former stage should consist of rest in bed, restriction of diet to nourishing liquids, hot poultices or fomentations frequently replaced upon the parts, perhaps local depletion and the hypodermatic administration of morphia to control pain. The bowels should be kept open and free from the accumulation of gas or feces by the administration of saline laxatives and enemas, perhaps with the administration of turpentine with the latter. Intense pain is as often an indication for operation as for the administration of morphia. Long continuation of the symptoms, or relapses would be strong indication for surgical interference. Tedious recovery, relapse, or recurrence points to danger to the patient from liability to general peritonitis or perforation at any time. They would point further, as a rule, to the appendix as the source of irritation and danger—indeed, in man that worse than useless appendage must be regarded as the root of most evil in the region under consideration. After suppuration operative measures are demanded. Many risks are to be taken rather than those of purulent peritonitis. Later all available diagnostic skill must be exerted to detect a pericæcal abscess, should it point in an anomalous situation. We must ever bear in mind the surgical rule always to attack pus at its source, if possible.

The Operation.—On account of the nature of the case there is rarely any opportunity for preparatory treatment for the operation. Asepsis should be rigidly observed at the time of the operation. The aspirating or exploring needle should never be used for exploring purposes; it is dangerous. The patient supine and extended, the field of operation is thoroughly cleansed, shaved, and washed with bichloride solution 1 : 1000, and finally with ether. The line of incision is slightly oblique or vertical and lateral. The lateral incision can be made of less size and directly over the appendix. It has many other advantages. It should begin at a point about an inch above Poupart's ligament and to the outer side of the right linea semilunaris, to be continued upward in a vertical direction or outward and upward and carried down until pus, cæcum, or peritoneum is reached. From numerous dissections, the speaker had found that the appendix is normally placed immediately under a point two inches distant from the right anterior superior spinous process on a horizontal line drawn from this process toward the median line of the body.

When the abscess cavity is reached gas is usually first discharged. The wound can then be enlarged, if necessary, in order fully to expose the cavity underneath. Irrigation, with boiled water at a temperature of 105° to 110° and careful sponging, now permit a clear view of the surroundings of cæcum and appendix. The latter is usually the seat of trouble. It would be well to excise it in any case whilst we have the chance; for any cæcal trouble would be likely in time to excite trouble in the appendix. Without a doubt it should be so treated if found inflamed, perforated, or harboring foreign bodies. This can best be accomplished by ligaturing it as close as possible to its cæcal attachment, with a strong silk thread, and cutting it off beyond the ligature. Cæcal perforations, if found, should be cleaned and curetted and then closed with Lembert's suture; even ulcers which have not perforated might thus be turned into the bowel lumen. If the general peritoneal cavity has not become involved, the walls of the abscess should be gently curetted, washed with a mercuric solution, 1 : 1000, and a large drain carried to the bottom of the wound and brought out at its most dependent part. The external wound should, with the exception of a suture or two, be left thoroughly open and lightly filled with an antiseptic dressing. A rope of absorbent cotton should be placed in the glass tube, a large mass of cotton should cover the abdominal and wound surface. A four-tailed bandage completes the dressing.

If the general peritoneum has become involved, the entire abdominal cavity must be washed out with hot distilled water, temperature of 105° to 110° F. or bichloride of mercury solution 1 : 10,000. The intestines should be cleansed with a sponge, and a foreign body, if that has been the cause of the trouble, searched for. Should peritonitis be far advanced, the intestines must be withdrawn and all adhesions separated with the finger or knife. During the process of cleansing and before they are returned to the abdomen, they should be carefully protected with towels wrung out of hot water. In all cases of general peritonitis a glass drainage tube must be carried to the bottom of the pelvic cavity and kept in working order by ropes of absorbent cotton which act by capillarity. Should the cause of morbid action be impaction of feces or a foreign body, in the cæcum itself, they must either be excised or urged along the bowel by prudent force. It can properly be said that there is no fixed time for operation in cases of pericæcal abscess. When symptoms strongly indicating the presence of pus are seen it is far safer to operate at once than to wait. Delay is prognostic of the gravest consequences to the patient, the prognosis growing worse every hour that the operation is postponed.

The after-treatment resolves itself into the relief of pain and keeping the wound open and in a thoroughly clean aseptic condition. The rules of abdominal surgery govern the treatment.

DR. J. MCFADDEN GASTON, of Atlanta, read a paper on

THE APPENDIX VERMIFORMIS; ITS FUNCTIONS, PATHOLOGICAL CHANGES, AND TREATMENT.

He first reviewed the anatomical characters of the organ in much the same manner as those who just preceded him. He did not regard it as a safety valve for the cæcum, but rather as a loop-hole for the entrance of matters prejudicial to it and the adjacent structures. He thought also that the appendix performed an active part in the production of the fecal odor, without, however, supporting his view.

He reiterated a former statement that he could not acquiesce in the view of pathologists which attributes the degeneration of the cæcum and appendix to a low state of vitality in their tissues, but on the contrary he held that they are highly vitalized and that it is from being overtaxed in the performance of functions connected with the excrementitious process that they are so subject to disease. Although looking upon the appendix as worse than useless, as already stated, the author held a very different view of the harmlessness of its removal, since in dogs experimented upon by himself, the operation was generally followed by death, from shock, within twenty-four hours; whereas, removal of the ileum was followed by no such untoward symptoms. Under the head of treatment nothing was added to what had been stated by the previous essayists.

WEDNESDAY, MAY 9TH.—MORNING SESSION.

DR. JOSEPH RANSOHOFF read a paper on

THE CÆCUM AND APPENDIX; THEIR RELATIONS TO HEALTH AND DISEASE.

DR. S. L. MCMURTRY, of Danville, Ky., followed with the report of

A CASE OF TYPHLITIS WITH PERFORATION; LAPAROTOMY; RECOVERY.

Occurring in a young physician, who for several months had suffered from occasional attacks of colic, not severe but coming on without warning, attended with nausea and vomiting, and attributed to indigestion. The intensity of the pain with its location, excited suspicions of renal colic in the minds of his attendants. Morphia was administered freely, and laxatives for the constipation which existed. January 23d, a slight almond-shaped induration was first detected, dull to percussion. The induration increased until it became an oblong, sausage-shaped tumor in the right iliac fossa. There was moderate fever. On the evening of January 26th hemorrhage of the bowels began, thirty-two ounces of blood being passed. Hiccough was added to the other symptoms, which, with increased frequence of the pulse, tympanites, and serious vomiting established the diagnosis of cæcal or pericæcal inflammation. On the morning of the 27th, cold perspiration, rapid pulse, and cold extremities were interpreted as signs of perforation and impending collapse.

When he saw the case on the morning of the 27th, the patient was in the condition just described, with frequent vomiting of green serous fluid, characteristic of peritonitis, and bloody stools. The tumor, distinct in outline, was readily recognized as the caput coli. Immediate operative measures were determined upon. The lateral incision immediately over the tumor was made under thorough antiseptic precautions. The peritonitis was found to be limited, but recent, severe, and bearing evidences of spreading. The vermiform appendix was normal. Upon the anterior and external surface of the cæcum were two gangrenous perforations, one somewhat larger than a twenty-five cent piece, the other a little larger than a ten cent piece; both black and round in shape. The larger was complete, the smaller scarcely so. With the scissors the edges were trimmed off, the rents closed with five and three silk Lembert sutures respectively, passed beneath the muscular coat but not into the mucous. The toilette was made with scrupulous care. Immediate improvement followed, and the recovery was complete.

At the close of his report, he briefly reviewed the history of the operation he had performed, as well as that of affections of the cæcum. With reference to the time for operation, he said that when pus forms in the retro-peritoneal tissue and is making its way toward the surface delay may facilitate its access by allowing the peritoneum to be pushed aside; but this advantage does not counterbalance the benefits of an exploratory incision, which should be resorted to as soon as grave symptoms suggest it. The aspirator is unreliable and unsatisfactory as an exploratory means in these cases and its use is attended with danger of peritoneal infection. The exploratory incision is much more free from danger and more satisfactory. As soon as the diagnosis of intra-peritoneal inflammation is made, abdominal section should be performed. To wait, administering opium, is neither conservative nor surgical. In the case reported, the speaker thought the success due to the early recognition of the lesions by the gentlemen in attendance, and the prompt acceptance of the proposed operation by the patient.

DR. ANDREWS, of Chicago, objected to the too speedy resort to laparotomy in these cases. He reported a case, somewhat similar in character to that reported, in which he had performed the operation, but only after a fecal fistula had formed. It was a perfect success so far as the operation was concerned; not, however, preventing the patient from succumbing to Bright's disease a short time after.

DR. S. W. GROSS, of Philadelphia, remarked with reference to the propriety of performing laparotomy in cases of perforating appendicitis, cæcitis, etc., that there are cases in which the abscess points posteriorly and opens behind the cæcum. Of course, no surgeon would think in a case like that of opening the abdominal cavity. But he thought that in all cases in which there is perforation of the cæcum no surgeon will wait very long before he does laparotomy. We are liable at any time to meet with a case of walking typhoid; intense pain is felt in the iliac region, which pain is circumscribed. There are elevation of temperature and increase of the pulse-rate. In such a case he would not hesitate to lay open the abdomen. He would not wait for any other symptom to appear. He would infer that perforation had

occurred and that the symptoms were the general symptoms of peritonitis. He thought that if we neglect these cases the patients will almost certainly die; and on the other hand that if we operate we will almost surely save them.

Dr. Nelson, of Connecticut, reported a case of a young man who had been sick about ten days, pulse 100, temperature about 100° F.; skin dry, sallow and dusky; tongue somewhat coated. He had some pain in the right iliac region. A tumor presented, which showed evidences of pointing in two or three places. He aspirated, found pus, evacuated it and the patient had no further trouble. He thought the case has important bearing on the advice to operate in all cases and early. He reported also another case in which there was a spontaneous evacuation of a large quantity of fetid pus, followed by a relief of symptoms resembling those of perforating appendicitis. There is a certain degree of danger, he said, in these operations that we open not only the abdomen, but also the intestine, and he thought there was some danger of a fistulous opening remaining, although he could not recall such a case. He did not recognize so great an amount of danger associated with the introduction of a needle as belongs to the making of an incision with the knife.

Dr. Weeks, of Maine, remarked that the point of importance is the line of incision in the cases in which laparotomy is indicated for perforation of the appendix and cæcum. There exists to-day a doubt as to the best point of incision. From his own experience, particularly that obtained from several cases seen within the last few months, he expressed a preference for the incision directly over the cæcum, by which the operator comes directly upon the seat of trouble. With reference to the point at which the cæcum may be found, he regretted that the anatomies and surgeries are so obscure. The incision should begin one inch inside and about two inches above the anterior superior spinous process.

Dr. Dixon, of Kentucky, reported a case in which he had operated last February, by the lateral method. He found a cavity filled with fetid gas and pus, and in the bottom of it a large perforation of the intestine. After cleansing the cavity as thoroughly as possible and ligating the appendix, until then following as nearly as possible the rules laid down by Smith, the incision was closed by Lembert's suture, a drainage tube being left in the opening.

Dr. H. H. Mudd, of St. Louis, remarked that the difficulty here, as in all cases of abdominal operation for obstruction, is in the diagnosis and the determination of conditions which demand, or do not demand, operative procedure. Ileo-cæcal obstruction affords almost as good an opportunity for diagnosis as any abdominal condition that we have. We have three sources for the formation of a tumor in this region, the accumulation of fæces, the accumulation of gas, and the infiltration of serous fluid about the walls of the intestine. Now if we have symptoms of obstruction preceding the final development of a tumor, we have something to guide us, and if supervening upon this we have a sudden acute attack of pain, which is persistent, which is accompanied by increased distention, which is accompanied by the usual symptoms of perforation, then we have conditions which favor operative procedure at once. But if we have developing slowly with these symptoms, a tumor, it may be the result of infiltration of serum in the cellular tissue, then we have a condition in which we should wait for some time. He had seen a number of those cases recover by simply watching, and he had seen others get well after a laparotomy.

He reported also a case of abscess in the lumbar region from which a lumbricoid worm escaped, followed by speedy recovery. He had seen a case last week in which he made a laparotomy under rather unusual circumstances. The patient had had recurring attacks of pain; had been in the hospital eleven weeks with symptoms of obstruction, presenting a tumor a little to the right and near the median line. Folds of the intestine overlay the tumor, and it was possible to hear the gas and fluid gurgling upon palpation. Rectal examination revealed a soft tumor and fluctuation was easily elicited. He thought he had an extra-peritoneal tumor. He made a laparotomy and found a large abscess in the peritoneal cavity, opened it and drained it. The post-mortem, three days after, revealed these conditions: The colon and a loop of the small intestine were in process of uniting, the colon being in front of the tumor. Three inches of small intestine surrounded this mass held down in the pelvic cavity, their lumen being obliterated by the distention of the abscess and the pressure caused by this abscess, which had been occasioned by a long-continued perityphlitis and appendicitis. At no point did he think that this abscess could have been reached without perforating the intestine itself. The question which had troubled him most, and he thought it a practical question, was: Have we or not in perityphlitis, typhlitis, appendicitis, etc., a better chance to interfere after suppurative peritonitis has developed? We may be able to determine that we have a local peritonitis, but do not know whether it is suppurative or not, and the question arises, Does our patient have a better chance for recovery after it has become suppurative? In regard to the incision, he was not so sure that the inguinal region is the best line. In many cases it will answer, but not as a rule, because there is no part of the intestine so frequently displaced as this one.

Dr. J. McF. Gaston, of Atlanta, inquired whether the cæcum was seriously involved in the trouble, because he considered this quite different from mere perforation and extravasation into the peritoneal cavity. He did not understand whether there was, in this case, any precaution against permitting the fecal matter to gain access to the peritoneal cavity. If feces had thus passed into the peritoneum, it would be highly proper thoroughly to wash out the cavity.

Dr. McMurtry replied that his was a typical case of perforative peritonitis. This was a case of septic peritonitis, arising from the perforation. Peritonitis is a septic disease. Of course, it was a case of infective peritonitis from the infection that was in the bowel. It seemed to him that confusion had entered the discussion from the fact that no distinction had been made between laparotomy and the opening of an abscess. If you have perforation, and an abscess forms in the tissue, opening that is not laparotomy.

Dr. J. Price, of Philadelphia, opposed the use of the aspirator and trocar. With them we make a small opening, drain off the accumulated matter, but see nothing. Surgeons who have had no training have naturally some fear of laparotomy. We have, however,

learned to regard it as an operation which is attended with comparatively little danger. At present there is nothing so simple as dealing with pus. He had no fear of deluging the peritoneum with pus. With regard to diagnosis, he stated that he would prefer to depend upon the diagnosis made by the general practitioner, than that of a surgeon, in affections of this region.

DR. E. M. MOORE, of Rochester, stated that he had listened to the papers with intense interest, but he had failed to hear one or two things which come within the experience of every surgeon. Now, is it not the experience of every one to have cases of what used to be called perityphlitis—attacks of pain in the right side, coming on day after day and getting well, and the rule is that they get well? He had seen it over and over again, and his experience has always been that if the inflammation was sufficiently local it was sure to get well. Did he understand Dr. Price to say that the operation of cutting into the peritoneum is absolutely free from danger? He must confess that he was utterly astounded! He had heard it stated that immunity pertained to diagnostic laparotomy, but that was not stated here. He then referred briefly to the differentiation of phantom and other tumors of the abdomen from affections of the cæcum, and concluded with the statement that he had not found the operation of laparotomy so innocent as it is claimed by some.

DR. MCLEAN, of Ann Arbor, remarked that it seemed to him bold to say that the peritoneal cavity can be opened with impunity. It would be a mistake to permit the dictum to pass from the Surgical Section of this Association that the abdominal cavity can be opened with perfect safety.

AFTERNOON SESSION.

DR. R. HARRY REED, of Mansfield, Ohio, read a paper on

INTESTINAL OBSTRUCTION IN ITS SURGICAL ASPECTS.

The aim of the paper was to prove by the presentation of cases, that pseudo and "veracious" obstruction of the bowel exist, both ante-mortem and post-mortem. A number of cases were reported, in each of which he had elicited all the ordinary symptoms of intestinal obstruction, and yet in not a single case was there any real obstruction. Two of the cases were not relieved by surgical interference, and collapse and death were the termination.

GENERAL BUSINESS.

DR. S. W. GROSS moved that hereafter, when titles of papers to be read before the Section are forwarded to the Secretary, they shall be accompanied by a set of conclusions drawn from the paper, and that in case this requirement is not complied with, the title of the paper shall not be published as a part of the programme.

Adopted.

OFFICERS FOR THE ENSUING YEAR WERE ELECTED AS FOLLOWS:

President.—N. P. Dandridge, M.D., of Cincinnati, Ohio.

Secretary.—W. O. Roberts, M.D., of Louisville, Kentucky.

DR. CHARLES B. PENROSE, of Philadelphia, presented a paper on

INTESTINAL OBSTRUCTION IN ITS SURGICAL ASPECTS.

Surgical operations are necessary in intestinal obstruction for two purposes—for diagnosis and for treatment. The inefficiency of the treatment now generally employed is shown by the mortality following obstruction. This is a mere mechanical occlusion of the alimentary tract, which, theoretically at least, is always amenable to some form of treatment. The mortality of all kinds of acute obstruction is nearly one hundred per cent. when treated by medicinal means alone; and according to Rockwell's table, published in the *Annals of Surgery* for February, 1888, the mortality in all cases of intestinal obstruction which were submitted to operation, between the years 1877 and 1887, was forty-six per cent. The mortality after medicinal treatment is due to the inability of drugs to overcome the mechanical occlusion, and the high mortality after surgical treatment is due to the too great delay of the operation, which also renders laparotomy for intestinal obstruction more fatal than the same operation for other cause. Enterotomy and colotomy once frequently resorted to, are now rarely employed for intestinal obstruction. They are safe operations, and generally empty the intestines; they do not, however, relieve the obstruction. They are made in the dark; the opening may be made below the obstruction; the jejunum may be caught and the patient perish from inanition; a gangrenous loop of intestine may be left in the abdomen, or a cancerous mass, and cause death. As primary operations they are rarely demanded.

He preferred the median abdominal incision in laparotomy for obstruction, owing to the liability to anomalous intestinal localization, the difficulty of locating the obstruction, and the possibility of multiple obstructions. One of the most useful guides to the operator, in his search for the obstruction, is the finding of a loop of the intestine which is more congested and darker than its neighbors. The distended loop should be followed from the stomach toward the rectum. Collapsed loops of intestine will also lead in the opposite direction to the obstruction. These signs failing, the systematic search should be begun; hernial pouches being usually first examined.

The various methods for relieving the obstruction were next reviewed. The formation of an intestinal anastomosis, an old method recently brought into notice by Senn, has been performed but twice on man, with fatal result. The improved technique introduced by Senn promises to bring it into successful application. If an obstruction cannot be relieved or resected, an artificial anus must be formed. The operation of resection of intestine was briefly described, as performed by Treves. The production of an artificial anus, after resection, was carefully described. With reference to the operation, the speaker said that he admitted that an artificial anus is a misfortune to be avoided if possible, and that the ideal method, in case of obstruction, where resection was necessary, is immediately to restore the continuity of the intestine; a procedure not always attainable. He did not think that improved technique would ever do away with the production of an artificial anus. The method of closing an artificial anus was next described by the essayist; then the closure of the external abdominal incision.

Referring to the production of artificial anus, for ob-

struction, he said that its value is so great that he would urge its use not only for the peritonitis and distention following strangulation of the intestines, but also in peritonitis or intestinal paralysis of any other origin where there are great abdominal distention and fecal accumulation. Continual irrigation of the peritoneum, its application, and the method of its performance were made the subject of especial consideration.

In conclusion, he asked attention to the following points:

The use of an exploratory laparotomy in cases where the diagnosis of intestinal obstruction is doubtful. The necessity of early operation in the treatment of this condition. The necessity of a temporary artificial anus after resection for obstruction. The value of a temporary artificial anus as a means of avoiding subsequent obstruction when there has been great abdominal distention and fecal accumulation. The value in some cases of continued irrigation of the peritoneal cavity.

Dr. N. Senn, of Milwaukee, then read, by abstract, a paper on

RECTAL INSUFFLATION OF HYDROGEN GAS AS AN INFALLIBLE DIAGNOSTIC MEASURE IN THE DETERMINATION OF PERFORATION OF THE INTESTINE, ETC.

(See page 569.)

During the reading of his paper, he made three experiments in demonstration of his method of determining the presence of intestinal perforation. In the first, a dog was thoroughly anæsthetized, hydrogen gas was then made to enter the bowel through the anus by being forced from a four gallon balloon through a rubber tube attached to a nozzle like that of the ordinary fountain syringe. A weight equivalent to about one hundred and fifty pounds was placed upon the balloon. A second tube was passed into the œsophagus, and in an incredibly short time the hydrogen escaping from the œsophageal tube was ignited from a spirit lamp, demonstrating that the gas had been forced through the entire length of the alimentary canal. The second experiment was also made upon a dog thoroughly anæsthetized. An incision was made in the abdominal wall a little below and external to the umbilicus; a loop of intestine, the small intestine, was withdrawn and an incision made into it and the bowel returned. The hydrogen was then forced into the rectum, and in a very short time was ignited as it escaped from a tube inserted into the abdominal wound. Finally, the same demonstration was made upon a dog, under anæsthesia, after receiving a pistol-shot wound perforating the intestine. Each of the demonstrations was a perfect success.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, May 1, 1888.

The President, George W. Jacoby, M.D., in the Chair.

Dr. Leonard Weber presented a paper upon

PARALYSIS AGITANS, WITH CASES.

The disease had been first described by Parkinson in 1817. Charcot had differentiated it from disseminated sclerosis. Progressive tremor and muscular weakness affecting first one limb and subsequently spreading to other limbs were its chief symptoms. According to Charcot, the head was always respected. There was apparent diminution of muscular force, and in well-advanced cases movements were slow and uncertain. There was loss of the faculty of equilibrium. In trying to walk the patient would run, appearing to be running after his lost centre of gravity. There was bending of the body to a stooping posture and an immobile facial expression with a fixed stare. Death occurs from marasmus or intercurrent disease. The onset was insidious, a hand, a foot, or even a thumb had been first affected. The crossed form was rare, and the hemiplegic form was more common than the paraplegic. Charcot referred to cases in which pain had been the first symptom, tremor following later on. Deglutition was not interfered with, the bladder and rectum but seldom. There might be annoying cramps, but contractures did not occur. Deformity might be present, giving to the hands the aspect of arthritis deformans. Glycosuria had been noted. This complication had been present in a case of his own. In an advanced stage there was disturbance both of thought and action. Neuralgias were present with a sense of fatigue and restlessness, requiring frequent change in position. There was a subjective feeling of heat.

Marked melancholia or general hallucinations may be present with even maniacal attacks. Remak had differentiated a cerebral and spinal form. In two of his own cases cerebral, and in two others spinal symptoms had predominated. Nothing definite to account for the tremor had been found in either the brain or cord. It is a disease which affects the lower strata of society particularly, and men rather than women. It is a disease of advanced life, though Meschede has reported a case in a boy of twelve years, where it had developed after a kick in the face by a horse; and Duchenne one in a man of twenty. It is said to be more frequent among English and American people than among those of other nations. Powerful emotional and moral shocks have produced it, also irritation of the peripheral nerves by traumatism. Prolonged damp cold is a cause; also, in the reader's opinion, sexual excess. The reader had not observed that syphilis had anything to do with its production. Heredity is said not to be a factor, but in one of his own cases the patient's father and two brothers, and in another one brother, had been affected.

Arsenic, ergot, and nitrate of silver have no retarding action. The comfort of the patient may be increased by using Brown-Séquard's bromide mixture, leaving out the iodide of potassium. Hyoscyamine had not been of any value in the reader's experience, producing head symptoms and even maniacal attacks. He had used the amorphous preparation in one-tenth grain doses. Antipyrin in fifteen to twenty grain doses gave rest at night in some cases; chloral, too, had been useful, but the effect of both had been transitory. He had found paraldehyde superior to either as a hypnotic in these cases. It was given in emulsion, fifteen to thirty grains to a dose. It did not affect the stomach, did not weaken the heart, and did not lose its efficiency by use. The galvanic current relieves the feeling of fatigue. Tepid half baths with cold affusions to the head and spine are even more effective and prompt. The reader has had twelve cases, five of whom had been under his

care sufficiently long for study. He briefly referred to these cases.

Case I. was a man of seventy years, in whom the disease had existed for twenty-four years. The patient is still able to get about. The disease was produced by cold.

Case II. was a woman of seventy years, first seen by the reader in 1884. This patient was a very cultivated lady, with fine intellect, and a great knowledge of men and affairs. The disease dated from 1876, and an occasion upon which she had received news of the illness of a loved daughter. The expression of face in this case was markedly sad and immobile. There was little neuralgia, no spastic paralysis, and no contractures. A peculiar feature was atrophy of the epidermis of the hands, forearm, feet, and legs. Death occurred in 1887 from pneumonia. Nightly suffering had been in this case relieved by paraldehyde during six months.

Case III. was a man of fifty-three years, a German, addicted to drinking and smoking in excess. The disease had existed for seven years and glycosuria was present. The weight, which had been three hundred and twenty pounds, had been reduced, but not below two hundred and eighty pounds. Œdema of the legs had been present in this case for six months. Paraldehyde in a dose of thirty grains at bedtime gave a good night's rest.

Case IV., a German, aged sixty-three years, was a market dealer, presenting as causes for his illness exposure to rheumatic influences connected with his business, and sexual excess. The right hand had been first affected, and in the course of the following year the arm and shoulder. The right leg had been seized during the last six months. There was paræsthesia but no neuralgia in this case.

Case V. was a German, aged seventy-two years, whose father and two brothers also suffered from the disease. The left upper and lower extremities only were affected, thus differing from the usual hemiplegic form, which affects the right side. It was to be remarked, however, that this patient was left-handed. The shaking was violent in this case. The patient was easily excited, and suffered with vertigo and headache.

DR. C. L. DANA felt that the obscure points of pathology and treatment should receive consideration. We do not know the nature of the disease nor how to cure it. It was his opinion that paralysis agitans is a degenerative disorder of the voluntary motor system. The sensory symptoms and the mental inquietude are explained by the close relations between the motor and sensory centres. The speaker had had twenty cases under his own observation and had seen thirteen others in the Bellevue out-door department. 2 had been between thirty and forty years of age; 5 between forty and fifty; 13 between fifty and sixty; 9 between sixty and seventy, and 4 between seventy and eighty. Of 31, 20 had been males and 11 females. Of 34 in whom the race had been mentioned, 26 had been Irish; 6 German; 1 Russian, and 1 born in the United States. The Celtic element had thus greatly preponderated, a fact not entirely explained by the large percentage of Irish attendants at this dispensary. The disease seemed increasing in frequency. From 1876 to 1879 the Bellevue dispensary had presented but 7 cases of paralysis agitans in a total of 2300 cases; while from 1885 to 1888, 11 were recorded out of a total of 2200.

He could corroborate the statement that rheumatic influences are active in its production. He too had had a case complicated with diabetes, and he had had 4 cases in which the head had been affected. He thought this not uncommon. It might be shown in the muscles of the angles of the mouth and tongue. In treatment, hyoscyamine had given the best results. He had used, however, not the amorphous but the crystalline form in $\frac{1}{100}$ to $\frac{1}{60}$ grain doses. Given thus, it had never failed to exert a palliative action.

DR. M. A. STARR called attention to a monograph upon paralysis agitans, by Anton Heimann, published in Berlin six weeks ago, and only last week received here, in which the theory of cortical origin referred to by Dr. Dana was supported by the report of a case. In this case, which had developed under the writer's observation, the four limbs were affected. The lesion could be located as hemorrhage into the internal capsule. Coincidently the paralysis agitans had ceased upon the hemiplegic side. The inference was that the paralysis agitans was due to impulses from the cortex through the internal capsule, and that the irritated cortical centres were cut off from the muscles by the injury. Gowers had demonstrated, too, that the rate of vibration in paralysis agitans was 8 per second. It is known that irritation of the cortex, of a moderate degree, in monkeys, produced tremor of the muscles characterized by 8 vibrations per second.

In regard to the extension of the tremor to the head: while Charcot had stated that the head never was affected, the majority of German observers among whom were Seeligmüller, Strumpell, and Heimann, added to Gowers, in his new book, had found the head affected in a considerable proportion of cases. The speaker had had 7 cases of paralysis agitans under his care during the last two years. The tremor had affected the head in two of these cases. He could join Dr. Dana in his endorsement of hyoscyamine, given in the crystalline form and $\frac{1}{100}$ grain doses. This remedy had had a good effect in all of the cases which he had seen.

DR. L. C. GRAY considered the origin of the tremor very obscure. He recalled a case presenting the typical symptoms of disseminated sclerosis. The patient was under observation in the hospital for a year and a half, and the post-mortem showed nothing but a cortical meningitis, no lesion in the brain or cord. The speaker did not agree with Dr. Weber that the diagnosis between paralysis agitans and disseminated sclerosis was in all cases easy to make. Voluntary tremor might be present in both, and in the earlier stages diagnosis might be impossible. One of the most typical cases which he had known had had movements of the head. This case was that of a woman of seventy-five years, who had had paralysis agitans for thirty years. It had started one day, when on a ferry-boat, upon seeing a baby fall into the water, and buoyed up by its long clothes float down the stream. Upon getting home she had found her upper lip quivering like that of a rabbit. This had been the commencement of a widespread affection.

DR. GRAEME HAMMOND had seen three or four typical cases of face tremor. In a case of which he had the brain, the paralysis agitans had been present for eight years. There had been no change in the voice, but during the last year there had been paralysis of the tongue, lips, throat, lungs, and heart, which finally

terminated life. Post-mortem there was absolutely nothing found; no softening in the medulla and no change in the cortex. A few years ago, the speaker had collected all the reports of autopsies which he could find of cases of athetosis, chorea, ataxic tremor, and paralysis agitans.

Where any lesion was found it occupied the position of the gray nerve cells of the optic thalamus, corpus striatum or cortex. Where spastic spasm was present, either combined with the tremor, or alone, the white fibres of the internal capsule were affected as well. Where spastic spasm was not present, the lesion did not affect these tracts.

Dr. Rockwell had had two or three cases under forty years. He thought that the younger cases responded best to palliative treatment. He recalled a case from Peru which he had treated with hyoscyamine $\frac{1}{100}$ grain dose and the galvanic current. This patient had returned to his home apparently cured. The symptoms returned, he came back, was again subjected to the treatment, was again cured and had remained well for a year.

Dr. Sachs regarded Dr. Heiman's argument as ingenious but not conclusive. Hemorrhage into the internal capsule is the commonest cause of hemiplegia in middle life. Hemiplegia is not very uncommon in the course of paralysis agitans and it does not interfere with the tremor in the usual case. In regard to the involvement of the head, he had a case now under treatment in which the head was affected. He used hyoscyamine in the crystalline form, and had found it so reliable as a palliative that no other drug was required in his experience. Even in severe cases the tremor was lessened by means of it.

Dr. Petersen referred to the fact that when in the Poughkeepsie Asylum while administering the hydrobromate of hyoscyamus for headache he had incidentally relieved the tremor of paralysis agitans.

Dr. Weber thought that Charcot's rule for the involvement of the head would be found in the main correct. General shaking would move the head, but tremor of the intrinsic muscles he thought rare. In regard to Dr. Rockwell's case, he would hesitate about pronouncing a cure. Paralysis not unfrequently presented intermissions of a year or two but would ultimately return. In regard to the hyoscyamine, he had tried it some years ago; possibly the quality had not been as good as that now obtained. He would again give it a trial in the crystalline form.

CORRESPONDENCE.

EXSECTION OF EXTRAUTERINE PREGNANT CYSTS.

To the Editor of The Medical News,

Sir: I notice that in your leading article of March 24th you say: "Mr. Tait denies that a diagnosis can be made prior to rupture, which may be correct so far as his personal observation has extended." Permit me to correct this, it is not what I have said, it is only what I am made to say by a well-known American writer on the subject, who appears to delight in misrepresenting me. What I do say is, what Campbell and Parry, and many others have said, that extrauterine pregnancy can rarely be diagnosed before the period of rupture, because we rarely see the cases before that time. The patients have so few symptoms that they do not seek assistance. I have now seen nearly seventy cases, and have seen only one before the period of rupture. The patient had no symptoms which indicated pregnancy, but I diagnosed occlusion and distention of a tube, and I advised its removal. In three days it burst, and the bursting I diagnosed, but as a case of burst pyosalpinx, I only discovered the differential mistake at the operation.

I am, etc.,

Lawson Tait.

Birmingham, May 1, 1888.

OLIVE OIL IN THE TREATMENT OF GALL-STONES.

To the Editor of The Medical News,

Sir: In reading the article on "Gall-Stones or Soap?" in your issue of May 12, 1888, one is struck by the fact that the patients were relieved of pain in the cases treated by Dr. D. W. Prentiss, as was also the case with those mentioned in the article by Dr. Thomas W. Streets, U. S. N.

A few weeks ago I was called to see an officer who was laboring under an attack of hepatic colic, and who is subject to such attacks; remembering my friend, Dr. Streets' report, I gave a tumbler of olive oil, and put the patient under the influence of chloroform at once. When the chloroform passed off, I gave 15 grains of bromide of sodium every three hours, and he slept comfortably, with short intervals of wakefulness, for twelve hours. During the day two more doses of olive oil were given, each containing half a tumbler of oil. The oil did not act upon his bowels, and it took a good deal of Hunyadi-Janos water to move them; no gall-stones or other concretions were found in his stools, and he made a rapid recovery.

The point I wish to call attention to is that after the first dose of oil the patient was relieved of pain, and the delirium which had existed passed away. I omitted to state that a hot water bag was kept over the seat of pain for some hours.

His former attacks were of long duration, and he then found gall-stones in his stools. Does it not seem as if the olive oil has some specific action in these cases?

Yours truly,

A. A. Hoehling.

NEWS ITEMS.

Are Permanent Solutions of Bichloride of Mercury a Necessity?—The *American Druggist* for March, 1888, writes that, in connection with the answer to a query, relating to the stability of solutions of corrosive sublimate intended for antiseptic purposes, it seems fair to say that there may be good reason to doubt whether it is desirable to render the solution permanent. It is not improbable that the efficacy of this preparation consists very largely in the nascent chlorine liberated during the conversion of the bichloride into calomel; and while, from a pharmaceutical point of view, it may be more satisfactory to have a solution which does not deposit the calomel, therapeutically such a solution may be the least desirable.

An Analysis of Preparations for Bleaching Hair.—The *American Analyst* of March 1, 1888, reports that recent analyses have shown that of the preparations for bleaching the hair to "the delicate golden shade so much admired by the court circles of Europe, and the best society of the United States," to quote from a label on one of the bottles, all depend for their action upon the decolorizing and corrosive influence of nascent oxygen or nascent chlorine. The bases used in the various nostrums for this purpose are peroxide of hydrogen, aqua regia, and bronzer's acid. Peroxide of hydrogen is the mildest and most innocuous of the trio named. It is a colorless liquid which destroys the natural color of the hair, and which, if used long enough, turns it an unnatural grayish-white. It is rather expensive, and is, therefore, used much less than the two other acids. It produces sores upon the scalp, and gives rise to skin complaints that resemble tetter, salt-rheum, and scald-head. The two acids are equally vile. They attack and eat the hair and skin alike. The former they partly bleach and partly burn to a handsome gold color; the latter they stain to about the same hue as does a light application of iodine. Besides the dermatologic troubles named, they cause maladies hardly distinguishable from eczema and erythema. One curious disease that they cause is an inflammation of the cells of the hair follicles. The cellular walls break down and lymph, and often blood is extravasated in appreciable quantities. All three bases produce falling out of the hair and premature baldness.

The Suppression of Quack Medicines in Germany.—Kultusminister von Gossler recently announced his intention of securing the coöperation of the Imperial Government in suppressing all advertisements of secret remedies throughout the German States.

Honors to von Brücke.—The Emperor of Austria has conferred on Hofrath Professor E. Brücke, Professor of Physiology in the University of Vienna, the Order of the "Ehrenzeichen für Kunst und Wissenschaft." This distinction was created by the Emperor last year, and has hitherto, as far as medical men are concerned, been conferred only on Hyrtl.

The Decrease in the Prices of Drugs.—The following figures are taken from an old price-book of one of the leading drug stores in this city, and show the great decrease in price of many medicines in recent years: Acid hydrocyanic, 25 cents a drachm; acid succinic, $300 an ounce; alcohol, 25 cents a pint; brucine, $50 an ounce; delphine, $80 an ounce; emetine, $36 an ounce; linium usitatissinium, 17 cents a pound; morphine, $50 an ounce; narcotine, $100 an ounce; sulphas cinchonæ, $10 an ounce; sulphas quininæ, $1.50 a drachm; hatcase (oiled silk), $1.50 a yard; Prussian blue, 25 cents an ounce. Tinctures were 6 or 12 cents an ounce; ointments, 12 cents an ounce; and syrups, 6 cents an ounce by weight, or 8 cents by measure.—*Popular Science News*, April, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 15 TO MAY 21, 1888.

TOWN, F. L., *Major and Surgeon* (U. S. Army).—Post Surgeon at the Post of San Antonio, Texas, will take charge of the office of the Medical Director at these Headquarters, and perform the duties of that officer during his absence on leave.—*S. O. 51, Department of Texas*, May 11, 1888.

BROWN, HARVEY E., *Major and Surgeon*.—Directed to continue on duty at Fort Barrancas, Florida, until further orders.—*S. O. 115, A. G. O.*, May 18, 1888.

WYETH, M. C., *Captain and Assistant Surgeon*.—Will be relieved from duty at Fort Barrancas, Florida, at the expiration of his present leave of absence, and will report in person to the commanding officer, Fort Huachuca, Arizona, for duty at that post.—*S. O. 115, A. G. O.*, May 18, 1888.

KNEEDLER, WILLIAM L., *First Lieutenant and Assistant Surgeon*.—Will accompany, from Fort Snelling, Minnesota, that portion of the Twenty-fifth Infantry destined for Fort Shaw, Montana Territory. From Cascade, Montana Territory, he will accompany the portion of the Third Infantry *en route* from Fort Shaw, Montana Territory, to Fort Snelling, Minnesota.—*S. O. 40, Department of Dakota*, May 14, 1888.

WOOD, LEONARD, *First Lieutenant and Assistant Surgeon*.—Leave of absence extended two months.—*S. O 114, A. G. O.*, May 17, 1888.

Par. 12, S. O. 49, Department of Texas, May 5, relative to HARRIS, H. S. T., *First Lieutenant and Assistant Surgeon*, accompanying the Eighth Cavalry to the Department of Dakota, is amended by par. 1, S. O. 50, Department of Texas, May 9, 1888.

Par. 1, S. O. 50, Department of Texas, May 9, is revoked by par. 1, S. O. 51, Department of Texas, May 11, 1888.

HARRIS, H. S. T., *First Lieutenant and Assistant Surgeon*.—Will be relieved from duty at Camp Pena Colorado, and proceed to San Antonio, where he will report to the commanding officer of the battalion of the Sixteenth Infantry, for duty as Medical Officer with that battalion to its destination to the Department of the Platte. Upon completion of this duty, he will return to his proper station, Camp Pena Colorado, Texas.—*S. O. 51, Department of Texas*, May 11, 1888.

Par. 15, S. O. 49, Department of Texas, c. s., relative to CLENDENIN, PAUL, *First Lieutenant and Assistant Surgeon*, accompanying the Sixteenth Infantry to its destination, is revoked by S. O. 51, Department of Texas, May 11, 1888.

CLENDENIN, PAUL, *First Lieutenant and Assistant Surgeon*.—Will proceed from Fort McIntosh to Fort Davis, and report to the Commanding Officer, Eighth Cavalry, for duty as Medical Officer with that regiment on its march to Fort Concho, from which place Lieutenant Clendenin will return to his proper station.—*S. O. 51, Department of Texas*, May 11, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING MAY 19, 1888.

KERSHNER, EDWARD, *Surgeon*.—Detached from the U. S. Steamer "Pensacola," and wait orders.

SAYRE, J. S., *Assistant Surgeon*.—Detached from the U. S. Steamer "Pensacola, and wait orders,

JONES, W. H., *Surgeon*.—Detached from the Navy Yard, League Island, and ordered to the "Pensacola."

COOKE, G. H, *Surgeon*.—Ordered to the Navy Yard, League Island.

CRAWFORD, MILLARD H., *Passed Assistant Surgeon*.—Ordered to the "Vandalia."

WIEBER, F. W. F., *Assistant Surgeon*.—Detached from the "Vandalia," and ordered home.

STONE, E. P., *Assistant Surgeon*.—Detached from the Naval Hospital, New York, and ordered to the "Pensacola."

HARMAN, G. E. H., *Passed Assistant Surgeon*.—Commissioned a Surgeon, May 12, 1888.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked. Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LII. SATURDAY, JUNE 2, 1888. NO. 22.

ORIGINAL ARTICLES.

NOTE ON THE TREATMENT OF SYPHILIS BY THE HYPODERMATIC INJECTION OF CALOMEL.[1]

BY J. C. WILSON, M.D.,

ATTENDING PHYSICIAN TO THE PHILADELPHIA HOSPITAL AND TO THE HOSPITAL OF THE JEFFERSON COLLEGE OF PHILADELPHIA.

THE treatment of syphilis by the intramuscular injection of calomel, as first practised by Scarenzio, in 1864, was prominently brought to the notice of the profession in Germany by Neisser, in September, 1885. Since that time a large number of communications upon this subject have appeared in the German, and more recently in the French journals. It is a remarkable fact, however, that this method of treatment has received but little notice among English and American physicians. Two papers only, those of Bloom and Morrow, have thus far appeared in American literature. Neither of these has embodied any extended clinical observations, a fact that is more noteworthy in view of the multiplying reports of the growth of this method of treating syphilis on the Continent, and especially in Germany.

The object of the present communication is to call attention to the details of this treatment as practised by the writer, and its results in a limited series of cases. The method is the natural outcome of efforts to render the treatment of syphilis more exact, and to keep it more completely within the control of the physician by the administration of specific remedies hypodermatically. It marks a step in the advance of the therapeutics of syphilis beyond the hypodermatic use of the soluble salts of mercury, as the bichloride, formerly advocated, and still occasionally employed in cases in which it is necessary to obtain the full effect of mercury rapidly. The difference between the therapeutic effects of the soluble and the insoluble mercurial salts hypodermatically injected is, however, an important one. In the case of the former, absorption readily occurs, and the effects of the drug are manifested with great promptitude; thus, Hutchinson quotes Bloxam as saying that one-third of a grain of bichloride of mercury dissolved in twenty drops of water and repeated hypodermatically on three consecutive days, will usually salivate freely; whereas the insoluble salts, introduced by the hypodermatic method, undergo chemical changes in the presence of the fluids of the tissues with comparative slowness, thus keeping up a prolonged and relatively mild influence until their chemical conversion and absorption are completed. The gradual nature of this process is shown by the fact that, in one of my cases, slight ptyalism occurred on the ninth day after the injection of one grain of calomel. Much difference of opinion has been expressed as regards the relative advantages of the mode of treatment under consideration; the greater number, however, of those who have published their observations regard it as possessing certain positive advantages over the methods hitherto practised. Among these advantages may be named the following:

A. As over the administration of the preparations of mercury by the mouth:

1. The absence of any directly unfavorable influence upon the digestive apparatus (nausea, loss of appetite, colic, diarrhœa), especially in cases where mercury in sufficient doses is not well borne.

2. Precision of dosage.

3. Control of the administration by the physician, and, therefore, better opportunity, especially in private practice, to observe the effect of the drug, as well as the general condition of the patient, at fixed intervals.

4. Simplification of the treatment as regards the patient himself, and diminution of the liability of his condition becoming known.

5. Promptness of action.

6. Diminished risks of salivation.

B. As over treatment by inunction, in addition to the above advantages, we have:

1. Absolute cleanliness. This point is of much importance in private practice. Mercurial inunctions are not acceptable to the better class of patients, and are feasible only in cases where the symptoms are urgent, and the patient fully realizes the gravity of the situation.

2. Convenience of administration in all respects.

C. As over the treatment by fumigation, etc., in addition to the above, we have:

1. Comparative safety of the method of treatment.

2. Absence of the necessity for attendants, and for the use of apparatus of any form on the part of the patient.

D. As over other forms of treatment in ordinary use, the fact that stubbornly rebellious symptoms

[1] Read before the College of Physicians of Philadelphia, April 4, 1888.

often yield with promptness to hypodermatic injections of the insoluble salts.

The disadvantages of this treatment, as compared with the methods in general use, are:

1. Pain.
2. Danger of the formation of abscesses.

It may be said at this point that both of these disadvantages are reduced to a minimum by attention to the details of the little operation, and especially by the observance of the rule to introduce the medicament deeply into the substance of the muscle.

Some degree of burning pain is, however, produced by almost every injection. It is, as a rule, moderate, and comes to an end in the course of a few minutes. It is, on the contrary, however, sometimes quite severe. Exceptionally, the injection has caused no pain whatever beyond the mere prick of the needle.

The danger of the formation of abscesses is very slight when the injection is properly performed. Antisepsis must be complete as regards the material injected, the syringe, and the patient's skin at the point of puncture, and the calomel must be thrown deeply into the muscular substance, the needle being entered perpendicularly to the plane of the surface. The most convenient site is the lateral aspect of the gluteal region in the fossa behind the great trochanter. Smirnoff and Sofiantini state that calomel injections in this region are never followed by abscesses. Shadek says "abscesses never occur after deep intramuscular injections of the quicksilver preparations; coagulations—that is to say, nodes and induration at the point of injection—are rarely seen." Watrazewski saw only 4 abscesses follow 257 calomel injections. In my own private practice, in thirty-two injections in six patients once only slight fluctuation occurred at the seat of puncture. It disappeared in the course of a few days. In the cases treated at the Philadelphia Hospital, several small, superficial abscesses developed at the point of injection. These were among the earlier cases, and the procedure was practised without due regard to antisepsis.

On the other hand, Kopp and Chotzen counted 48 abscesses after 768 injections of 0.1 of a gramme (1.5 grains) of calomel. Krecke caused suppuration of the subcutaneous tissue in 21 instances out of 171 injections, while Monti, Bockhardt, and others, have abandoned the treatment on account of this danger.

There can be no doubt, in view of these varying results, that the occasional formation of abscesses is due to faults in technique. It is, therefore, largely, if not indeed wholly, avoidable, and constitutes no real objection to the treatment.

Two of the insoluble salts of mercury have been used, calomel and the yellow oxide. My own observations have been made with calomel alone. Neisser suspended the calomel in water with a little gum Arabic. The original formula was

Calomel,	
Sodii chlorat.	āā 5.0.
Aquæ dest.	50.0.
Mucilag. acaciæ	2.5.

The formula given by Bloom is,

Calomel by vapor . . .	5.0 (℈iv).
Sodii chloridi	1.25 (℈j).
Aquæ dest.	50.00 (f℥xiijss).

It is obvious that this mixture defeats the object of the treatment in view of the rapid chemical changes by which bichloride of mercury and metallic mercury are formed at the expense of the calomel. After some experience, calomel was administered by various observers in suspension in liquid vaseline, by others, in pure olive oil. One of the difficulties of the injection of calomel is found in the liability of the needle of the ordinary hypodermatic syringe to become clogged. For this reason both the vaseline and oil are objectionable. My own injections, after a few early trials with the above substances, have been made with glycerine, as suggested by Smirnoff, and in order to secure greater accuracy of the dose and to overcome the tendency of the calomel to settle at the bottom of the vial, I order the doses from the apothecary, separately, in drachm vials, each containing

Calomel by vapor	grain 1.25
Glycerine (pure)	♏ xv.

A number of these vials are ordered at once, and are protected from the light. At the time of using, the cork is removed and a few minims of recently boiled water are forcibly injected from the needle of the syringe into the bottle in order to displace the calomel that has settled. The bottle is then thoroughly shaken until the calomel is suspended. The mixture is next poured into a little conical porcelain capsule, and quickly taken up through the nozzle of the syringe. The needle is then adjusted, the air expelled, and the operation performed in such a manner that the drug is thrown into the muscular mass. A grain of calomel, approximately, is the usual dose. The formula calls for one and a quarter grain for the reason that notwithstanding the greatest promptness, a certain amount of the calomel remains at the bottom of the capsule, and a little in the syringe itself.

The antiseptic precautions consist in thorough disinfection of the apparatus employed immediately before each injection by means of water boiled for some minutes in a test-tube, and in the careful cleansing of the skin at the point of puncture, by a solution of corrosive sublimate 1 : 1000. Burning pain usually follows, lasting for some minutes, and the circumscribed deep infiltration, which may be detected after the injection, becomes the seat of moderate tenderness, and more or less induration, lasting for some days, or even a week or two.

When we come to consider the transformations which the insoluble mercurial salts undergo when thus injected, we enter a field as yet but little investigated. It is probable that to a slight extent chemical reactions take place with certain organic principles, notably albumen, with the formation of albuminate of mercury, but that the greater part of the calomel undergoes in the constant presence of the alkaline fluids of the tissues gradual conversion into a double chloride of mercury and sodium. In this respect it follows the course of mercury introduced into the economy by way of the alimentary canal.

The following cases were treated in the Philadelphia Hospital, and the notes are condensed from the ward histories taken by Dr. Hutchinson, Resident Physician.

Case I.—J. A., male, æt. forty-eight; admitted September 23, 1887, to Medical Ward 2, bed 10; Irish, a store-porter, moderate drinker. No hereditary tendency to disease of the nervous system. Chancre in 1861 or 1862; lymphatic enlargement; stubborn faucial and buccal symptoms; no recollection of a rash; prolonged treatment by mercury. In 1867, spinal symptoms, staggering gait, dizziness, and difficulty in holding his water. Systematic treatment for two years, with complete recovery. He then married; wife's first pregnancy resulted in miscarriage. The second child was healthy, and is still living. Four children born subsequently died in early infancy from "marasmus." In 1875 there was recurrence of the spinal symptoms; he then was treated in the Orthopædic Hospital; states that recovery rapidly took place under strychnia and increasing doses of iodide of potassium; continued well until the spring of 1887, when spinal symptoms recurred, together with loss of sexual power and desire, marked ataxia, burning sensations and numbness, especially in the limbs and feet. Knee-jerk much exaggerated in both legs. Examination of the eyes by Dr. de Schweinitz showed insufficiency of the internal recti, oval disks distinctly gray in the second layer, and distention of the lymph sheaths along the arteries and veins; no distinct retinal changes except haziness. Diagnosis as to eyes, probable early gray degeneration of the optic nerve. Hypodermatic treatment from Nov. 11, 1887, to Feb. 17, 1888; total number of injections, seven; result, very decided improvement. Patient transferred to the surgical ward, for the treatment of cystitis.

Case II.—G. M., male, æt. thirty-seven; admitted to Medical Ward 2, bed 2, September 28, 1887. Primary sore occurred in 1876; secondary lesions of the mouth and throat, with falling of the hair; no recollection of a rash. Two years later, symmetrical, circumscribed ulcers of the shoulders and thighs, the scars of which remain. In 1879, sharp pains in the knees and ankles, lasting for some months, and disappearing under treatment. In 1886, acute pain and swelling of the knees and ankles, always aggravated at night, kept him in bed for eleven months. Upon admission to the Hospital, there was well-marked periostitis of the clavicles, tibiæ, and radii. Slight improvement only under large doses of iodide of potassium. On December 11, 1887, other medication having been stopped, he was given calomel hypodermatically, and had in all five injections at intervals of a fortnight. Very decided improvement. He was subsequently treated by Dr. Bruen with hypodermatic injections of bichloride of mercury.

Case III.—J. J., male, æt. thirty-seven, Italian laborer, admitted to Medical Ward 8, bed 9, December 24, 1887, complaining of vague pains in various parts of the body and constant headache. The initial lesion occurred five weeks prior to admission. Lesions of the tonsils and throat. About January 16, 1888, well-characterized macular eruption appeared over the whole body; enlargement of the superficial lymphatic glands. January 17th, hypodermatic treatment begun, and he received in all eight injections. On March 23d, the following note was made: "The patient better in every respect; the eruption has disappeared; the superficial lymphatics have undergone resolution; the patient free from pain and feels perfectly well. He has had at no time any stomatitis or diarrhœa." This patient received on one occasion two grains of calomel by hypodermatic injection. A superficial abscess occurred at the site of one of the injections.

Case IV.—C. McG., male, aged twenty-eight, Irish, blacksmith, admitted to Medical Ward 8, bed 10, January 27, 1888. The initial lesion occurred October 1, 1887. He suffered with severe pains in the head, arms, and body; considerable induration about the point of the chancre on the dorsal aspect of the penis in the sulcus. Inguinal lymphatics much enlarged, also the post-cervical and epitrochlear glands. A profuse papular eruption covered the whole body. The treatment by calomel, hypodermatically, commenced January 28th, and he had in all nine injections. During the course of the treatment an abscess formed at the side of the neck, and two or three small abscesses formed in the gluteal region at the site of the injection. There was no stomatitis or diarrhœa. Within two months of the beginning of the treatment the sore on the penis had healed, the glands had undergone resolution to a considerable extent, and the eruption had disappeared, with the exception of a few scaly papules in the region of the lips, the lower part of the abdomen, and the thighs. March 15th, the patient was still doing well.

Case V.—L. S., male, æt. twenty-five, roofer by occupation, American, admitted to Medical Ward 2, bed 18, February 25, 1888. He first observed the initial lesion some time during the autumn of 1887. There was phimosis, for which circumcision was performed. Secondary symptoms, sore throat, constant headache, enlargement of the superficial lymphatics, uniform papular rash over the body and legs. Treatment was commenced February 26th. In all six injections were given up to March 15th, when it was noted that the glands were undergoing resolution, that the rash had, to some extent, faded, that the headache had disappeared, and that his general condition was improving. There were no abscesses, no sore mouth, and no diarrhœa.

Case VI.—J. F., æt. twenty-five, Irish, admitted to Medical Ward 8, bed 24, October 20, 1887. The initial lesion occurred fifteen months before admission, and was followed by non-suppurating enlargement of the glands of the groin. He had suffered with iritis in both eyes, but not at the same time. Severe periosteal and articular pains. Treatment by hypodermatic injections of calomel was commenced in January, 1888. After the second injection the patient refused to continue the treatment on account of the pain attending it.

The following cases were treated in private practice:

Case VII.—X., male, æt. forty-five, a man of leisure, had the initial lesion in 1873. Intense and protracted secondary lesions affected the mucous membrane of the mouth and the cutaneous surface; prolonged mercurial treatment. A period of about five years passed without symptoms of any kind. In 1881 there appeared extensive, stubborn ulceration of the tongue, very little modified by treatment by mercurials and iodides, and local treatment with nitric acid. He came under my observation in 1882. There was deep serpiginous ulceration of the left border of the tongue, with extensive cicatrices of the right border; scaly eruption of the palms of both hands, not symmetrical, with deep, linear, fissured ulcers of the flexures; thick, scaly patches upon the soles and borders of both feet, with considerable thickening of the skin; a large, scaly patch on the left side of the scrotum. Decided improvement under alternating courses of iodide of potassium and protiodide of mercury, with frequent applications of nitrate of silver to the lingual ulcers. The latter in the course of a few months had healed, and since have only occasionally, and for short intervals, given trouble. The scaly patches have undergone occasional improvement, but never disappeared, notwithstanding the fact that the patient has been steadily under observation to this date, and for most of the time under treatment. Mercurial inunctions, although frequently proposed, have never been practised, owing to the patient's unwillingness to subject himself to the inconvenience. Treatment by hypodermatic injections commenced November 4, 1887, and was continued somewhat irregularly until the end of February, 1888, five injections in all having been administered. After the second injection, the scaly patches upon the hands, feet, and scrotum absolutely disappeared. On the ninth day after the first injection slight salivation was noted.

Case VIII.—F. H., male, æt. thirty-two, a travelling salesman, came under observation with the initial lesion in April, 1886. I had the opportunity of seeing the female from whom the disease was contracted, then suffering from intense secondary symptoms. F. H. developed in due course of time superficial ulcers of both tonsils, mucous patches, macular rash, and enlargement of the superficial lymphatics; none of these symptoms, however, being intense. The general health continued good. After a year of systematic treatment with protiodide of mercury, with occasional brief intermissions, the patient still presented a few reddish, scaly papules upon the forehead at the edge of the hair, upon the fingers and the legs; these lesions, however, not being symmetrical. In March, 1887, iodide of potassium was given in moderate doses, and continued until November, 1887, with the effect of modifying but not curing the cutaneous lesions.

Hypodermatic treatment commenced December 10, 1887. It was interrupted by the absence of the patient from the city until February 16, 1888, when the second injection was administered. The patient was unable to return until March 10th. He then stated that after the second injection a very decided improvement in his symptoms had occurred, and requested that the treatment should be regularly continued. From that day until the present time he has received four injections at intervals of a week, making six injections in all. The lesions have entirely disappeared.

Case IX.—Mrs. R., widow, æt. thirty-eight, was sent to me from the central part of Pennsylvania, by a medical friend, February 10, 1888. She had been ill three years with a teasing cough, attended by scanty expectoration, occasional night-sweats, but without loss of flesh. She had consulted a number of physicians without benefit. The appetite was fairly good; the temperature as taken in the mouth at 4 P.M. was normal. There was dulness over the right lung anteriorly in the mammary region, with abundant subcrepitant and crepitant râles heard in the infra-scapular area and extending down the anterior border of the lung. Percussion elsewhere yields good resonance, and especially is this noted in the supra-clavicular region on both sides; examination of the sputum showed no bacilli.

February 27. The signs not having changed and the patient having a normal evening temperature, the history was carefully investigated. There was no hereditary tendency to phthisis. The patient married twelve years ago, a man somewhat younger than herself, whose occupation compelled him to be much absent from home. Within a year the wife miscarried at the sixth month. Two years later a child was born apparently healthy. It developed snuffles when one month old and died at the age of four months of "marasmus." The husband complained from the time of marriage of frequent severe headache. The attacks of headache after a time became so violent that he was obliged to discontinue his occupation for periods of several days together. Later the headaches were followed by confusion. There is no history of any special condition of the eyes nor of paralysis until about three years before his death. At this time he was seized with unconsciousness and irregular palsies. This attack was not followed by recovery; on the contrary, his mental condition became progressively feeble, he lost the power of locomotion and died paralytic one year ago.

Mrs. R., his widow, informs me that shortly after her marriage she had sore throat which lasted for more than a year despite treatment, and that at that time she almost wholly lost her hair, which, however, afterward grew in; does not recall any eruption.

29th. Treatment by hypodermatic injections was

commenced and has been continued up to the present time, five injections having thus far been administered. The area of percussion dulness is much less extensive, the subcrepitant râles are not heard, and a few crepitant râles only can be elicited on forced inspiration after efforts of coughing. The diagnosis in this case is not, perhaps, positive, but there is warrant for the assumption that these symptoms and signs are due to gummatous infiltration of the lung.

CASE X.—Mrs. S., æt. fifty-six, has suffered for many years with intense paroxysmal headaches accompanied by disturbance of hearing and hallucinations, followed by deep stupor at intervals of from six weeks to three months. These attacks last from two or three to six or eight days. In the intervals there is a feeling of confusion and dull headache, easily excited by mental or physical effort General nutrition good. The eye grounds have been examined by the late Dr. Little and by Dr. William Thomson with negative results. The urine has never been albuminous. There is no cardiac disease. No history whatever is to be obtained in this case. The patient's husband presents no indications of having suffered from syphilis; there are three grown-up daughters all in good health. The oldest, however, has, to a well-marked degree, the physiognomy of hereditary syphilis with characteristic narrowing and notching of the upper central incisors. This deformity was so conspicuous that she had the teeth removed and replaced by artificial pivoted teeth. The other daughters show nothing characteristic. The symptoms of this patient never improved under mercurial treatment by the mouth or under iodide of potassium. On several occasions, mercurial inunctions have been followed by a cessation of the headaches for a period of some months, and a mitigation of the severity of the paroxysms upon their recurrence. On more than one occasion she has been ptyalized as a result of this treatment. Treatment by the hypodermatic injection of calomel was commenced November 20, 1887, and continued at intervals of, at first, a week and later two weeks until the present time. Eleven injections in all have been administered. From the time of the commencement of this treatment, the patient, although suffering from occasional dull headache and the old sense of confusion, has had no recurrence of her attacks.

CASE XI.—N. S., female, æt. seventeen, the third child of syphilitic parents; with the typical facies of hereditary syphilis, prominent frontal bosses, sunken nose, and notched teeth, developed, at the age of fifteen, interstitial keratitis with double iritis resulting in total blindness. She was successfully treated by Dr. Charles S. Turnbull, improvement gradually taking place under frequently repeated small doses of biniodide of mercury. Within a year there has appeared a copious, thickset, acneform eruption, most copious over the sides of the face, the shoulders, and the thighs. This eruption has the color of lean ham; is papular and occasionally pustular. The hypodermatic treatment was commenced March 2, 1888, and has been repeated at intervals of ten days, three injections in all having been administered up to the present time. Under this treatment the eruption has rapidly improved, a large proportion of the papules have entirely disappeared, and those which remain have lost their vivid copper-red color.

CASE XII.—B., æt. forty-one, was seen in consultation December 31, 1887, with Drs. C. M. Wilson and Murray Cheston. The details of the history were not known further than that he had been under the care of an ophthalmic surgeon for serious syphilitic eye trouble, which had improved under specific treatment. The patient had been disinclined to take care of himself, or to follow the directions given by his medical adviser. The day before he came under observation he had complained of unusually severe headache upon the left side, and had gradually lost power of the right arm and leg. When seen he was completely aphasic; the intelligence was clear. Two hypodermatic injections of calomel were administered, but in view of the gravity of the case and lack of experience in regard to this treatment, it was abandoned for mercurial inunctions, under which the patient rapidly regained his speech, and, to a certain extent, the use of the paralyzed side. The treatment is now being conducted by a female evangelist of the "faith-cure," under whose care the patient had been for some weeks prior to the attack in which I saw him.

Whole number of patients treated, twelve; injections, sixty-nine.

My thanks are due to Dr. Hutchinson, Resident Physician at the Philadelphia Hospital, for his interested pains taken in this clinical study, and to my colleagues, Drs. Bruen and Steinbach, for courtesies in regard to the observation of cases transferred, under the rules of the Hospital, to their wards.

RECENT VIEWS REGARDING THE PATHOLOGY AND TREATMENT OF PERTUSSIS.[1]

By EDMUND C. WENDT, M.D.,
VISITING PHYSICIAN ST. JOSEPH'S ASYLUM, CURATOR AND PATHOLOGIST OF THE ST. FRANCIS HOSPITAL AND THE NEW YORK INFANT ASYLUM, ETC.

The present era is one of important and far-reaching change in medical opinion, more particularly as regards the essential nature of many of the most prevalent maladies. It is not at all surprising, therefore, to find recent views concerning pertussis differing materially from those which were accepted ten, or even five, years ago. With the advent of new ideas on pathology, new methods of treatment have naturally arisen. The purpose of this paper is to give a brief account of the more important views recently enunciated concerning the pathology and treatment of pertussis. The inquiry will also be pertinent, whether we have made any true progress in these directions, or whether we have to do merely with the rising tide of popular innovation.

In the first place, then, What is the nature of pertussis?

The drift of modern research runs almost exclusively in one direction, namely, that of regarding whooping-cough as a disease due to the invasion of microörganisms.

But while most modern observers are ready to admit the parasitic origin of the affection, considerable differences of opinion obtain regarding the particular kind of organism supposed to be specific, as well as the precise point of its location within the body.

As long ago as 1870, Letzerich[2] described a microorganism alleged to be present in the sputum, and on the mucous membrane of the respiratory organs of patients having pertussis. His observations were soon confirmed by some writers, but others disputed his claims. The most recent researches have resulted in showing that the organisms of Letzerich are harmless saprophytes, and not the pathogenic microbes of pertussis.

The organism discovered by Tschamer[1] is identical with the fungus known as *capnodium citri*, which is found on orange-peel and apples. It is certainly not the specific microbe of pertussis.

Deichler,[2] of Frankfort, has also discovered an organism in this disease. And, strangely enough, it is not a minute plant, but an animal belonging to the protozoa. This author makes the rather guarded statement that, while the animalcule in question occurs only in pertussis, and evidently has some pathogenic significance, it may not be the sole exciting cause of the disease. It will strike the reader that a more modest microörganism has not of late years been discovered on German soil, a circumstance which probably accounts for the contempt in which it appears to be held by those German writers who take the trouble to mention it at all.

Henke[3] has described small round cells, which he found in the sputum, and which he supposed to be peculiar to pertussis. From his description, however, it is clear that they were merely lymph corpuscles, showing in their interior the well-known phenomenon of molecular movement.

Poulet's[4] *monas termo* and *bacterium termo* have nothing to do with pertussis, and the Frenchman's claims in an opposite direction cannot be upheld.

In 1883, Burger[5] found a small rod-shaped organism in the sputum of patients having pertussis. He regards it as the exciting cause of the disease. But the methods employed by Burger are not above criticism, and Koch has refused to accept his arguments as convincing.[6] Cultures and inoculation experiments were not made by Burger. From his description it is apparent that he did not see the bacillus of Afanasieff, presently to be considered.

All these observations (as well as a number of others that need not be mentioned here) were undeniably prompted by the *à priori* consideration that pertussis ought to be due to the presence of a microorganism. Indeed, not a few authors have taken the ground that while we might not yet know all about the presumed microbe, treatment, in order to be rational and effectual, must be chiefly of the antiparasitic kind.

So long as ten years ago Hagenbach[7] maintained that whooping-cough was a catarrhal affection of the mucous membrane of the respiratory tract, associated with the invasion of fungi. According to this author, the characteristic paroxysms of cough are due to reflex action, starting from irritation of the terminal filaments of the superior laryngeal nerve.

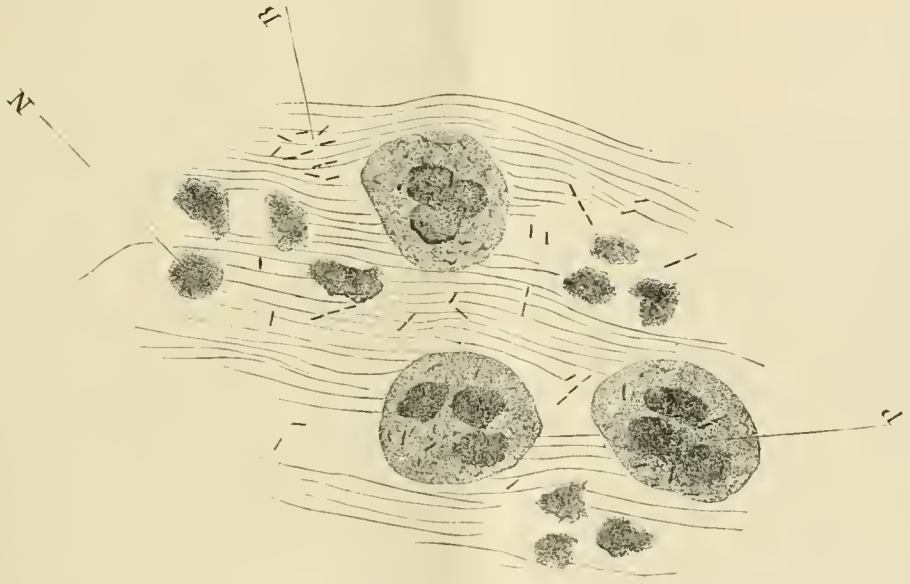
[7] Gerhardt's Handbuch der Kinderkrankheiten, vol. ii. p. 551.

Widerhofer[1] describes whooping-cough as a bronchomycosis.

Baginsky[2] places the disease among the constitutional infectious maladies. But by calling it an infectious catarrh of the mucous membrane of the respiratory passages, he admits that it may just as well be classed with the "local contagious" maladies.

Michael,[3] of Hamburg, following the suggestions of Hack, Schadewald, Sommerbrodt, Wille, and others, asserts that the disease is due to reflex disturbances, caused by the presence of microbes in the mucous membrane of the nose. This has led to the nasal treatment of the malady, a method which has found many followers.

FIG. 1.



Sputum from a case of pertussis. *P*, pus corpuscle containing the specific bacilli; *N*, nuclei from broken-down corpuscles; *B*, group of bacilli. (The ordinary atmospheric bacteria, often found in the sputum, have been omitted from this drawing.)

The discussion on whooping-cough, which occurred last year at the German Congress of Internal Medicine,[4] was an interesting debate on a very debatable subject. Vogel, Hagenbach, Michael, Heubner, Prior, Schliep, Sonnenberger, Binz, and Cohen, were the principal speakers. As already pointed out, the drift of opinion was in the direction of assuming the parasitic origin of the disease. No noteworthy discovery was announced, however, and as for treatment, there were about as many different opinions as there were participants in the discussion.

We come finally to the most recent pathological announcement, that of Afanasieff, which appeared in four successive numbers of the *St. Petersburger medicinische Wochenschrift*, in October, 1887. Borrowing the language of the *Lancet* (modified in a few particulars), this author

"has succeeded in finding and cultivating what he believes to be the true bacillus of whooping-cough. This microbe differs distinctly from all other bacteria which have been described (Fig. 1). It is somewhat like Friedländer's pneumonia bacillus, but is shorter and thinner than the latter; besides, in gelatine it does not form nail-shaped cultures, those which are produced having no hemispherical head. Its potato cultures, too, are quite different from those obtained from Friedländer's bacillus. Afanasieff's bacillus exhibits a remarkable degree of vitality, for jelly cultures that have become dry and have been kept for four months, appearing under the microscope to be more or less destroyed, are still capable of producing fresh cultures when fresh media are inoculated from the dried mass. Dr. Afanasieff's researches were chiefly made from the sputum of some of his own children, who were affected with whooping-cough. The mouth was well washed out with a permanganate of potash solution, and the mucus coughed up after the next paroxysm or two examined. In this mucus, after staining with methyl-violet, and occasionally in the pus-corpuscles contained in it, the bacilli could be seen with a magnifying power of from 700 to 1000 (Zeiss's eye-piece 3 or 4, $\frac{1}{12}$ oil immersion objective) as short rods (Figs. 2 and 3), sometime single, sometime in twos, or even in short chains running in the direction of the mucus, sometimes again in small clusters. Their length was from 0.6μ to 2.2μ. Other bacteria were also found. But they were numerically insignificant, as compared with the bacilli under consideration.

Pure cultures were easily made on agar-agar, meat-peptone jelly, potato, etc. Dogs and rabbits were

inoculated with a fluid culture mixed with chloride of sodium solution, some by means of injections into the trachea, others by direct injections into the lungs. All the animals were seriously affected, and many of them died. The symptoms were some-

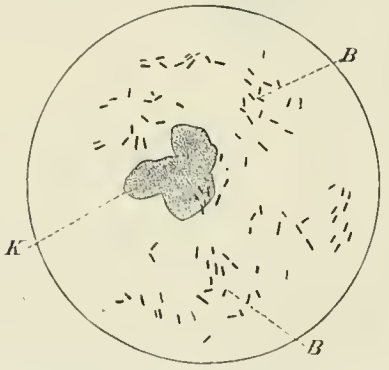
what similar to those of whooping-cough, including cough, dyspnœa, and redness of the eyes. Many of the cases were complicated by broncho-pneumonia. On examining the bodies of those animals which died, the mucous membrane of the air-passages was found much reddened, and coated with a tenacious clear mucus, in which, as well as in the pneumonic patches in the lungs, the bacilli were found (Fig. 4). Similar appearances and the same bacilli were observed in the bodies of children who had died from whooping-cough."

FIG. 4.



Specimen taken from a patch of broncho-pneumonia artificially induced in a rabbit. *K*, pus corpuscle; *B*, bacilli pertussis. (After Afanasieff.)

In my opinion the bacteriological researches of this Russian observer are far more important and convincing than any hitherto undertaken.[1]

[1] If I may be permitted a personal remark in this place, it is that I know the author to be a most careful, painstaking, and conscientious observer. Twelve years ago while we were studying together at Strasburg, under the supervision of Waldeyer and v. Recklinghausen, I had ample opportunities to admire the excellence of all his laboratory work. Afanasieff is the author of numerous contributions to histology and pathology, that have always been favorably received by recognized authorities.

The discovery of Afanasieff has been confirmed by a Russian observer, Semchenko. His papers were published in the *Vrach*, and the *Lancet* of January 7, 1888, mentions his views as follows:

"Dr. Semchenko, having investigated the whooping-cough bacteria described by Professor Afanasieff, has satisfied himself that they are the true specific cause of the affection. They appear in the sputum on the fourth day of the disease, if not still earlier. They go on developing in the tissues of the body, and simultaneously with their multiplication the severity of the disease increases. The bacteria disappear before the paroxysms of whooping-cough have ceased, generally when these have been reduced to from two to four in the twenty-four hours. When complications, such as catarrhal pneumonia, arise, they are accompanied by a great increase in the number of whooping-cough bacilli found in the sputum, the pneumonia developed under these circumstances having, according to Dr. Semchenko, several points of difference from ordinary attacks of catarrhal pneumonia. The examination of the sputum of whooping cough patients is apparently useful, not only for diagnostic purposes, but also as a guide to the prognosis of the course of the disease."

My own experience with the bacillus described by Afanasieff permits me to state that it is probably always present in pertussis. In the few cases in which I failed to find it, the method of obtaining the sputum was very likely at fault. I am unable, however, to confirm the assertion of Afanasieff, that the small pellet of mucus which is coughed up at the end of a paroxysm contains the pertussis bacilli in almost pure culture. I have invariably found other varieties of bacteria (such as commonly occur in the sputum of bronchitis) along with those of whooping-cough.

Moreover, it has not been my fortune to be able to demonstrate the bacillus pertussis, except in those cases where the clinical features of the disease were already so well marked, that a microscopical confirmation was not needed. Hence, I cannot agree with Semchenko in ascribing any great diagnostic significance to the discovery of these bacilli in a given case.

I had occasion to examine the sputum from a few cases of suspicious cough, that later developed into characteristic pertussis, but in none of them could I find the bacillus of Afanasieff, during that early stage.

Again, in two cases that were on the high-road to recovery I still found as many bacilli as during the height of the disease. In this respect also, my own observations are at variance with those reported by Semchenko.

I, nevertheless, have no doubt concerning the etiological significance of Afanasieff's discovery. But what practical benefit will result therefrom to the practitioner of medicine remains to be seen.

We certainly require no bacillus for diagnostic purposes. And in cases which are as yet doubtful, the bacillus is not found. At least such has been my rather limited experience.

Before closing this short account of recent pathological views on whooping-cough, mention should be made of the observations of v. Herff,[1] which are not without interest. This author, while suffering from pertussis, studied the appearance of his own larynx. According to him, there exists, during the entire course of the malady, a moderate amount of inflammation of the mucous membrane of the respiratory organs, from the posterior nares down to the bifurcation of the trachea. At the outset of the disease, this inflammation is but a mild catarrhal one. It gradually increases in severity, and again abates during the period of defervescence. In his own case, the inflammatory action was quite intense at the arytenoid cartilages and those of Wrisberg and Santorini. But the posterior wall of the larynx between the vocal cords, and the under surface of the epiglottis, were most severely affected. The vocal cords themselves appeared intact.

During the paroxysms, v. Herff claims to have seen a small pellet of mucus on the posterior aspect of the larynx, and on a level with the vocal cords. On removing this pellet the paroxysm came to an end at once. Irritation of this part of the larynx induced an attack. But a paroxysm was not produced by irritating other parts of the larynx. The author maintains, therefore, that this inflammatory action in the interarytenoid space is responsible for the spasmodic attacks characterizing pertussis. About the probable lodgement of microbes at this point he is strangely silent for a modern observer.

On examining the modern therapy of pertussis, we shall find that, in addition to the countless old remedies, almost every new drug has been tried. That the curability of an affection varies inversely in proportion to the number of remedies employed in its treatment is a trite experience. Judged by this rule, whooping-cough must still be regarded as a very intractable malady.

For obvious reasons, no attempt will be made, in this place, even to mention all the drugs that have been tried and recommended in pertussis, let alone discuss their merits.

Whatever is regarded by physicians as the essential something of the disease, that they have proceeded to attack. Those who look upon the infectious element as the chief factor of the disorder, naturally chose, and still choose other means of treatment than those who consider the respiratory catarrh as most important, or than those who hold that the morbidly heightened nervous irritability is chiefly responsible for the trouble. Those, finally, who believe in the parasitic origin of pertussis have recourse to one or another of the various antiseptics or parasiticides. Mention has already been made of the nasalists, who direct all their efforts against the offending mucous membrane of the nose. They employ for this purpose sprays and insufflations of various antiseptics and sedatives. This treatment is said to prove very successful. In an editorial notice touching the nasal treatment of pertussis, the *Lancet* of January 15, 1887, says, "It is doubtful whether the theory of this fashionable method is correct; but, supposing it should be, it is equally dubious whether the good that results may not be from the mere treatment of catarrh as such, apart from its supposed cause." I fully concur in this view of the alleged success attending this method of treatment in whooping-cough.

It was at first proposed to place the various remedies in groups, a plan which has been followed by Chéron.[1] But the groups soon grew to such formidable proportions that the limits of this paper would have been unnecessarily extended, had that idea been carried out. I have preferred, for this reason, to examine only a few methods of treatment, and to present for consideration my personal views as to what constitutes rational therapy in the present state of our knowledge.

To begin with, whether we accept the parasitic doctrine of the disease or not, I believe that the policy of absolute non-interference, still persistently advocated in some quarters, should be emphatically condemned. If we cannot attack the affection at its roots, something can surely be done to mitigate its severity and to reduce the frequency of complications. There is probably not one among us who has not witnessed the sad plight that neglected cases will sometimes fall into. I would ask whether the large mortality still ascribed to pertussis is not, in a great measure, due to irrational medication rather than, as some maintain, to over-treatment?

It goes without saying that proper alimentation and the best hygienic conditions attainable, will always contribute toward the success of any plan of treatment. How difficult of accomplishment these measures are among the poor and shiftless, is only too well known. But, even among the better classes, the necessity of pure light, of fresh air, and of proper food, furnishes a text for almost daily preaching.

I am a firm believer also, in the propriety, or rather the necessity, of employing every possible means of protection for the unaffected members of a family. The time is surely past when the profession can countenance the opposite custom of encouraging the contagious diseases of childhood to affect as many members of one family at a time as possible. The mother may be anxious "to be done" with a

[1] Deutsches Archiv f. klin. Medizin, vol. xxxix.

[1] L'Union Médicale, October 18 and 20, 1887.

particular disease for her offspring. But I conceive it to be our duty to oppose energetically all such dangerous nonsense, even at the risk of incurring the wrath of some wiseacre guardian of the nursery.

As to particular drugs in the management of pertussis, I believe that individual preferences in respect are often the result of accidental causes. We certainly possess no specific for pertussis. It is to be remembered that there are seasonal and other variations in the intensity of the disease. If we accept the bacterial origin of pertussis, this varying degree of severity would depend upon the degree of infection. Some such explanation certainly appears necessary, in view of the fact that equally honest observers do not obtain equally good results from the same drugs.

Turning now to medicines, we find that narcotics and sedatives are as largely employed as ever. Many new combinations have indeed been put forward, but it does not appear that special virtues belong to any particular drug.

Vetlesen[1] has warmly advocated the use of belladonna combined with cannabis indica. He tells us that in 116 cases he obtained excellent results 83 times. In 30 patients the disease lasted only from 8 to 14 days. I have no personal experience to record with this combination, but on general principles I am hopelessly sceptical concerning such surprising results. I may say, in this connection, that I have employed belladonna unstintingly, a few times unwillingly, to the danger-point. Yet, I have never seen it shorten the duration of the disease, although the severity of the spasmodic cough was favorably influenced.

The bromides and chloral have found favor with many writers. For myself I have come to regard them as indispensable in the severer cases. I have fearlessly employed them alone or in combination.

The action of cocaine, locally as well as internally, is extolled by numerous observers. Prior recommends as highly efficacious, solutions having a strength up to 30 per cent., to be applied with a brush, to the pharynx and larynx. I have feared to employ the stronger solutions of cocaine, and the weaker ones (up to 4 per cent) have not given me much satisfaction.

By several writers the various salts of quinine (Binz, for example, favoring large doses of the tannate) have been strongly urged for internal as well as local use. My own experience with quinine is so slight that I am not justified in commenting on its utility.

Carbolic acid, iodoform, corrosive sublimate, resorcin, the salicylates, pure benzol, eucalyptus, thymol, boric acid, in fact every known antiseptic and parasiticide, has found its champion. Why any particular member of this group should be so much more beneficial than all the others, I am unable to comprehend. The use of antiseptic sprays, provided always that the patients are old enough to tolerate the necessary manipulations, would appear to be a rational means of procedure. I am bound to confess, however, that in my hands they have yielded less flattering results than I anticipated, after reading the glowing accounts of the successes of others.

I would put these questions before you: If pertussis is due to the irritation of toxic substances (ptomaines) produced by specific microbes, are we really fulfilling the indications of the disease, by incorporating other poisons into the system, impotent to kill the bacteria, but yet powerful enough to harm the young patients?

In other words, is not this much-vaunted specific medication of pertussis an illusion and a snare?

Is it not, after all, more rational so to fortify the system, that in what has been termed the "cellulo-microbian warfare," the cells may be the victors and not the vanquished?

Is it not safer and easier to assist the cells to fight their battle, than to attempt to kill the rapidly multiplying bacteria that are already lodged within them?

Although I have deprecated the habit of recommending particular drugs on the strength of gratifying personal experience, I cannot refrain from alluding to the use of antipyrin in pertussis. Dr. Sonnenberger,[1] of Worms, was the first to call attention to this new drug in the treatment of whooping-cough. He claimed such surprisingly good results from its employment that my sceptical faculty was immediately fanned into activity. Nevertheless, so far as my own limited experience goes, I must own that antipyrin has with me a better record than any other one drug. I can claim no cures from antipyrin. But what the drug has appeared to me to favor, was an easy course of the disease to final recovery, a mitigation of the paroxysms, especially at night, possibly a reduction in their number, and certainly a freedom from complications. This is higher praise than I can conscientiously bestow upon any other method of treatment. But I am far from claiming as much as Sonnenberger, for antipyrin, that author asserting it to be distinctly curative. As to the method of its employment, I have followed the directions of Sonnenberger, who gives one-seventh of a grain to very young children, and gradually increases the dose according to the age of the child. To adults he gives fifteen grains. The medicine is administered three times daily, and sometimes once during the night. Children take it readily when dissolved in a little water and raspberry syrup. The remedy should be continued throughout the attack.

[1] Norsk Mag. f. Laegevidenskaben, No. 6, 1886.

[1] Deutsche med. Wochenschrift, April 7, 1887.

I have said nothing about fumigation with sulphurous acid, a method urged for adoption by Mohn,[1] because I have not tried it. Antiseptic inhalations and others, in the pneumatic cabinet, as particularly advocated by a Dutch physician,[2] may also be mentioned here. I have not employed this method, and doubt whether it will find favor with the profession.

When a French physician asserts in all seriousness, that he cures whooping-cough by cauterizing the ulcerations on the under surface of the tongue,[3] we can only assure him that French pertussis and American pertussis are distinct and different maladies. As a summary allow me to submit the following conclusions:

1. There is constantly associated with whooping-cough a special microörganism, discovered by Afanasieff.

2. This microbe is a small bacillus, having properties that distinguish it from all other known bacteria.

3. The "bacillus pertussis" (*bacillus tussis convulsivæ Afanasieff*) can be readily demonstrated in the sputum of patients having the disease.

4. While its etiological significance appears established, it does not possess much diagnostic importance, since it is found only after the clinical features of the disease are already well marked.

5. The treatment of pertussis has not yet been materially advanced by this discovery.

6. Antiseptics locally applied do not appear to shorten the duration of the disease.

7. Hygiene and judicious alimentation are, in the present state of our knowledge, of, at least, equal importance with medicinal treatment.

8. Antipyrin and the bromides are reliable symptomatic drugs, and are devoid of danger.

9. A specific has not yet been found.

10. Abortive forms of pertussis may occur, but no plan of treatment now known can claim to have abortive efficacy.

712 MADISON AVENUE, NEW YORK

CONSIDERATIONS ON THE PATHOLOGY OF THE CÆCUM AND APPENDIX.[4]

BY JOSEPH RANSOHOFF, M.D., F.R.C.S.,
OF CINCINNATI.

WHEN Dupuytren,[5] in 1826, had first called attention to the relation of pericæcal abscesses to those of the right iliac fossa, observations in this field were rapidly instituted by continental writers. In 1830 Goldbeck,[1] of Heidelberg, first suggested the term perityphlitis for all the inflammatory conditions of this region. In 1834 a step was taken in the right direction when Copeland[2] first differentiated lesions of the cæcum from those of the appendix, and another by Albers,[3] who first described that special form since known as "typhlitis stercoralis." In 1836 and 1838 John Burne[4] contributed, in two excellent articles, further knowledge concerning lesions of the cæcum and appendix. Within recent years particularly numerous articles on the diseases of this region have appeared, and as a result their proper nomenclature is being gradually determined.

There are most excellent reasons, anatomical and clinical, for separating inflammations here present, into those of the cæcum and those of the appendix; each to be subdivided into those of the part itself and those of its peritoneal investment. There is, it appears, a rational basis for the use of the terms typhlitis to indicate inflammation of the cæcum, perityphlitis to indicate a like condition of its serous coat. Appendicitis, following in the path of With[5] and Fitz,[6] should be reserved for inflammation of the appendix, and peri-appendicitis or appendicular peritonitis for that of its peritoneum.

Of the varieties of cæcal and appendicular inflammation, those of the appendix are of far more frequent occurrence in grave cases than those of the cæcum proper.

Yet it is equally certain that typhlitis is far from uncommon, although mortuary records fail to show it. In the investigations of the anatomy of the part, I was struck by the frequency with which evidence of chronic catarrh, in the form of patches of indolent venous coagulation, pigment spots, and superficial abrasions were encountered in the cæcum. In all such instances the scybalous contents were covered with a layer of opaque mucus. This catarrhal condition is by no means confined to those who are habitually constipated, but is often encountered in the young, in whom the dependent position of the cæcum makes it a favorite seat for the retention of indigestible food. From this condition there is only a step, though a long one, to the typhlitis stercoralis of German writers, which, though doubtless of frequent occurrence, generally ends in recovery, and is, therefore, not anatomically demonstrated.

Given, however, a continuance of the cause, which, in contradistinction to that of peri-appendicitis, is rarely a foreign body, and the erosion be-

comes an ulcer. If the pressure effect of a hard fecal mass be the cause, the ulcer would probably be seated in the posterior wall of the cæcum, where, therefore, the localized peritonitis or intra-peritoneal abscess would be most likely to result. That such peritonitis may develop in any portion of the cæcal superficies is shown by the multiplicity of directions taken by perityphlitic abscesses in different cases. Whether the abscess presents itself above or below Poupart's ligament, the superficial position of the cæcum generally causes it to appear early. The only exception is that in which the pus travels toward the loins, under which circumstances the peri-cæcal trouble is probably secondary to a peri-renal, spinal, or iliac abscess.

The perforations which occur in the cæcum are not often produced by foreign bodies, although a number of such cases have been recorded. They are not infrequently produced by tuberculosis, although here, as in the case of foreign bodies, the appendix is preferably the part affected. The ulceration may, however, exist in the cæcum alone, the appendix remaining unaffected.

It is evident that the views entertained from time to time concerning the relative importance pathologically of the cæcum and appendix have vibrated like a pendulum. Dupuytren and his followers look on the cæcum as the part primarily at fault. Burne located disease in the same part, and Habershon[1] followed in the same direction. In the more recent contribution of Kraussold[2] and Berner, the appendix has been given greater prominence than ever before; whereas formerly, as Kraussold puts it, the appendix was treated in a stepmotherly way, there is a danger now that the cæcum will share this fate. While in the acuter and more fatal forms of perforative inflammations of this region the appendix doubtless plays the more important *rôle*; of twenty-five cases recently collected by me,[3] only one being of the cæcum, it is unreasonable to ascribe every perforation to it from clinical evidence alone. Thus so admirable an observer as Fenwick[4] mentions a case in which an abscess of the thigh was opened and discharged feces. In another instance an abscess terminated in a chronic vaginal fistula. Since both cases recovered, what evidence is there that in either the appendix was principally at fault? Fenwick, with others, rightly claims that the occlusion of the orifice of the appendix is a common cause of perforation. How can we logically, in such a case, account for the continuance of a copiously discharging fecal fistula? It appears to me much more probable that cases of this nature are primarily of cæcal origin.

[4] Loc. cit.

On the other hand, the position of the appendix, the narrowness and tortuousness of its canal, the presence of a valve, the tendency of fecal or foreign matter to be retained in it, and the readiness with which it is displaced, all serve to make the appendix the principal seat of grave pericæcal inflammations. It is not remarkable, therefore, that autopsies will often reveal pathological conditions of the appendix where death has resulted from other causes. Züngel, Toft, and Kraussold have called particular attention to this fact. The latter writer even claimed that between the ages of twenty and seventy every third body will show traces of disease of the appendix, and that particularly in tubercular subjects it is often converted into a tubercular ulcer.

In over sixty examinations recently made, I found reasons for believing that in this section of the country, at least, the proportions quoted are entirely too large. In only eight cases were there either abnormal adhesions, unusually hard fecal masses, fibrous occlusions, or cicatrices on the surface. In only one instance was a foreign body, the stem of a raisin, encountered there. The discrepancy between these observations and those of the authors alluded to may be accounted for by the greater indulgence in animal diet by our people.[1] Speck calls attention to the greater frequency of the diseases of this region in Siberia, where the food, which is mostly vegetable, contains a large amount of indigestible residue.

The history of appendicitis is, for the most part, like that of inflammation in other narrow mucous canals with their catarrhal, ulcerative, and cicatricial phases. Recurring like typhlitis, and usually occurring like it about the period of adolescence, appendicitis is doubtless in many cases but the extension of disease from the cæcum. The catarrhal thickenings of Gerlach's valve or permanent stenosis of the appendicular orifice may cause the retention of excrement or mucus, either of which may form the nucleus of a concrement. This, or a foreign body, has been shown by Matterstock,[2] Fenwick, and Fitz, to be the cause of perforation in three-fifths of all cases. In other instances the appendix degenerates into a retention-cyst. Whatever the condition of the appendix, if at all grave, the peritoneum is sooner or later implicated. The favorable position of the appendix for forming adhesions and localizing abscesses without doubt often prevents a general peritonitis. On the other hand, the rupture of such adhesions or residuary abscesses may fatally infect the general peritoneum. Not infrequently, where there is no foreign body, the appendix degenerates into a firm fibrous cord, buried in adhesions and often difficult to find. These are the cases in which

[1] Quoted by Whittaker, Pepper's System of Medicine, vol. ii. p. 816.
[2] Gerh. Handle d. Kinderks. Treves, Brit. Med. Journ.

the progress of the appendicitis is made manifest from time to time by clinical phenomena, and in which the appendix, as the seat of recurring disease and a constant threat to the individual, may, as was recently done, be justifiably excised.

In a very fair proportion of cases (seven out of twenty-five) no foreign body or fecal mass is found, nor can the rupture of a cyst or tubercular ulceration account for the perforative peritonitis. In such instances the distal inch or two of the appendix is often found gangrenous, either adherent to the appendicular base or as a slough free in a pelvic abscess. This condition, it appears to me, is brought about by the displacement of the appendix and consequent torsion of its vessels; since the distal one-half inch or inch has no blood supply independent of the base, torsion of the latter would primarily involve the tip. A number of facts support this view. In the first instance, the appendix is not a pelvic organ under ordinary conditions. In perforative appendicitis of rapid development the abscess is, at least, often intrapelvic. In the second place the exciting cause of perforating appendicitis is, in one-fifth of the cases, a violence, such as might result from blows on the abdomen, excessive exercise, lifting, or vomiting. In the third place the gangrene is usually developed beyond the point of perforation. The latter is usually within one or two inches of the cæcal end; the gangrene, however, involves the tip. The subsequent pathological history of perforative appendicitis is outlined by rapidity of the effusion, and the facility or want of facility with which adhesions are formed. In many instances the contents of the appendix are thrown into the general peritoneal cavity and death ensues, with the rapidity and certainty pertaining to intestinal rupture from other causes and before adhesions form. In many cases, however, gradual drainage prepares the way for a limitation of the resulting abscess between the mesentery and mesenteriolum, and the small intestine within, and the cæcum without the omentum in front and behind all the reflections of the peritoneum over the psoas and eventually over the iliac fascia. Is it not possible, therefore, that except in foudroyante cases the danger of general peritonitis is somewhat overestimated.

When an abscess forms, what is more probable than its more or less rapid course toward the surface, above or below Poupart's ligament, toward the hypogastrium, or, as I have recently seen it, guided by an omental hernia toward the scrotum? Or that in other instances burrowing through the iliac fascia it should tend toward the loin; or opening into some hollow viscus, like the cæcum, rectum, or vagina, eventually to be recovered from?

It is beyond the scope of this paper to discuss the diagnosis and treatment of the conditions considered. But I may be permitted to append the following aphorisms. "Place not your faith in exploratory punctures; operate early and by lateral laparotomy when the symptoms are of the gravest, and a tumor is not forthcoming; reserving the incision parallel to Poupart's ligament for abscesses that are palpable."

HOSPITAL NOTES.

BAYVIEW HOSPITAL, BALTIMORE.

SURGICAL SERVICE OF W. B. PLATT, M.D., F.R.C.S.

FIBRO-ADENO-ENCHONDROMA OF THE NASO-PHARYNX; LONGITUDINAL DIVISION OF THE SOFT PALATE; REMOVAL OF THE TUMOR; PRIMARY UNION.

M. S., colored, aged forty-four years, widow, admitted Feb. 23, 1887. Patient has had a sore throat for a year, with difficulty of breathing through the nose. Upon one occasion, at night, she expectorated a mouthful of blood, some coming from the nose at the same time, no other hemorrhage; suffers with almost constant pain through the temples. This has been worse the last month. Menses regular; anorexia; insomnia; constipation. No history or evidence of syphilis. Patient is a thin, light-colored negress; voice weak; articulation indistinct. There is an oval, movable, smooth, subcutaneous lump, the size of a pigeon's-egg, just below the lobe of the left ear. This is said to have been there eight years. With widely opened mouth, the soft palate was seen to be very tense, and thrust downward so as nearly to touch the depressed tongue; uvula pushed far to the right; the velum glided to the right in the first act of swallowing. With the finger a slightly uneven, rounded, very hard, immovable body, apparently about an inch and a half in diameter, was felt arising from the right side of the naso-pharynx. The finger could not be pushed up behind the soft palate for further examination, nor was a rhinoscopic view possible.

Operation.—The patient being etherized, and the mouth held open by a dilating screw gag, the velum was incised in what was, at the time, the median line, although the line of the septum had been carried far to the right by the pressure of the growth. The incision lay over the most prominent part of the growth, and the velum was, previous to this, tightly stretched over it. The cut extended from the hard palate entirely through the soft palate. Owing to the projecting African jaws, the distance from the mouth to the posterior pharyngeal wall was much greater than is usual in Caucasians, and rendered the operation more difficult. Various previous patient attempts under ether to pass a wire around the growth through the nostril had failed. Neither was it possible to encircle it by passing the snare upward from the pharynx before dividing the velum. The palate on each side immediately retracted, leaving a V-shaped gap, through which the tumor projected. A galvano-cautery wire was then passed around the growth and tightened. The current was not strong enough to heat the wire, and a steel wire of a Jarvis's snare was, after some difficulty, placed in position. The tumor was nearly sessile, and extended downward and backward from the margin of the left Eustachian tube, as near as could be determined. The

wire was slowly tightened; about twenty minutes being occupied in the process. A moderate, but steady, flow of blood took place from the point of attachment of the tumor, which was finally controlled by sponges saturated with a saturated solution of ferric alum. The incision in the palate was now brought together by five silver sutures. The wound united by first intention. The sutures were removed in from five to nine days; the only unpleasant symptom was some pain in the region of the left Eustachian tube, and also a slight toothache, due to prolonged pressure of the gag. At the end of four weeks the patient could speak with nearly normal articulation, and swallow without trouble. For three or four weeks there was considerable induration at the former site of the tumor. This gradually disappeared.

The growth measured nearly an inch and a half in its greatest diameter, and an inch across the divided pedicle. A microscopic examination of it at the Johns Hopkins Pathological Laboratory, which was kindly made by Professor Welch, showed the tumor to be a fibro-adenoma, containing occasional cartilage cells.

Remarks.—The choice of an operation for the removal of a naso-pharyngeal growth depends upon its size, location, and character. When there is no reason to believe the tumor to be malignant, and it is possible to surround it by a snare, this should always be attempted through the nares, or, if the nostrils be entirely obstructed, upward through the pharynx around the growth. When these two procedures are not practicable, the entire velum may be divided longitudinally, as in this case, according to the recommendation of Manne; or if the growth be smaller, by a large button-hole, as proposed by Maisonneuve. If the growth be situated still further forward, Nélaton advises trephining the hard palate in addition. Huguier, and others after him, used a transverse incision in the soft palate, to secure better union, and in order to interfere less with the function of the palate. Such interference would probably, as a matter of fact, be greater from the tearing of the tissues in the transverse operation than from the clean longitudinal cut. The operations mentioned are but a fraction of the "preliminary operations" which may be necessary before proceeding with the removal of the growth itself. They are, however, the principal palatine preliminary operations; the others, the maxillary, the osteoplastic, and nasal operations, are intended for new growths, or for such as from their location or size cannot be reached through the divided palate. The danger in these operations is hemorrhage, and it is sometimes necessary to perform a preliminary tracheotomy, inserting Trendelenburg's canula, or else filling the larynx with sponges. When hemorrhage does take place, it is to be controlled by pressure, hot water, artery forceps, or where none of these is practicable, by styptics, preferrably ferric alum (saturated solution) or ferric persulphate. It is usually recommended to leave the naso-pharynx stuffed with sponges after operation, until the danger of a recurrent hemorrhage is past. Nothing of the kind was done in this case. The bleeding was once thoroughly stopped, and the pharynx simply washed out several times daily by thorough gargling. The patient was shown at the Clinical Society of Baltimore eight weeks after the operation. When seen again by me, six months later, there was no return of the growth.

MEDICAL PROGRESS.

A Successful Splenectomy.—In the *Annali Clinici dell' Ospedale degl' Incurabili in Napoli* for May and June, 1887, Prof. Agostino Casini has recorded a case in which he successfully excised a "wandering" and hypertrophied spleen. The patient was a woman, aged twenty-two, who for four years had suffered from frequent attacks of malarial fever, sometimes accompanied by jaundice. Three years before she came under the care of Dr. Casini she became conscious of uneasy dragging sensations in the abdomen, and noticed a tumor in that region which steadily increased in size, whilst her general health became gradually worse. On examination the belly was seen to be enlarged, especially on the left side. A smooth, rounded, rather hard swelling was felt occupying the forepart of the cavity; it extended upward nearly to the margin of the ribs, downward to the plevis, and laterally to a line passing downward from the anterior axillary border. The tumor was freely movable, and was not adherent to the abominal parietes. It could be rotated so that its upper edge was directed forward perpendicularly to the wall of the belly, the anterior surface thus becoming the inferior, and the posterior the upper. On the rounded margin a notch could be distinctly felt. The mass could be moved upward and to the left, so as to be almost covered by the ribs; displacement toward the right, on the other hand, caused a feeling of dragging and stretching on the left side. There was some fluid in the abdominal cavity. On April 20, Professor Casini opened the abdomen in the middle line, and removed the spleen. There were some adhesions to the kidney, and especially to the pancreas, which formed part of the pedicle. The latter gave a good deal of trouble, and had to be tied in a number of separate pieces, a portion of the pancreas, which could not be detached, being seized between the blades of a pair of forceps, and crushed off; the stump of the pancreas was then stitched up, and, after careful cleansing of the peritoneum, the abdomen was closed. Very little blood was lost in spite of the difficulty which had been felt in securing the vessel of the pedicle. The spleen weighed three kilogrammes and 100 grammes (6¾ lbs.). The temperature on the first and second day was 100.4° F., after which it fell to a point a little above normal. On the seventh day the sutures were removed from the abdominal wound, which had healed by first intention. A few days later a small abscess formed in the abdomen on the left side above the level of the umbilicus; the patient, however, soon afterward passed a quantity of pus in her urine, and continued to do so for some time, the swelling meanwhile gradually disappearing. Toward the end of May she was discharged cured, and six months later she was still in perfect health. This makes the ninth splenectomy that has been performed in Italy, the first having been done in 1874. Of these operations five had a fatal result; the remaining four, which have all been performed since 1881, have been successful.—*British Medical Journal*, May 12, 1888.

Rectal Medication for Children.—Jacobi writes that the rectum of the infant and child has been rising in the estimation of the practitioner since the times of thermometry;

for it is certainly the safest and easiest place to take the temperature. For therapeutical measures it is also invaluable.

The rectum of the young is straight, the sacrum but little concave, the sphincter ani feeble, and self-control gets developed but gradually. Thus a rectal injection is easily either allowed to flow out or vehemently expelled. Therefore one which is expected to be retained must not irritate. The blandest and mildest is a solution of six or seven parts of chloride of sodium in a thousand parts of water. This may be made to serve as a vehicle of medicine, unless incompatible with the latter, which will be but rare. An enema which is to be retained must be tepid and small in quantity, half an ounce, or little more or less, and carried up well into the rectum, for the immediate contact with the sphincter may produce its expulsion. Care must be taken to exclude air from the syringe, which, for small quantities, must be a well-fitting piston syringe, of hard rubber, with a long nozzle. This must be well oiled, and introduced, not straight, but with a gentle turn, so as to avoid folds in the anal mucous membrane (in the same way a thermometer *ought* to be introduced). The nozzle must not be too thin, as it is liable to be caught; the smallest nozzles of fountain syringes are, therefore, in most cases improper; the larger size is more appropriate for any age. The injection must be made while the patient is lying on his side, not on his belly, over the lap of the nurse, for in this position the space inside the narrow infantile pelvis is reduced to almost nothing.—*Archives of Pediatrics*, May, 1888.

The Treatment of Tonsillitis.—Hillaby, in the *Practitioner* for April, 1888, describes his mode of treatment as follows:

Open the bowels freely with a good dose of mistura sennæ co., put the patient on milk diet, and administer the following draught:

R.—Sodii salicylatis . . . . grs. x–xv.
Tincturæ aurantii corticis . . ♏ x.
Aquæ . . . . . ad ℥j.—M.
To be taken every four hours.

When the inflammation in the throat begins to subside, reduce the dose of salicylate and continue to give it in smaller doses for a few days after all throat symptoms have disappeared.

Conception after Ovariotomy. — Wetherill, in the *Lancet* of April 28, 1888, reports the following extraordinary case, in which Dr. Bantock reports his operation as follows:

"The case was one of fibroid tumor of the uterus, in a state of cystiform degeneration. There were adhesions to the omentum (rather extensive and requiring many ligatures) and to the parietes low down on the left side of the middle line. After these were all broken down and bleeding points secured by ligatures, I tried to lift out the tumor, but it so invaded the broad ligament on the right side that its removal in the usual way was impossible. Fancying there was nothing now to be done but to remove the ovaries with the view of checking the growth of the tumor, I removed the left ovary, which was easily got at. The *right* ovary was nowhere to be found. I now looked again very carefully at the tumor, and, as it felt as if there might be some deep-seated fluid in it, I tapped it, and got out nearly a pint of dirty-looking fluid. There was nothing for it now but to lay open this cavity; its interior presented a very ragged appearance, characteristic of these cases. There was no way of removing the tumor, either by enucleation or along with the uterus, with the slightest prospect of success, so I laid the cavity very freely open in the direction of the abdominal wound, and stitched the edges to the corresponding edges of the parietes, leaving a large opening into the cyst. This I stuffed with iodized cotton-wool, after freely applying the thermo-cautery to the bleeding surfaces of a deep incision into a rounded portion of the tumor. The wound was kept open from time to time, small portions of the tumor were cut away (this always requiring the cautery to stop the bleeding), and a pointed cautery thrust into the tumor in various directions. Suffice it to say that in about three months the tumor had wasted away, so that very little of it remained, and, after a short time longer, the wound closed."

So much for the operation. The patient left the hospital a mere shadow of herself before her illness. Her life seems to have trembled in the balance for some time after the operation. Returning home, she came under my care. For four years she enjoyed fairly good health, having nothing more than an occasional attack of cystitis. She was now quite *embonpoint* and married. Then comes the marvellous portion of her history. She conceives! During the whole period of gestation she suffered from nothing except a little inability to hold her urine. This was worse when she had a little cold, each expulsive effort to cough causing her to expel the urine involuntarily. This, however, yielded to belladonna, morphia, and spirits of nitrous ether. In July, 1887, I delivered her of a fine healthy child. The duration of labor was quite normal, occupying in all about twelve hours. I forgot to mention that the cause of the involuntary acts of micturition might have been the anteversion of the pregnant uterus; in fact, she had pendulous abdomen. Since that time she has been in perfect health. She nurses her baby boy herself.

Oil of Turpentine as a Hæmostatic in Epistaxis.—Billroth has found oil of turpentine an excellent hæmostatic in epistaxis, and Ernyei reports a case recently treated, which had resisted other treatment, and which yielded to three tampons dipped in oil of turpentine, after bleeding had persisted for eight days.—*Correspondenz-Blatt für Schweizer Aerzte*, May 1, 1888.

Digitalin, Hypodermatically.—Huchard, in the *Revue Gén. de Clin. et de Thér.* of April 12, 1888, reports the following formula for the hypodermatic use of digitalin:

Digitalin. . . . . gr. 1½.
Alcohol. . . . . ℥ 10½.
Aquæ . . . . . ℥ 10½.

Dose.—Ten drops, injected deeply into the muscles of the nates or back, twice daily.

The Treatment of Diabetes.—Hofmeister, of Carlsbad, in the *British Medical Journal* of May 5, 1888 concludes that:

1. We are in total ignorance as to the etiology of diabetes mellitus.

2. The quantity of sugar found in the urine is of no

significance at all in judging of the severity and danger of any particular case of diabetes.

3. The smallest traces of sugar, found only by most careful chemical examination of the urine, are of considerable importance in a great many cases, so that they cannot be left out of account in trying to arrive at a correct diagnosis and prognosis.

4. The dietetic treatment must be adapted to the special requirements of each case, as there are cases in which without regard to the amount of sugar excreted, complete abstention from starchy matters is not only useless, but directly injurious.

5. According to the present knowledge, strict antidiabetic diet, combined with the use of the waters of Carlsbad, is the best method of treating diabetes mellitus.

MAYER, also, of Carlsbad, believes (*Ibid.*) that as far as the treatment is concerned, it appears that everything should be avoided that may impair the action of the heart and kidneys; for we know that organs which are in a state of hyperactivity easily become diseased. I may here refer to the frequent occurrence of valvular disease in nephritis, and of nephritis in diabetes. The latter I have found recorded in 30 out of 66 cases contained in the records of the Pathological Institute of Berlin. Stokvis has forcibly drawn attention to the same point in his able paper on diabetes read before the late Medical Congress at Wiesbaden, while I have seen nephritis in 64 out of 380 cases, although not frequently in the form of granular contracted kidney.

The principle of sparing the suffering organs as much as possible has, in my opinion, to be carried out particularly as regards diet. In many cases a rigid nitrogenous diet cannot be enforced. I have, on this account, during the last few years, frequently added milk to the diabetic diet, and can fully corroborate the favorable testimony which Hoffmann gave on this point before the late Medical Congress.

A Plan to Obtain Vaccine Lymph without Rupturing the Pustules.—DR. GRIGG, of Queen Charlotte's Lying-in Hospital, suggests a method of obtaining vaccine lymph without rupturing the vesicles, which must commend itself to the practitioner. The method has the further advantage of increasing the supply obtainable. He allows a drop of pure glycerine to fall upon the ripe vesicle, and this has the effect of withdrawing the lymph from the interior without any solution of continuityof the investing membrane. Judging from the results obtained by Dr. Grigg, in nearly three thousand cases, in only one of which did he fail to secure a satisfactory effect, the lymph thus obtained is fully as active as ordinary lymph. Dr. Grigg remarks incidentally that lymph obtained from infants less than fifteen days of age is always scanty in amount and unreliable. He also records the fact that in cases where only one of the punctures proves successful in the first instance, a more satisfactory result may be obtained by revaccination from the solitary vesicle, which remains stationary until the second crop attains the period of maturity, and then the whole number go through the retrograde changes together.—*Medical Press*, April 18, 1888.

General Rules for Cataract Operations.—KNAPP, in the *Archives of Ophthalmology* for March, 1888, lays down the following general rules for cataract operations:

1. Keep out bacteria or wash them off by germless, unirritating liquids: boiled water, boric acid and other indifferent substances dissolved in boiled water.

2. Prevent the multiplication of germs by antiseptics: watery mercuric bichloride, or alcoholic biniodide, chlorine water, nitrate of silver, and other substances in very weak solutions.

3. Perform the operation with the utmost degree of neatness and accuracy, and with a minimum of traumatism, avoiding bruising, scratching, and tearing of any kind, so as to reduce septic conditions to a minimum.

4. Endeavor to obtain primary union by freeing the wound from all foreign substances, by perfect coaptation of its edges, and by maintaining the greatest possible immobility of the organ until the closure of the section is firm.

5. Avoid constitutional infection of the wound. It is dangerous to operate for cataract as long as the constitution of a patient is under the active influence of a specific disease; for instance, articular rheumatism, acute or chronic suppuration, syphilis, and the like. In some incurable diseases—for instance, diabetes—we must select the time when the vitality of the patient is least reduced.

A Hæmostatic Pill.—HUCHARD prescribes:

Ergotin,	
Quin. sulph.	āā grs. 30.
Pulv. fol. digital.,	
Extr. hyoscyami	āā gr. ⅓.

Ft. pil. 20 in number.

To be used as indications demand.

Phenacetin as an Antipyretic.—GRENFELL reports, in the *Practitioner* for May, 1888, ten cases of diseases attended by pyrexia in which phenacetin, in five grain doses, proved useful, as follows:

Phenacetin is a slightly reddish, inodorous and tasteless powder soluble with difficulty in water, a little more soluble in glycerine, but most readily in hot alcohol; it is insoluble in acids (except glacial acetic acid) or alkaline liquids. Though absolutely tasteless it is most conveniently administered in capsules with water, this method admitting of the most accurate dosage.

In cases of pyrexia the action of the drug begins within half an hour after administration. The patient generally perspires freely, and feels drowsy. Sleep often follows, and pain is relieved, while the patient always says that he feels more comfortable after it.

The most satisfactory dose for an adult is about eight grains, and children bear the drug well. Since the above notes were written, it has been extensively used as an antipyretic and as an analgesic in neuralgia, and with good results..

The Treatment of Ozæna by Inhalation.—NOQUET prescribes:

Chloral. hydrat.	gr. ¾
Acid. boric.	gr. 90
Glycerin. pur.	ʒ 2½
Aq. lauro-cerasi	ʒ 5
Aq. destill.	ʒ 50

The spray should be thrown into the posterior nares, and the patient should expire it through the nostrils. —*Revue de Thérapeutique*, May 15, 1888.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,

PHILADELPHIA.

SATURDAY, JUNE 2, 1888.

THE PASSAGE OF GERMS THROUGH THE LUNGS.

ONE of the greatest difficulties in the germ theory of disease is that caused by our ignorance of the way in which the germs gain entrance to the body they infect. Experiment alone can never prove that an infection must arise in any given way. It can only show possibilities, while complete knowledge can only be gained by the slow lessons of general pathology and epidemiology. Nevertheless, it is necessary to learn all the possibilities of the relative ease with which various germs can cause infection, for as long as the impossibility of any one mode is not demonstrated, we cannot exclude it.

Most of the work heretofore done in experimental infection has been by feeding or inoculation. BUCHNER (*Münchener med. Wochenschrift*, Nos. 16 and 17, 1888) has recently made some interesting experiments in the inhalation of germs and has come to conclusions somewhat different from those heretofore held. The methods used consisted in exposing animals to a spray of dilute cultures of various bacteria, in such a way that only the finest mist of the spray reached them. They were thus not exposed to wetting through, and at the same time the minutest spray bubbles contained enough germs to produce the desired effect. Control experiments were made by feeding, so as to exclude accidental infection through the alimentary canal by swallowed spray. It was found that this accident was very rare, and also that the amount necessary to cause infection through the intestinal tract is much larger than that for the lungs. The bacteria used were those of anthrax, with their spores, and those of chicken cholera and septicæmia.

It was learned very early that an irritative reaction hindered the passage of germs through the lung. Especially was this the case when large quantities of bacilli were used, and in these experiments so great was the irritation that a hemorrhagic pneumonia resulted. The best results, therefore, were obtained from cultures in which the bacilli had been killed by drying, so that the spores alone reached the lung in condition to multiply. The development of the bacilli was a rapid one, and in a few hours the increase could be demonstrated by the microscope and by cultures. Nor could there be any doubt that an entrance to the lung had been effected, for the pulmonary capillaries contained bacilli in quantities proportional to the time elapsing between inhalation and examination.

The mode of entrance is clearly and, in our opinion, accurately explained by Buchner. That it is not through the lymphatic circulation can be supposed by the rapidity with which it occurs. While Arnold's experiments in dust-inhalations go to prove that a passage through the lymphatic gland is almost impossible for these particles, experiments with tuberculosis and glanders demonstrate that infectious matter can pass through with comparative rapidity. In Buchner's experiments, however, the passage was so rapid that it could not be other than a direct one. Buchner explains the *modus operandi* by an action much like that of leucocytes in inflammation. The chemical irritation exerted on the walls of the capillaries causes the formation of stomata, through which the bacilli grow. These experiments, therefore, show that the idea of "intact lung" is one that must be considered with certain limits.

Buchner's experiments also show what forms of infectious material are best adapted to pass through the lungs. They are preëminently the blood parasites, or those which are able to live and multiply in the circulation. The germs of anthrax, recurrent fever, and malaria are the most striking examples of the blood parasites so far known, while those of tuberculosis, typhoid fever, and cholera occupy, according to our present knowledge, but a doubtful position among them.

In infections caused by blood parasites the point of entrance cannot always be found. So in one of Buchner's experiments the kidneys and spleen were

affected very early, although the lungs showed no macroscopic lesion. This, probably, explains the mode of infection in "rag-pickers' disease." Even in the case of germs not strictly blood parasites it is possible for them to penetrate the lung capillaries and be transported to that part of the body where they afterward set up morbid actions. Typhoid fever may sometimes be caused in this way.

It must be remembered, in studying the subject of infection through the lungs, that although a smaller quantity can affect the system in that way than through the alimentary canal, still, outside of laboratories, the latter mode must be by far the most frequent. It is only necessary to mention typhoid fever and cholera to indicate our meaning.

ANTISEPTIC PROPERTIES OF CHLOROFORM.

Salkowski calls attention to the antiseptic properties of chloroform in an article in the *Deutsche med. Wochenschrift* of April 19, 1888. Having used chloroform for some years to preserve specimens of urine he was led to study its action on fermentative processes and certain pathogenic bacteria. Chloroform dissolves in water in the proportion of about 5 to 1000 by volume, and in that proportion protected from evaporation, prevents the fermentations due to bacteria, such as ammoniacal in urine, the alcoholic, lactic, milk, and hippuric, and the putrefaction of albuminous material, while the action of unorganized, soluble ferments—enzymes—as ptyalin, pepsin, trypsin, etc., is not affected. This latter fact was partially known before. In this way chloroform is particularly convenient in revealing the presence of minute quantities of ferments, the actions of which are only developed after some months. Microörganisms are avoided, the organic tissues are not acted on by the preservative, and the latter can be removed, at will, by evaporation.

Anthrax and cholera bacilli are easily killed by chloroform, though the anthrax spores resist its action. Among the manifold uses of chloroform are the following:

For preserving urine, urea solutions, watery solutions of ferments of all kinds, pathological fluids of all kinds, except blood which gradually coagulates; in digestion experiments, especially with trypsin, etc., and for preserving small anatomical preparations, chloroform water or the vapor alone may be used, except when extraction of blood coloring-matter would offer an objection.

Salkowski also points out some further uses of chloroform which are worthy of trial. These are: the preparation of solutions for hypodermatic injection; as an intestinal antiseptic; and in case of need as an external antiseptic and disinfectant. It might also be used in mouth washes.

In a note Salkowski writes that most of the ethylic chlorine compounds possess antiseptic properties, though not excelling chloroform, and that the latter, from its volatility, is the one most available as a respiratory antiseptic. Further experiments are promised on this subject.

A NEW MIASMATIC DISEASE.

Gerlier has extended the list of cases of vertigo with palsy—*le vertige paralysant*—previously described, and has sought, in an article in the *Revue Médicale de la Suisse Romande* for January and February, 1888, to render the clinical picture of this curious disease more exact. The cases occurred at a number of scattered farms, in the neighborhood of Ferney, Switzerland. The sudden paroxysm, occurring, as a rule, in the afternoon, is characterized by disturbances of vision, transitory palsies, and spinal pain. The patient, seized at his work, all at once bows his head, leans upon any implement he happens to have, and, in the attitude of the peasant in Millet's picture, "The Angelus," awaits, immobile, the end of the attack. The attacks are much less common in the morning after a night's rest than later in the day. They are provoked by very trifling movements, excitement, and so forth. The duration of a single attack does not usually exceed one or two minutes, but they are apt to occur in series, extending through some hours.

Gerlier regards the disease as due to an infection which acts chiefly upon the nervous system, and which is derived from the surroundings of improperly drained stables.

The Medical Society of New Jersey will hold its Annual Meeting at the Heath House, Schooley's Mountain, on Tuesday and Wednesday, June 12 and 13, 1888, commencing at 4 o'clock P. M., on Tuesday, under the Presidency of Dr. John W. Ward, of Trenton.

The Ontario Medical Association holds its Eighth Annual Meeting at Toronto, on Wednesday and Thursday, June 13th and 14th next.

The Twenty-third Annual Meeting of the Michigan State Medical Society will be held in Detroit,

Thursday and Friday, June 14 and 15, 1888, beginning at 10 o'clock in the morning.

The British Columbia Medical Council has elected the following officers for the ensuing year:

President.—J. C. Davil, M.D.

Vice-President.—W. J. McGuigan, M.D., M. C. P. and S., Ont.

Registrar and Secretary.—G. C. Milne, M.D.

Treasurer.—E. B. C. Harrington, M.D.

Solicitor.—Mr. Walker.

The sale of narcotic medicines at country grocery stores is dangerously prevalent. At Mineola, on Long Island, the grocer of the town, who knows nothing of pharmacy, sold to a customer a quantity of bromide of potassium, from which an overdose was taken by the patient and death was the result. An inquest was held and a verdict of censure was entered against the storekeeper for having, without license and in violation of the State law regulating the sale of poisons, sold the deadly dose.

Dr. H. W. Boone, a missionary to China, publishes in the *China Medical Missionary Journal* an account of his visit last year to this country and to its leading universities and hospitals. He notes, in terms of commendation, the changes that have come over the method of medical instruction since his own days of earlier study, specifying the growth of clinical teaching and of laboratory work. Of the profession he gives a bird's-eye view in a few words: "There is an earnestness among the higher grades of the profession which strikes one; they love their work for their work's sake, and they are fully imbued with the dignity of their profession. The successful ones are well paid and they live in the elaborate and expensive style of the world around them. They are of the world, and yet by their profession they are above it. Much excellent work is being done there; the leading schools are well up to the times, and the standard of medical and surgical work among the leaders of the medical world is a high one."

A great variety of denominations and nationalities about New York find the means to establish institutions of healing in the name and interests of their respective classes. A French hospital is the latest to be projected. Two houses will be purchased, at a cost of $55,000, and fitted up with a capacity of fifty free beds and ten private rooms; a dispensary will be added later, if the necessities of the poorer element of the French colony appear to demand it.

At the meeting of the Board of Trustees of the New York Post-Graduate Medical School, held on Monday, May 28, 1888, the following appointments were made in the Faculty: Abraham Jacobi, M.D., Professor of Diseases of Children; Robert F. Weir, M.D., Professor of Clinical Surgery; Peter A. Callan, M.D., Professor of Diseases of the Eye; L. Bolton Bangs, M.D., Professor of Diseases of the Genito-Urinary Organs and of Venereal Diseases; Joseph E. Winters, M.D., Professor of Diseases of Children; O. B. Douglas, M.D., Professor of Diseases of the Nose and Throat.

Dr. William A. Hammond, being about to remove to Washington, has resigned his position as Professor of Mental and Nervous Diseases. Dr. Hammond was one of the founders of the School.

Professor Wroblenski, member of the Medical Faculty of the University at Krakau, died recently from blood-poisoning contracted during an experiment performed before his class.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Thirty-ninth Annual Meeting, held at Cincinnati, May 8, 9, 10, and 11, 1888.

(Specially reported for The Medical News.)

SECTIONS.

SURGERY.

(Concluded from page 589.)

Thursday, May 10th.—Morning Session.

Dr. E. H. Bradford, of Boston, presented a paper on

THE FORCIBLE AND IMMEDIATE REDUCTION OF OLD SUBLUXATIONS.

The essayist proposed a method of treating especially old subluxations of the knee-joint, as follows: The patient being anæsthetized, the knee is forcibly flexed in order to break up the intra-articular adhesions. An apparatus devised by the essayist is then applied and pressure from behind forward by means of screw-force brought to bear upon the head of the tibia. The skin is abundantly padded, and the nerves and vessels are sufficiently protected by the muscle bellies of the region. After this is effected the limb should be held straight and secured against recontraction by a plaster-of-Paris bandage, applied high up in the thigh and including the whole leg and foot. The patella and joint should be well protected with cotton before the application of the plaster.

DR. P. S. CONNER, of Cincinnati, reported a case of

PRIMARY SARCOMA OF THE SCALP,

in which he had twice removed a sarcomatous growth from the scalp of Mrs. S., aged thirty-five years, white, native of eastern Kentucky. The primary growth had been noticed fifteen years before as a hard lump, the size of a bean, on the back part of the head. For thirteen years it remained of stationary size, then grew rapidly, until when excised, October, 23, 1885, it looked much like a second head, and weighed, after removal, about five pounds.

Eighteen months after the operation the patient noticed a small tender spot, and soon after a hard lump, which increased slowly for three months, then more rapidly. She was about a month advanced in pregnancy when the recurrence was observed. After her confinement, in January, 1888, the growth was excessively rapid, measuring, in March, antero-posteriorly, eighteen inches, laterally, seventeen and one-half inches. The mass was again removed and weighed seven and a half pounds. Five weeks after the operation, the patient left for her home, the granulating wound being in excellent condition.

The interesting points in the case, the speaker said, were the long absence of any change in the original nodule, the marked influence of pregnancy and lactation upon the growth of the tumor, both primarily and in recurrence, and lastly the immense size of the growth. A primary sarcoma of the scalp is of great rarity. No hard, indolent lump in the scalp should be permitted to remain, even though for years in an unchanging and unchanged condition. Probably benign and to continue such, it may not be so now or in the future.

DR. JOSEPH M. MATHEWS, of Louisville, presented

SOME OBSERVATIONS UPON TWO THOUSAND OPERATIONS ON THE RECTUM,

in which he confined himself to the consideration of hemorrhoids, especially the internal variety. The causes, classification, dangers, and treatment were fully discussed. Referring to the classifications proposed for this class of diseases, the speaker stated that he thought the division into external and internal piles sufficient for practical purposes, as there was no ground for the making of distinction between the so-called venous, arterial, and capillary dilatations. He strenuously opposed the treatment by carbolic acid on account of its danger; quoting in this connection what is said by Dr. Andrews in his later work on *Diseases of the Rectum*. The clamp and cautery and excision were also considered. The speaker preferred the ligature to all other methods of treatment.

DR. H. H. GRANT next read a paper entitled

INTRA-PERITONEAL RUPTURE OF THE BLADDER.

Though among the rarer lesions for which abdominal section is appropriate, the still rarer comparative success after the operation lends an interest to the few recorded recoveries after laparotomy for its relief. He asked attention to the history of the operation, now about ten years old. It is a remarkable fact that though indefinite references to the propriety of attempting suture of the bladder after laparotomy for rupture have been made by Gross, Larry, Cussock and others, yet except the suggestions of Holmes in his *Principles and Practice of Surgery*, in 1875, nothing like a definite operation is mentioned for it in any text-book on surgery published prior to 1880. Mr. Revington (Heath's *Surgical Dictionary*) declares that up to that time intra-peritoneal rupture of the bladder, however treated, had been uniformly fatal, excepting only Watters' case (*Med. and Surg. Rep.*, Feb. 1862) of laparotomy without suture.

This is, perhaps, the only laparotomy for the lesion under consideration until Mr. A. Willett, in 1876, closed by suture the bladder rent and abdominal wound (*St. Barthol. Hosp. Rep.*, 1876, xii.). Thus to Mr. Willett is due the credit both of the originality of the operation and the details of its performance. His operation was not, however, a success, as death occurred from peritonitis in twenty-three hours. In 1878, Mr. Christopher Heath (*Med.-Chirurg. Transact.*), forty-eight hours after accident closed by continuous catgut suture an intra-peritoneal rent; leakage and extravasation occurred and death on the sixth day.

In 1883, Pilcher (*Treatment of Wounds*, p. 370) commenting on these cases, describes with references to Vincent and Stein, the operation afterward successfully done by MacCormack in two cases in 1886, and now recognized with slight modification as the perfect technique.

He presented a table which he had formed in part from that of MacCormack, published in 1877, with fuller details supplied to some of his cases, published since his table and the addition of four cases operated upon since that time. He then reported a case upon which he had operated by this method, the steps of which were fully described, with the result a perfect success.

All observers, he said, are in accord as to the importance of an early operation, within eight to ten hours after the accident if possible. The symptoms are usually distinct and the diagnosis clear—great pain, severe shock, desire to urinate with futile attempts, perhaps a little bloody water by catheter. Yet the condition may be greatly obscured. Most authors refer to intra-peritoneal rupture of the bladder as a rare accident; but the essayist thought its appearing rare was due in a great measure to its being frequently overlooked.

AFTERNOON SESSION.

DISCUSSION ON ABDOMINAL SURGERY.

DR. P. S. CONNER, of Cincinnati, in opening the discussion, expressed regret for the absence of Dr. Hunter McGuire, to whom he had assigned the opening address. He felt sure that he voiced the sentiments of the Section when he expressed his high appreciation of the papers presented to the Section yesterday; papers which presented the results of experience and experiments, which give us positive rules in the treatment of cases of the most difficult character. And last of all there was presented the most beautiful demonstration that had ever been given to the profession of this country. Nothing could excel the labor and patience with which were worked out the experiments presented yesterday. Dr. Senn, literally absolutely, in every sense, threw light upon an exceedingly dark subject. No cases give us more anxiety, either in the detection of the difficulty or in the treatment of it than those of intestinal obstruction. If we were to believe all that we read and a good deal that we hear, we would suppose that it is an easy matter to determine the character of an intestinal

obstruction. The diagnosis has been very positively laid down, but, however clear the diagnosis may be in the books, it is very different with patients in bed. It is sometimes very easy to determine what the nature of the difficulty is; in other cases, notwithstanding the employment of the most accurate methods of investigation, it is very difficult to determine what the difficulty is or where that difficulty is located. In most cases it is easy to determine what is to be done when the diagnosis has been made, but, after all, it is the determination of the difficulty itself that gives us most trouble.

Leaving out of consideration the inquiry whether the case is one due to an intussusception, a constricting band, a twist of the intestine, the pressure of a tumor, etc., we have two kinds of cases to deal with: First, rapidly developed obstruction in patients of good health, and, second, slowly developed obstruction in patients whose health may be good or bad. We might add to this a third variety, namely, those cases in which the suddenly developed obstruction follows chronic trouble in the intestinal tract.

Letting the patient alone may and frequently will terminate in recovery, but it will frequently result in the death of the patient. When recovery follows the let-alone plan of treatment, we congratulate ourselves upon the successful issue of the case. Who of us, on the other hand, has not seen active interference made in these cases where it terminated fatally?

To discuss this question to-day is a very different thing from discussing it ten years ago. Abdominal surgery has made rapid progress; some of it, he was about to say, too rapid and apt to lead in the wrong direction. Active interference is the only rule in the treatment of intestinal obstructions to-day. The proper discovery of the seat of the lesion, the removal of the difficulty and putting the patient in a proper way for recovery are the ends we seek. A world of truth was expressed yesterday by Dr. Moore when he took exception to the remark that the abdomen might be opened with impunity. It is not a little thing to open the abdomen. That laparotomies have killed patients we know too well. Failure of success is often due more to the condition of the patient than to the character of the difficulty.

DR. S. H. WEEKS, of Portland, Maine, expressed his high appreciation of the great value of the papers that had been read. He desired to emphasize the fact that the discussion was limited to the treatment of intestinal obstruction in its *surgical aspects*. It is not every case that is to be treated by surgical measures; many cases are to be treated by medicinal means. He then narrated a case which simulated the passage of biliary calculi, and was so diagnosticated before laparotomy was much in vogue; but the autopsy, four days later, revealed an obstruction which could have easily been relieved by surgical means. He spoke also of a case presenting almost the same symptoms in which the obstruction, high up, was occasioned by the binding down of the omentum after it had wound itself around a loop of the intestine; and of a third case in which he operated upon a man almost moribund, found the obstruction, removed it and gave almost instant relief. The operation, he remarked, should not be too delayed, until the intestine becomes gangrenous.

In conclusion, he remarked that the modern surgeon should no more permit his patient to die unoperated upon with an internal strangulation than he would permit him to die of an external strangulated hernia. Sudden stoppage, great pain, great prostration, feeble pulse, anxious expression, restlessness, nausea, vomiting—these symptoms speedily becoming pronounced, are those upon which we rest our diagnosis of an acute obstruction. And when the surgeon feels that he is in the presence of an acute obstruction, a great responsibility rests upon him, and he makes a great mistake if he fails to perform his duty.

DR. D. S. CAMPBELL, of Detroit, read a paper on

ELECTROLYSIS AS A PRIME AGENT IN THE REMOVAL OF NASAL AND PHARYNGEAL NEOPLASMS.

The therapeutic value of the galvanic current in urethral hypertrophic catarrh, fibromata, and mucoid growths of the uterus, etc., owes its demonstration chiefly to Apostoli, of Paris. The essayist had come to the conclusion, after careful manipulation of this particular kind of chemical force in a large number of cases suffering principally from nasal and pharyngeal neoplasms, that its therapeutic value is worthy of consideration. He dwelt, for the most part, upon the nature of the galvanic current and its effect upon living tissues, from which he passed to the illustration of the results which follow its systematic application in a case of fibroid tumor. His experience led him to the conclusion that the strength and frequency of application, as well as the strength of current employed, must correspond to the peculiarities of individual growths. No rules can be advanced.

DR. H. LANDIS GETZ, of Iowa, next described and exhibited

AN ANTISEPTIC SURGICAL CABINET.

The cabinet was devised for the purpose of enabling the surgeon and gynecologist to avoid the application of chemical agents to fresh wounds in order to render them aseptic, especially in major operations. The cabinet consists of a gauze-covered framework about six feet in all dimensions. In constructing it, the frame is first put together in a position to surround a window. Just before the cloth is suspended over the frame, it is dipped in a solution of mercuric bichloride, 1 : 500 or 1 : 1000, thus, as the essayist claimed, being rendered impervious to microörganisms. The floor was covered with the same aseptic cloth. A special arrangement was added for the introduction of fresh air from without. The advantages claimed for it by the inventor are briefly: It purifies the air by a process innocuous to the wound surface; it is easily and quickly constructed; cheap, simple, efficient; it admits circulation of air without currents; strong germicides may be used without danger to the patient: and many other features of greater or less supposed value.

DR. W. VAN HOOK, of Chicago, called attention to the method employed by Dr. David Prince, of Illinois, for rendering the air in the operating-room aseptic, and stated that it has proved successful in the room used by its originator. He did not believe, however, that a perfectly aseptic room could ever be devised, for the reason that every operator carries enough germs in his mouth and nostrils "to poison the entire mass of humanity." Owing to the agglutinating properties of the mucus lining the air passages, however, these germs are not expired with the expired air, which has been found to be comparatively aseptic.

DR. T. D. DAVIS, of Pittsburg, then read a paper on

GRADUAL DILATATION OF ŒSOPHAGEAL STRICTURES.

He stated in introduction that he referred only to cicatricial strictures of the œsophagus. These are produced by any cause that will destroy its coats. When either its mucous or submucous coat is destroyed, the resulting cicatrix is composed of smooth, hard, imperfectly organized tissue that projects in ridges, or causes the adjacent mucous membrane to be puckered up in folds. If the continuity of the deeper tissues be destroyed and the muscular coat is destroyed, the resulting cicatrix is very firm and callous, and the passage much contracted. Secondary hypertrophy of the mucous membrane may follow. The various causes which may produce cicatrices of the œsophagus were next reviewed, chief among which was the drinking of concentrated lye. The number of individuals, for the most part children, who are annually victims of this dreadful accident, the speaker said, is appalling, and far beyond the published reports. The speaker thus described the first case in which he had practised gradual dilatation:

In April, 1880, Henry C., aged four years, had been playing in the yard and came crying into the house with his mouth bleeding. . . . From information received afterward, I have no doubt that he swallowed a solution of concentrated lye from an old empty can that had been carelessly thrown in the yard. . . . In five weeks I was called to see him again, when I was informed that he was having repeated attacks of vomiting. He had lost considerable flesh and his face presented the haggard, anxious look of craving hunger. An œsophageal stricture was at once diagnosticated, and with the assistance of Dr. W. R. Hamilton, a No. 2 flexible catheter was with great difficulty passed through to the stomach. The difficulty was caused first by the great dilatation of the œsophagus that had taken place above the stricture, making it extremely hard to find the natural passage and avoid making a false opening through the attenuated walls; and, secondly, by the size of the stricture itself which grasped firmly the small catheter. . . . Immediately after the passage of the catheter, the child was able to swallow a few spoonfuls of milk, but in a few hours the tenacious mucus would again accumulate and occlude the passage. In a short time the child realized the relief afforded him by the dilatation and waited rather anxiously for the operation, often bringing me the tube to insert. In order not to hurt him, to retain his cooperation, I increased the size of the tubes very slowly, and thus stumbled upon a very satisfactory plan of treatment—that of very gradual dilatation.

After six weeks of this careful dilatation, the speaker entrusted the operation to the parents, and in five months the œsophagus had obtained a size equal, as he believed, to that of the normal passage in a child of that age, admitting of the passage of No. 2 rectal bougie.

In conclusion, the following propositions were advanced:

1. Too much weight has been given to spasmodic stricture of the œsophagus by Michel, Campbell, Smith, and others. That involuntary muscles can even have tonic spasms at all is a question, but to hold with Campbell that such a spasm can continue for eight days calls for a stretch of the imagination beyond my power. At no time did I have any evidence of spasmodic stricture in these cases. Any difficulty in introducing the dilators was due solely to causes mentioned. The relief given by passing the bougie is readily explained, not by its overcoming spasm, but by its removing the tenacious mucus, or some article of food that had clogged the passage or lodged on the shelf of the stricture.

2. The advantage of the early introduction of the bougie to prevent dilatation of the œsophagus above the stricture is clearly manifested by the history of these cases.

3. The second case certainly contrasts the rapid and gradual plans of treatment to the great advantage of the latter. To "make haste slowly" is the only safe rule. The gradual method being almost painless and giving great relief, secures the coöperation of the patient. It avoids, too, great irritation and danger of inflammation and rupture, all of which are likely to follow rapid dilatation.

4. Is not the occurrence of seventeen accidents in Pittsburg alone enough to second Dr. Campbell's proposition that some legal restriction should be placed on the sale of this intensely dangerous substance?

FRIDAY, MAY 11TH.—MORNING SESSION.

DR. WELLER VAN HOOK, of Chicago, read an abstract of his paper on

SACRO-ILIAC TUBERCULOSIS.

The clinical characteristics of tuberculosis at the sacro-iliac joint partake of all the general characteristics of tuberculosis of other joints. The sense of deep bogginess over the joint indicating chronic inflammatory involvement of the deep structures, and œdema of the soft parts above are present here as well as in morbus coxarius. The loss of function, the pain on pressing the bones together, the tenderness over the joint cavity, the change in attitude, the tumefaction and finally, the sense of fluctuation yielded by fluid exudates are common here as in tuberculosis of the knee or ankle. In older cases in which cold abscesses have formed and have opened outward, we find fistulæ running in a great variety of directions from the starting-point in the joint itself.

Notwithstanding the study which has been bestowed upon these joint affections, we are compelled to limit our deductions, after locating the disease, to a determination of its tendencies from a single symptom—viz., the presence or absence of cold abscesses; for other symptoms are of comparatively little prognostic value. Of thirty-eight cases of sacro-iliac tuberculosis with abscess, collected by the essayist, only one, that of Hilton, recovered without operative interference of some sort.

On the other hand, with the observance of hygienic laws, with the application of complete mechanical rest, fifteen out of a total of sixteen collected cases without abscess went on to complete recovery, the only death being due to an older suppurating tuberculosis of the knee-joint. But though the cases without abscess tend to recovery, we have numerous examples to prove that cases originally devoid of abscesses can proceed, chiefly under imperfect treatment, to local extension, abscess formation, and eventually death.

The moist form without mixed infection may end in recovery, as doubtless did Hilton's case, by resorption of fluid matter and capsulation of the detritus. Instead of

the fluid being resorbed, it may be discharged externally, the original focus being enclosed as before in a scar.

Death occurs in the moist form from sapræmia or septicæmia due to mixed infection; from simultaneous or intercurrent local tuberculosis elsewhere, as in the intestine, peritoneum, and lungs; or from general miliary tuberculosis.

Previous to the period when radical operations came into vogue for the treatment of tubercular arthritis, the treatment of sacro-iliac tuberculosis was on a par with that of other joints. Erichsen, in his celebrated clinical lecture of 1859, describes the treatment as properly including, besides internal remedies, rest with counter-irritation during the period prior to abscess formation, and opening of abscesses by valvular incisions when they are large and chronic. He regarded operative interference as out of the question. The essayist here stated that Dr. L. A. Sayre, of New York, had reported to him a case, not published, in which he had in 1853 opened the joint of a child posteriorly and gouged out carious bone with recovery.

It is only within the last five years that operators have begun to consider seriously the question of radical treatment of the disease, operations having been performed by Tiling, of St. Petersburg, in 1883, and two in 1887 by Gant, of England.

He recommended two operative procedures, according to the extra- or intra-pelvic location of the abscess. The method of reaching the lesion when the abscess is extra-pelvic is that practised in the cases operated upon by Sayre, Tiling, and Gant—namely, by simple incision over the joint, and curetting with the usual instruments. When only intra-pelvic abscesses have formed, and we have reason to believe that the disease process lies chiefly in the anterior part of the joint, we must have resort to the second procedure, by which, if possible, the posterior and sound part of the joint need not be disturbed. It must be remembered that the articular surfaces of the sacrum and ilium are directed antero-posteriorly—that is, almost perpendicularly to the flat surface of the skin overlying the sacrum. Hence the broad expansion of the joint surfaces lies at a depth in the adult of two and a half to three inches from the surface. This surface may be reached thus: The patient lying on the unaffected side with the thighs in exaggerated flexion, a longitudinal incision exposes the posterior superior spinous process of the ilium from which the periosteum and tendinous attachments of muscles are removed by dull instruments. With a pretty large chisel a piece of bone is now cut away from the iliac spine so as to allow the passage of the finger into the pelvis, the interosseous ligaments having been divided by a knife. The anterior and larger part of the articulation is thus exposed to the touch of the surgeon, who, with the aid of a Volkmann's spoon with a long curved handle, can easily reach tubercular matter both in the bones and in the soft parts. An operation done by the speaker under the direction of Dr. Christian Fenger was narrated in illustration.

In conclusion the following points in treatment were proposed for further consideration:

1. Hygienic and symptomatic treatment, with counter-irritation by means of the thermo-cautery where pain exists or where improvement is slow, should be combined with complete mechanical rest aided by extension in all cases where abscesses have not formed.

2. Cases exhibiting abscesses should invariably be subjected at the earliest practicable moment to a thorough radical operation by curetting performed posteriorly—that is, directly—when the abscess is extra-pelvic in origin; performed as just described, anteriorly, whenever the abscess originates within the pelvis.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 11, 1888.

SECTION ON NEUROLOGY.

W. R. BIRDSALL, M.D., CHAIRMAN.

DR. W. H. THOMSON read a paper on

DIPHTHERITIC PARALYSIS,

which will appear in full in an early number of THE MEDICAL NEWS.

DR. A. JACOBI referred to the course and kinds of diphtheritic paralysis. There are undoubted cases of central origin on record, he said, and a few cases of ataxia had been observed. He believed that Dr. Thomson was correct in assuming that the paralysis is not to be taken as sequela of diphtheria, but rather as really part and parcel of the disease. If there is any disease which runs an indefinite course it certainly is diphtheria; this course sometimes being extended for many months. One difference between this and the other contagious diseases is, that once having had it, the subject is all the more liable to subsequent attacks. In many instances, he believed, those repeated attacks simply show a continuation of the disease, which is hidden away in the tonsils or lymph bodies, and liable at any time to fresh outbreaks.

As a rule, the paralysis first appears in the fauces, affecting deglutition, and then successively in the muscles of ocular accommodation and in the extremities. Finally, there may be respiratory paralysis, which often proves fatal. This order cannot be relied upon in every instance, however, and, in making a diagnosis in cases where there have been no throat symptoms, one of the main points to be depended upon is the fact that in diphtheritic paralysis only a comparatively small number of muscles is usually affected at the same time. Another point is the fact that the sphincter muscles are so rarely affected that this can be said to be almost never the case.

He then went on to say that paralysis not infrequently comes on during the acute stage of diphtheria. In heart-failure, which is so common an occurrence in this disease, there is no doubt a failure of the heart nerves, either the sympathetic or the pneumogastric. This is an accident liable to occur in any case of diphtheria, and he had therefore always insisted on the free administration of alcoholic stimulants and cardiac tonics from the very first. After symptoms of heart-trouble have once appeared it is usually too late for such remedies to do any good. Respiratory paralysis is about as fatal as heart failure. Hence the most energetic measures are called for to combat it, and strychnia and electricity should be pushed to the utmost extent possible.

DR. ANDREW H. SMITH said that it seemed to him very remarkable that we should so frequently have recovery from diphtheritic paralysis when the anatomical lesions were as marked as they were. The paralysis

had always also been somewhat of a stumbling-block to him in trying to accept the hypothesis that diphtheria is originally a merely local disease. He had no doubt that there were cases of diphtheria in which no membrane ever appeared, and the fact that instances are on record in which diphtheritic paralysis occurred without any previous throat symptoms, certainly goes to sustain the idea that diphtheria is essentially a general disease; while the membrane is only an indication of it, just as the erythema of scarlatina is the outward manifestation of that disease. In scarlatina and the other exanthemata the eruption does not constitute the disease. Dr. Smith then referred to the case of a child whose mother had diphtheria in which the diphtheritic membrane appeared, not in the throat, but in the groin, where the skin was chafed. It is also remarkable, he went on to say, that in cases of diphtheritic paralysis not preceded by the appearance of membranes in the throat, the paresis usually begins in the fauces. This would seem to indicate a peculiar predilection of diphtheria for this region, aside from the simple deposit of membrane there.

DR. L. PUTZEL said that he did not understand exactly what Dr. Thomson meant by the post-latent stage of diphtheria. This disease is different from scarlatina because in scarlatinal nephitis the bactenum which is the exciting cause of the acute affection still remains in the system. It seemed to him more probable that the acute attack of diphtheria leaves the nervous system in a weak condition, in which any slight cause may bring on paralysis. As regards the fact that the paralysis usually makes its first appearance in the fauces, the reason for this seemed to be because the throat is so much affected in the acute attack. As to those rare cases in which paralysis occurred without any previous local trouble, he was not aware that a sufficient number of them had been observed to base any conclusion upon.

DR. MALCOLM MCLEAN described a very severe and prolonged attack of diphtheritic paralysis occurring in his own person a few years ago, in which, he said, more muscles and a greater extent of cutaneous surface were affected than is usual in cases which recover. It lasted for four and a half months, and involved the muscles of respiration as well as those of the throat and of both the upper and lower extremities, but did not affect the sphincters. With the paralysis there was marked hyperæsthsia. On the fourth day of the acute attack of diphtheria, which preceded the paralysis, symptoms of heart failure appeared, and the heart continued weak throughout the course of the subsequent paralysis. On one occasion the pulse fell to 32 (afterward suddenly rising for a time to 160), and this was accompanied by a most violent attack of angina pectoris, which nearly proved fatal. The ordinary rate of the pulse was 52. The practical point which Dr. McLean said he wished to impress was the necessity in such cases of the most absolute rest. In his own case he was treated for a long time with faradization and galvanism, and in order to receive the treatment was taken in a carriage to the office of the gentleman who applied them. Although they were employed with the greatest skill, he only grew worse instead of better; with the exception that the original paralysis of the fauces was markedly relieved. At length so great was the pain and discomfort which he suffered that he determined to take absolute rest in bed; and as soon as he adopted this course he began to improve. He remained in bed for a month, and the result was so satisfactory that he was firmly convinced that in these severe cases unless this absolute rest is insisted on, no other treatment will be of any avail.

DR. S. SEABURY JONES mentioned a case of tabes dorsalis which occurred in a druggist who had received a wound in the hand while asssisting at a tracheotomy performed on a diphtheritic patient, the paralysis commencing in the wounded hand. In such cases, according to Trousseau, the paralysis sometimes attacks the throat first. He then referred to the case of a mother whose child had diphtheria, but who did not have any membranes, as far as could be ascertained, although she complained of her throat. The woman consulted him for difficulty in swallowing, with numbness of the tongue and impairment of the sense of taste. The case resembled one of bulbar paralysis, but the patient made a good recovery under the use of iron and strychnia. In diphtheritic paralysis he believed the lesion might be either central or peripheral; but Trousseau in his classical work had brought out so beautifully all the points in connection with the subject that little or nothing remained to be said upon it.

DR. BIRDSALL said that as regards the pathology of diphtheritic paralysis, he also believed that while in many instances there was simply a neuritis, cases of undoubted central origin sometimes occurred. In the latter, however, the central lesion was apt to give rise also to peripheral degeneration. In adults diphtheritic paralysis is relatively more frequent than in children, and it very often occurs in cases in which the original attack of diphtheria is very slight. As to the matter of heart failure, it is a question whether the trouble is of the same nature as the paralysis noted after the acute attack, or whether it is merely functional in character. A point against its paralytic origin is the early stage at which it occurred. As to the etiology of diphtheritic paralysis it seemed to him entirely possible that it might be due to the original poison causing the disease; the delay in its appearance being perhaps attributable to the comparatively long time which it takes for such toxic agents to act upon the nervous system.

DR. THOMSON said that he had purposely refrained from taking up the subject of heart failure in the paper, since it presented so many complications. He doubted very much, however, whether it was due to the mere cause as the later paralysis. In many cases he believed there was myocarditis, and it seemed probable that this was the fact in Dr. McLean's case. He had not touched upon the topic of therapeutics in the paper, but he quite agreed with Dr. McLean that electricity is of no service. It is highly desirable to stimulate the peripheral extremities of the nerves, and this can be best accomplished by applying to the throat equal parts of honey and red or black pepper. In paralysis of the extremities a solution of pepper (a drachm to the pint) is also a useful local application. As to Dr. Putzel's reference to the post-latent period of diphtheria Dr. Thomson said that the paralysis is an indication of processes going on subsequently to the acute stage, and this post-latent stage he believed to be a general characteristic of all the acute fevers. The post-latent stage varies in its manifestations in the different diseases, and it seems probable that its phenomena are due to the presence of ptomaines in the system.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, May 4, 1888.

THE PRESIDENT, JAMES PERRIGO, M.D., IN THE CHAIR.

DR. RICHARD MACDONNELL exhibited a heart with a

PATENT FORAMEN OVALE.

He said that, during the practical anatomy course of last session at McGill University, a heart was found in which the foramen ovale was patent. The body was that of a woman aged twenty-five, who had died in the Montreal General Hospital, of phthisis, with empyema. Dr. MacDonnell saw her first in 1883, when she came to the out-patient department with primary syphilis. She was very thin and very delicate, but there was no evidence whatever of any vascular derangement. Her mental faculties were defective. During that year she was a constant attendant at the clinic, presenting well-marked symptoms of secondary disease in many of its forms, notably alopecia, sore throat, and iritis. In 1884 and 1885 she was admitted into the wards on several occasions and her chest was examined frequently, but no evidence of cardiac disease was ever made out. The last admission was upon May 8th, when distinct evidences of phthisis were apparent. She died on the 7th of June, 1887, with extensive softening of the right lung, with thickened pleura containing pus. Dr. MacDonnell thus had the case under observation for four years without ever having perceived any cardiac symptom or physical sign. The opening in the fossa ovalis was of large size.

DR. BELL presented a specimen of

EXOSTOSIS BURSATA,

which he had removed from the inner side of the lower end of the right femur of a boy aged twenty. The bony growth was about the size of an orange and appeared to spring from the condyle below the epiphyseal line. It had a bony pedicle three-quarters of an inch long and half an inch in diameter, and grew upward and inward. Its surface was covered with cartilage in small isolated nodules, which were closely placed and formed a continuous layer over its surface. The whole was inclosed in a perfectly formed synovial membrane, which was continuous with the periosteum of the pedicle. This sac contained half an ounce of clear amber-colored synovial fluid in which loosely floated fifty-four cartilaginous bodies, looking exactly like the floating cartilages found in the knee-joint. These varied in size from a bean to a small pea.

The tumor was first noticed nine years ago as a small, soft and "movable" growth about as large as a marble. It grew steadily, and only four years ago became fixed and felt hard. There never was pain in connection with it, but the patient complained of its inconvenience, and the fatigue of the muscles in walking up-stairs.

Dr. Bell stated that the only record of any similar cases he had been able to find, was in a paper read by Dr. Fehleisen at the Fourteenth Congress of German Surgeons, held at Berlin in 1885. Fehleisen reports a case which had recently occurred in Prof. Bergmann's clinic, and refers to another which had been seen in Billroth's clinic in 1863. These he believed to be the only ones on record at that time (April, 1885). Dr. Bell said these two cases corresponded exactly with the one now related by himself. In Bergmann's case the synovial membrane contained about 500 loose cartilaginous bodies, and in Billroth's case 35 were found. Billroth's case was carefully investigated by Rindfleisch, who came to the conclusion that it had originated, not as an ordinary exostosis from the epiphyseal cartilage, but as an enchondrosis of the cartilage of the joint which had pushed out a portion of the synovial membrane; this in time had become cut off from the joint cavity and had formed a separate sac over the tumor. Fehleisen, however, attributes these growths to a developmental error by which a group of cells, separate from the joint and lying dormant, suddenly springs into action and produces this special form of exostosis. He also points out that, although the ordinary exostosis which frequently grows from the epiphyseal cartilage at the ends of long bones, is often covered or partially inclosed in a *bursa mucosa*, these free cartilaginous bodies never occur in them. Moreover, he ascribes the origin of the free-floating cartilages to tufts of the synovial membrane, in which are formed minute islands of hyaline cartilage. These develop and are set free in the cavity of the synovial sac, both in large joints and in cases of *exostosis bursata*.

DR. FENWICK said that this case was a unique one as far as his experience went. He had in his possession a large exostosis of the lower end of the femur, which on section was found to be composed of cancellated structure. This had been obtained from the dissecting-room, and he was unable to say whether or not there was a bursa in connection with it, but it had been no doubt covered with cartilage.

DR. SHEPHERD said the case was a most interesting one from the light it threw on the formation of these floating cartilages in joints. He was convinced that the little buds of cartilaginous substance growing from the inside of the synovial membranes were the origin of the free cartilaginous bodies. They, no doubt, grew until they fell off from their own weight.

This form of exostosis he had never seen before; the ordinary exostosis is comparatively common and grows from the epiphyseal cartilage. They stop growing with the maturity of the individual. He had seen two well-marked cases within the last few weeks, one in a boy of sixteen which had reached a considerable size, and was continually growing. Billroth, in his *Clinical Surgery*, mentions a case of exostosis bursata olecrani.

DR. RODDICK exhibited a stone weighing fifteen drachms which he had removed from a man, aged fifty-two, by the

SUPRAPUBIC CYSTOTOMY.

Twelve years before he had removed a stone from the same man by the lateral operation. He remained well up to eighteen months ago, when symptoms of stone reappeared. He preferred the suprapubic operation on this occasion, because of the large size of the stone, and because he had formerly performed the lateral operation. He did not suture the bladder.

DR. FENWICK saw no reason why a previous lateral operation should contraindicate a second one, he had several times operated a second time with success; on one patient he had performed lateral lithotomy four times. He thought that entering the bladder by the perineum is the most natural way, and there is no danger of infiltration of urine as in the suprapubic. He had re-

moved very large stones by the lateral method by cutting both sides of the prostate.

DR. SHEPHERD said that in cases of suprapubic lithotomy he preferred suturing the bladder and putting a drain in the abdominal wound, so that if the bladder wound did not unite by first intention, there would be an outlet for the urine. The bladder should be drained by a catheter in the urethra.

DR. BELL said the bladder could not be drained thoroughly through the penis, and advocated a perineal drain.

Dr. RODDICK, in reply, said that the chief reason he had made use of the high operation, was the large size of the stone. With regard to suturing the bladder, most disastrous results had been reported by Thompson. He did not care to run the risk of urinary infiltration, a catheter introduced into the bladder through the penis would not effectually drain that viscus.

DR. SHEPHERD reported a case of

EXCISION OF THE RIGHT HALF OF THE LOWER JAW, WITH LIGATION OF THE INTERNAL JUGULAR VEIN,

for epithelioma which had recurred after removal from the lower lip eighteen months before. The patient was a man, aged fifty, and in good general health. There was some enlargement of the cervical glands. The jaw was removed without much difficulty and with little hemorrhage, but in dissecting out the infiltrated glands in the neck which were behind the vessels, the jugular vein was torn and had to be ligated. The patient made a good recovery, the temperature never rising above 100°. Dr. Shepherd mentioned that this was the fourth time he had tied the internal jugular vein in the course of operations on the neck, and that he had never seen any bad results follow.

DR. RUTTAN read a paper on a case of

POISONING BY BICHROMATE OF POTASSIUM.

The paper was based on a case of suicide by this salt. An Englishman, aged twenty-five, took about two ounces of bichromate of potassium in crystals, and was found in an outhouse vomiting, purging, and in great pain. When seen by the ambulance surgeon the vomiting had ceased. The patient was speechless and writhing on the floor, face contorted, and of a decidedly dusky hue, surface of the body cold, hands shrivelled and blue, respirations very rapid, mouth stained and filled with yellow fatty mucus. Vomited matter contained crystals of bichromate of potassium, but no blood. Abdomen retracted, and tender. At the hospital the patient was given a hypodermatic injection of ether, as the pulse was absent at the wrist. An attempt was made to introduce a stomach pump, but the patient died a few minutes after removal and within an hour of taking the fatal dose. When seen an hour after death, cyanosis was marked over face and neck, pupils were dilated.

The autopsy was made forty-eight hours after death by Dr. Lafleur. He reported cyanosis marked. Veins of pia mater were found distended and filled with dark chocolate-colored blood and without clot. Brain substance normal. The liver was of an intense purple hue and hyperæmic. Small intestine contained olive-green mucus with shreddy pieces of a yellow color. Mucous membrane slightly inflamed, but no loss of substance. Large intestine firmly contracted and contained but little mucus, stomach filled with mucus of a greenish-yellow color. No signs of severe corrosive action. Lungs crepitant, dark brown, and very frothy on section. Heart contained three ounces of dark chocolate-colored blood without clot. Muscles very red; seventy-two hours after death rigor mortis still very marked.

The blood was found to contain everywhere the neutral chromates of sodium and potassium; of the organs, the liver contained most of the poison, but it could be also detected in the tissues. The substance of the liver and kidneys could be stained a deep chrome yellow on suspending them in dilute acetate of lead for a few minutes. The stomach and small intestine contained, precipitated in the epithelium and in the mucus the insoluble green oxide of chromium. The blood was neutral. On spectroscopic examination it gave the absorption spectrum of methæmoglobin. (The absorption spectrum produced by the blood was shown to the Society.) Dr. Ruttan remarked on the rarity of these cases, and after comparing the symptoms and post-mortem appearances of this case with those recorded by others, concluded with some observations on the physiological actions of bichromates. As the result of a study of the recorded cases, and from a number of experiments made on rabbits and other animals by himself and Dr. Lafleur, he drew certain conclusions which are summarized as follows:

(*a*) The blood alterations resulting in the production of methæmoglobin, though hitherto unnoticed in these cases, occur whenever the dose is large or the poison rapidly absorbed.

(*b*) That neutral chromates do not produce methæmoglobin in the blood of living animals or in solutions of hæmoglobin. This action is peculiar to bichromates.

(*c*) Bichromates owe their rapid toxic action to this property which they have in common with several other powerful oxidizing agents.

(*d*) Bichromate of potassium may, like pyrogallic acid, potassium chlorate, nitrites, etc,, produce death without causing any symptoms of corrosive irritant action by profuse blood alteration alone. Cases were cited, notably one reported by Dr. Wilson, of Glasgow (*Medical Gazette*, vol. 33), and experiments quoted in proof of the similarity of action of bichromate to the methæmoglobin producers.

(*e*) If bichromate does not kill within a very few hours the symptoms and post-mortem appearances are indistinguishable from those produced by neutral chromates; hence the comparison of the physiological action of these two salts by writers on poisons. Usually, however, as in the case which formed the text of the paper, the salt acts both as a violent irritant and a methæmoglobin producer. In concluding his paper, the reader called attention to the dangerous ease with which this poison can be procured. The salt is used in many of the toy batteries sold to children and is never labelled poison.

DR. STUARD asked if Dr. Ruttan thought the ordinary symptoms produced by the nitrites are due to the production of methæmoglobin; if not, what are the symptoms produced by methæmoglobin?

DR. REED mentioned a case reported in the London *Lancet*, of a man who took four drachms of bichromate of potassium and died in fifty-five minutes. Cases of recovery have been reported after taking ten to fifteen grains. Symptoms were vomiting, pain and hemorrhage.

CORRESPONDENCE.

PROFESSIONAL PATRIOTISM.

To the Editor of The Medical News,

Sir: Having just read in The News a note from an officer of the army to *The Evening Post*, in which he asks permission "to place a flower on the grave of Dr. C. R. Agnew," who, in reply to him asking for his bill for professional services, said, "Captain, what I have done for you is only an expression of what I feel is due to every man who wears your uniform. You do not owe me anything,"—I beg leave to place a flower on the grave of another New York physician—the late Dr. Austin Flint—who, on the occasion of a professional visit to General Alvord, in Washington, in his last illness, in reply to him asking for his bill and urging the Doctor to accept a roll of greenbacks and adding, "You have been most kind and have done me good; you have been pleased to come to comfort me," replied tenderly, and I thought with some emotion, "General, I do not forget what you have done for us."

There are noble sentiments existing in the Faculty all around the world, but from the lips of professional men as eminent as Agnew and Flint, are more likely to attract the attention of the readers of your journal.

The writer recalls the words of the late Professor Gross who, in reply to one of his cloth asking for his bill, said with emphasis and a broad smile, "Dog don't eat dog," Doctor."

Basil Norris, M.D.

Vancouver Barracks, W. T., May 16, 1888

THE DANGER OF WASHING OUT THE PLEURAL CAVITY.

To the Editor of The Medical News,

Sir: Permit me to thank you heartily for your remarks (The Medical News, May 5, 1888, page 496) on "Epilepsie Pleurétique," a *new disease*, caused by the absurd custom of injecting disinfectants into the pleural cavity in all cases. I never injected but in one case, and in that I did so because the patient seemed to be running down, and I feared phthisis would supervene. I was convinced that a quantity of pus (*thickened*) was lying on the pleural cavity below the external opening, thus causing disease of the system generally. Accordingly, after I had allowed all the pus to drain away that could be made to come, I injected simple warm water, about a pint, and I was surprised and at the same time gratified to find that my diagnosis was thus confirmed. It came back *looking like pus*. I continued injecting about a pint several times, *most gently*, until the water returned almost as pure as it entered. I then desisted. The patient immediately began to improve and went steadily onward to a final cure.

This was a case evidently calling for an injection, but the custom of "washing out the pleural cavity" with simple water or antiseptic solutions in *all cases is a custom full of danger*. I am not surprised that the new disease of "Epilepsie Pleurétique" has been generated. To keep the external opening perfectly clean and let nature do her own work, has been my rule and successfully so far.

The profession of late has had one of its periodical frantic delusions. We now have one in regard to the use of "*antiseptic injections*" almost everywhere and at all operations. The consequence is that healthy women have been seriously injured and perhaps killed at times after healthy labors by injections into the womb, and all by the *folly of the profession*. We are likely to have more deaths and various diseases as the result of injections, unless we stop this course. Let us all follow your excellent advice, viz., emphasize the rule that *such injections* (pleural in this instance) "*should not be practised at all*," unless where actual gangrenous odor is found, or the patient, as in the case cited, is apparently running down from the retention of foul matter. I fully believe in your closing remark, viz., "to this rule there will be found few if any exceptions."

My experience since commencing the use of thoracentesis and thoracotomy is that once in 250 cases and 399 operations I have felt impelled to inject. I have never had a serious result to follow in any case. I do not think I should be able to say as much had I been *an intermeddler with injections in all cases* to kill the germs of disease *falsely* supposed to be ready to kill the patient unless strangled by our brave remedies.

Excuse this long letter, but I wanted to thank you for the editorial, and, as the mechanics say, "clinch your strong nail," so far as I could do so, by my experience.

Respectfully yours,

Henry B. Bowditch, M.D.

Boston, May 23, 1888.

NEWS ITEMS.

A Medical Congress in Spain.—The *Independencia Medica* states that a Medical Congress will be held at Barcelona from the 9th to the 15th of September, in connection with the Universal Exhibition which is shortly to be opened there. Among the subjects down for discussion we observe the following, which will suffice to show that our Spanish brethren are well abreast of the medicine and surgery of the day: Measures to be taken by the State for the prevention and cure of blindness, and for the improvement of the condition of the blind in Spain; present state of leprosy in Spain, and how to prevent it from spreading; indications for surgical interference in intestinal obstruction; identity or difference of scrofula and tubercle; localization of lesions in diseases of nervous centres; application of hypnotism and "suggestion" to the treatment of nervous affections; microorganisms in mineral waters, their influence on the chemical constitution and therapeutic effects thereof; laparotomy as an exploratory measure in penetrating wounds of the abdomen (more especially gunshot wounds); antiseptic midwifery; etiology and prophylaxis of cholera and yellow fever. A Pharmaceutical Congress will meet at the same time.—*British Medical Journal*, April 28, 1888.

A Universal Dictionary of Climatology.—The Imperial Observatory of Rio de Janeiro plans the publication of a universal dictionary of climatology For this purpose, the director, Mr. L. Cruls, has prepared and sent out a circular soliciting information from all official and private sources as to the climatic elements of places at which observations have been or are being carried on. A table is attached to the circular, in which the results of observations are to be inserted. The mean temperatures of the months of the year, the mean maxima and minima,

humidity, days and amount of precipitation, cloudiness, frequency of gales, days of frost, prevailing winds, the absolute maxima and minima, the mean annual barometric pressure, and the mean annual oscillation of the latter, are the points on which information is solicited.—*Science*, April 6, 1888.

An Epidemic of Milk Typhoid.—Dr. Brown, Health Officer of Carlisle, reports in the *Practitioner* for May, 1888, an epidemic of between thirty and forty cases of typhoid fever, of varying severity, in which the source of contagion was traced to milk. The cows which furnished the infectious fluid were suffering from a disease resembling typhoid in the human subject.

The Extirpation of Rabbits in Australia.—A telegram from Sydney states that the conference upon the means of dealing with the rabbit pest has resulted in the selection of an island where M. Pasteur's and other methods of extirpation will be thoroughly tried. The liability of other animals and birds to infection by the same means will also be tested.

Wood-wool Sheets for Accouchement.—These recently devised sheets are composed of a thick layer of wood-wool, inclosed in a gauze cover. They absorb discharges readily, deodorize all offensive matter, and are far more comfortable than rubber sheets. They are made at present in London.

Simple Tests for Poisonous Candies.—The *American Analyst* of March 15, 1888, writes that to test candy with respect to poisonous colors one needs a few ounces of alcohol, about an ounce of bleaching powder in solution (hypochloride of calcium), a little white woollen yarn, and a small bottle of aqua ammonia. See first whether the color can be dissolved out by alcohol; if it can, immerse the woollen yarn in the solution, and should the color adhere to the yarn and dye it, the probabilities are that it is a coal-tar color; if a red, it may contain arsenic. If the alcohol produces no effect, apply a drop of the bleaching powder solution to the surface of the sweetmeat; if the color fades out it is probably of vegetable origin and harmless.

"The poisonous color most frequently used is chrome yellow, a compound of chromium and lead. Its presence may be strongly suspected if the following tests have shown that none of the harmless yellows have been employed. The harmless yellows most commonly employed are turmeric, a vegetable color made from the root of a certain herb, fluorescein, a coal-tar yellow, and a number of vegetable yellows. Turmeric turns red when treated with ammonia. The other vegetable yellows fade when treated with the solution of bleaching powder. To detect fluorescein dissolve the candy in a tumbler of water and view the water in the sunlight against a black background. If fluorescein has been used, the green fluorescein will then be seen. When the tumbler is held between the eye and the light the color of the water appears yellow. If no results are obtained by any of these tests the suspected candy is probably colored by chrome yellow and is poisonous. Burnt umber, an iron-bearing earth frequently used to adulterate chocolate confections, may be detected in this way: Dissolve the confection in a glass of hot water; if a brown gritty residue remains undissolved on the bottom the presence of the umber is indicated."

CORRIGENDUM.

Page 582, 1st column, 21st line, *for* "five drachms three times daily," *read* "twenty grains every eight hours, or ten grains every four hours."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 22 TO MAY 28, 1888.

SUTHERLAND, CHARLES, *Colonel and Medical Director.*—To inspect the Medical Department at St. Francis Barracks, Florida, Fort Barrancas, Florida, Mount Vernon Barracks, Alabama, and Jackson Barracks, Louisiana.—*S. O 100, Division of the Atlantic*, May 19, 1888.

KIMBALL, J. P., *Major and Surgeon.*—Leave of absence extended two months.—*S. O. 117, A. G. O.*, May 21, 1888.

COWDREY, S. G., *Captain and Assistant Surgeon* —Ordered to accompany the troops of the Sixteenth Infantry from Fort Bliss, Texas, to Fort Douglas, Utah Territory, as Medical Officer. Will return to his station upon the completion of said duty.—*S O 54, Department of Texas*, May 19, 1888.

MCCREERY, GEORGE, *Captain and Assistant Surgeon.*—To accompany Seventh Cavalry from Fort Meade, Dakota Territory, to Fort Riley, Kansas. From Fort Riley he will return to Fort Meade.—*S. O. 42, Department of Dakota*, May 17, 1888.

ROBERTSON, R. L., *Lieutenant and Assistant Surgeon.*—Will accompany from Fort Keogh, Montana Territory, the Fifth Infantry to the Department of Texas; returning to his station on the completion of the duty.—*S. O. 43, Department of Dakota*, May 18, 1888.

EWING, C. B., *First Lieutenant and Assistant Surgeon.*—Will accompany the Twenty-second Infantry, as Medical Officer, to the Department of Dakota; returning to his station on the completion of the duty.—*S. O. 56, Department of Missouri*, May 17, 1888.

BANISTER, W. B., *First Lieutenant and Assistant Surgeon* —Granted leave of absence for two months, with permission to apply for an extension of twenty-seven days.—*S. O. 119, A. G. O.*, May 23, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING MAY 26, 1888.

DICKSON, S. H., *Passed Assistant Surgeon.*—Detached from the Receiving Ship "Dale," and ordered to Marine Barracks, Washington, D. C.

NASH, F. S., *Passed Assistant Surgeon.*—Ordered to the Receiving Ship "Dale," in addition to present duties.

RUTH, MELANCTHON L. *Surgeon.*—Granted one year's leave of absence from date.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE THREE WEEKS ENDING MAY 26, 1888.

WYMAN, WALTER, *Surgeon* —Leave of absence extended fourteen days, May 22, 1888.

MAGRUDER, G. M., *Assistant Surgeon.*—Relieved from duty at Marine Hospital, Chicago, Illinois, detailed as Medical Officer, Revenue Bark "Chase," during summer cruise, May 19, 1888.

ORIGINAL ARTICLES.

EXPERIMENTAL STUDIES ON SOME POINTS CONNECTED WITH THE CAUSATION AND TREATMENT OF THE SUMMER DIARRHŒAS OF INFANCY.[1]

BY VICTOR C. VAUGHAN, M.D.,

PROFESSOR OF HYGIENE AND PHYSIOLOGICAL CHEMISTRY IN THE UNIVERSITY OF MICHIGAN.

IN order that this paper may be presented in the best form for discussion, I will state certain propositions which I conceive to be true, and after each statement will briefly give the reasons for my belief.

I. *The factor which is most frequently operative in the causation of the summer diarrhœas of children under two years of age is to be found in the food.*

It is unnecessary to take any time in discussing this proposition, since Dr. Seibert, in his paper read before this Section in February last, has presented the relation of the infantile diarrhœas to the weather in a much more practical and authoritative manner than I could. From reading the discussion which followed that paper, I think that we agree that the weather is a mediate and not a direct and exciting cause of these diseases. Heat is operative indirectly in at least two ways. *First*, a temperature of 60° F., or higher, is necessary in order that the germs of putrefaction may be disseminated to a sufficient extent to find their way into the food and drink, and into the air inhaled. Certainly such a degree of warmth is required for the fermentation of food before it is taken into the body, and there can be no doubt that the conditions which lead to the digestive disturbances which characterize these diseases have their beginnings often in the food before it is eaten. The putrefactive germs taken into the stomach frequently find the conditions for their growth improved. The temperature is the most suitable, the putrefactive products already formed are sufficient to overcome the normal antiseptic and germicide properties of the digestive juices, and the absence of oxygen favors the multiplication of the anaërobic forms of life, and to this class belong most of those microörganisms which induce disease. *Secondly*, the great heat of summer depresses the nerve-centres, and consequently lessens the amount, and may alter to some extent the quality of the secretions normal to the stomach and upper intestine. Under the influence of great heat the tissues lose their tone, and that physiological resistance which every healthy organ manifests toward toxic agents is impaired. These, I take it, are the principal offices that the heat of summer performs in increasing the infantile mortality. There is no reason for supposing that meteorological conditions have a mysterious influence in the production of these diseases. They are active only so far as they aid in the multiplication and distribution of the germs of putrefaction.

II. *The changes whereby harmful substances are formed in the food either before or after it is taken into the body are fermentative in character, or, in other words, are due to microörganisms.*

That deprivation of the mother's breast as the source of its food greatly increases the danger to the child's health and life there can be no doubt. Statistics collected in every part of the civilized world show that infantile mortality is much greater among those artificially fed than among those nursing from the breast of the mother. Why is this true? Why will not a child thrive as well when fed upon cow's milk as when it takes its nourishment directly from the breast of the mother? In answer to this question we may say that there are several reasons. There are chemical differences in the composition of the milk of woman and that of the cow. Especially is this true of the proteids. Woman's milk is much more easily digested. All of this is true, but the chemical differences in the composition of the two kinds of milk are not, I am sure, the most potent cause of the great frequency of diarrhœas among children artificially fed. This most potent cause is to be found in the fact that milk taken directly from the gland of a healthy animal, be it a woman or a cow, contains no germs of any kind whatever; while, on the other hand, cow's milk, as fed to children, always contains germs, and too frequently it contains those which interfere with the normal digestive processes, and lead to serious disease. I have taken milk directly from the lacteal ducts of the cow, and have shown that it contains no germs. The method of procedure is as follows: Some capillary glass tubes are hermetically sealed, then sterilized by heat. When ready to obtain the milk, the ends are again heated and broken off. Immediately one end of the tube is carried into the duct (the udders having been previously washed with soap and water, then with a solution of bichloride of mercury, and lastly with

[1] Read before the Pædiatric Section of the New York Academy of Medicine, May 23, 1888.

alcohol), when the tube fills with milk by capillarity. The ends are now quickly closed with sealing-wax. These tubes, kept for some days at the temperature of the body, contain no germs whatever, and consequently no decomposition occurs. Market milk, introduced into similar tubes and sealed, when kept at the proper temperature decomposes within a few hours.

Escherich[1] has made similar experiments with the milk of woman, and has found that the secretion of the mammary gland of the healthy mother contains absolutely no germs, as it comes from the ducts. In these experiments we have what is, to my mind at least, an explanation of the great prevalence of summer diarrhœas among infants fed artificially. But, says one, that explanation will not do, because sometimes, though rarely, I will admit, cholera infantum and other diarrhœas do occur among nursing infants. This is true, but these cases can be easily explained. In the first place, the healthy mother furnishes a milk free from germs, but the unhealthy mother does not always do so. Escherich found bacteria in milk taken with proper precautions from women suffering from various inflammatory diseases of the breast, endometritis, parametritis, peritonitis, septicæmia, etc. The milk from these women, kept in sterilized tubes, became strongly acid, coagulated, and was found to contain numerous microörganisms, one of which resembled very closely staphylococcus pyogenes aureus. Pure cultures of this germ injected into rabbits caused death, and, on post-mortem examination, the organism was found in the blood in the heart, and in the kidneys.

These experiments show that the milk of the mother is not always the best food for the child. But even in those cases in which the mother's milk is good there are many ways in which putrefactive and pathogenic germs may find their way into the alimentary canal of the child. Among the poor and negligent classes the exterior of the mother's breast is not always as clean as it might be. Children nurse from excoriated nipples, and sometimes from suppurating glands. Indeed, the danger to the child in taking food from diseased breasts has not been appreciated until recently by the profession. Just ten years ago I heard a very able specialist in diseases of children say that he did not know why a child's stomach could not digest pus as well as anything else.

Then there are yet many other ways in which microbes may be introduced into the child's stomach. The infant creeping about the floor must try the taste of everything in his reach, and in many tenement houses few of the articles which would fall within the grasp of the child are germ-free. You may be inclined to think that these are over-statements, but when we remember that Beumer has shown that tetanus neonatorum is, sometimes at least, due to germs growing upon the pedicle of the cord, and due to cutting of the cord with unclean instruments, or dressing it with dirty rags, we will not think it at all improbable that the child playing upon a dirty floor may feed occasionally upon microörganisms.

Lastly, there is always the possibility, and in many localities the probability, that harmful agents will be inhaled with the air, when they may find lodgement in the pharynx, and be swallowed with the food. In an epidemic of cholera infantum, which occurred in Leicester eight years ago, Johnstone found the same bacteria in the stools and in the emanations from the sewers. Indeed it is a matter of surprise, when we think of the many ways in which germs may find an introduction to the alimentary canal besides being taken directly with the food, that the mortality from the summer diarrhœas among those fed exclusively from the breast of the mother should be so small as it is shown to be by the figures of Hope, Ballard, and others. However, when the germs are contained in the food they are taken into the stomach in greater quantities than when taken in any other manner; besides they have already begun to grow in the food and their products, already formed when the food is swallowed, have more or less depressing effect upon the tissues.

That a few germs introduced into good milk may soon render it poisonous is shown by the following experiment: April 27, 1888, to a gallon of good milk I added half an ounce of poisonous milk, placed the whole in a bottle, closed with a glass stopper, and allowed it to stand at the ordinary temperature of the room for two days. Some of the milk, which had coagulated, was now filtered, the filtrate neutralized with sodium bicarbonate and extracted with ether. The residue left, after the spontaneous evaporation of the ether, was administered to a puppy and soon produced severe retching and vomiting. The gallon of fresh milk had been rendered poisonous by the activity of the microörganisms contained in the half ounce of milk which had previously begun to putrefy. I might detail to you a great number of similar experiments, but as the results have been the same in all, repetition is unnecessary and would only weary you.

On the other hand, milk which has been sterilized and kept in sterilized vessels does not undergo these changes, even when the temperature is kept at the point most favorable to putrefaction. Last December, my assistant, Mr. Novy, placed some sterilized milk in a sterilized Erlenmeyer flask, plugged the neck with sterilized cotton, and placed the flask in a Koch's vegetation trough, where it was kept most of the time at a temperature of 98° to 100° F., for three months, when an examination failed to reveal the presence of any poisonous substance.

[1] Fortschritte der Medicin, 1885.

Hofsten,[1] from a study of the records of the foundling hospital in Stockholm—which have been kept since 1812—as well as from his own experience in the same place, concludes that cholera infantum is a highly contagious disease. He is led to this belief because it has frequently been observed that the disease appears in one ward, spreads to all the inmates of that ward, and extends no further; or it attacks all those in a certain part of the ward, or is confined to those having the same nurse. To my mind, however, this does not prove that the disease is conveyed from one to another. The children in the one ward, or portion of a ward, or those of the one nurse have their food prepared, most likely, in the same way, cooked in the same vessel, brought in on the same trays, and served by the same nurses. If the nurse is not tidy, all under her care are alike endangered. The same is true if the ward is not clean, or is not properly ventilated. I think that Hofsten's facts show that the children living under the same conditions are affected by a poison emanating from a local cause, more conclusively than they support his belief that the germ is conveyed from the sick child to the well one through the air.

I have never seen anything that would lead me to suspect that the microörganisms of the summer diarrhœas are given off either from the lungs, or the skin of the sick. On the other hand, I have supposed that the germs are excreted by the bowels and probably by the kidneys, and that being suspended in the urine and moistened by the watery evacuations, they would not be disseminated through the air; but if the stools and urine should be thrown out upon the ground and the bacteria should be dried, they might then be disseminated. The reason for suspecting that the microörganism is excreted by the kidney as well as the bowels, is the frequency with which albuminuria accompanies these diarrhœas. It certainly can do no harm to have the stools and urine of patients with these diseases disinfected.

If it be true, as is held by Taube[2] and Escherich,[3] that in the young child stomachic digestion is of less importance than intestinal digestion, and that the stomach is more a receptacle into which the milk is received for coagulation than a digestive organ, then we have the most favorable conditions for the growth and activity of the bacteria which are introduced with the food. These experimenters claim that the younger the child the less active is digestion in the stomach, and that in this organ the milk is coagulated and is passed through the pylorus undigested. Hammarsten,[4] some years ago, showed that this is largely the case in the dog and rabbit. Hofmeister and Tappeiner[1] find that the stomach does not absorb soluble substances as rapidly as does the mucous membrane of the small intestine; and Zweifel has stated, and in this he is supported by Hammarsten, that the proteolytic activity of the pancreatic juice is relatively well developed in the newly born. Furthermore, it has been demonstrated by Eichhorst[2] that the intestinal mucous membrane will absorb unchanged casein. The absorption of fats is largely dependent upon the bile, and the teaching of Frerichs that the milk sugar is absorbed from the stomach, is now known to be an error. This constituent of milk is digested, as has been shown by Dastre,[3] by a ferment found in the mucus of the small intestine, and is not affected by the gastric juice. These experiments convince us that the digestion of milk is nearly, if not quite, altogether accomplished in the small intestine. These teachings of physiologists are confirmed by clinical experience with cases of intestinal indigestion in adults, for in these cases we invariably find that milk aggravates the trouble.

With these facts before us, and knowing that cow's milk begins to ferment from the very moment when it is drawn from the udder; that it is often kept for hours in unclean vessels, in foul rooms, and at a high temperature, after which it is poured, we may say, often to overflowing, into the digestive reservoir, the stomach; bearing in mind these facts, I say, Is it any longer a matter of wonder that thousands of children die every summer in this city from cholera infantum and kindred diseases?

III. *The microörganisms which produce the catarrhal or mucous diarrhœas of infancy in summer may be, and probably are, only putrefactive in character, but those which cause the choleriform or serous diarrhœa, true cholera infantum, are more than putrefactive; they are pathogenic; they produce a definite chemical poison, the absorption of which is followed by the symptoms of the disease.*

While I believe that all the summer diarrhœas of infants are bacterial in origin, I do not believe that the same bacterium is present in all. The more I observe these diseases clinically, the more I study the subject experimentally in the laboratory, the more thoroughly do I disbelieve in their unity. In the choleriform diarrhœa the symptoms come on suddenly and violently. It is true that this affection may occur as an intercurrent disease in the course of an ordinary catarrhal diarrhœa, it may be true that it is more likely to occur under these conditions than in a child previously healthy; but when it does appear in such a case the symptoms change. You are all perfectly well acquainted with these symptoms, and Dr. Smith has described them graphically and accurately. This

disease differs from the catarrhal diarrhœas of infancy in symptomatology and in pathology, and there are reasons for the belief that there is also a difference in etiology, and if we accept the germ theory for these diseases we must believe either that the germs causing them are different, or that the same microorganism will produce in one child a well-marked train of symptoms and characteristic anatomical alterations, and in another wholly different effects and lesions. The poison of choleriform diarrhœa acts immediately on the nervous system, most probably having its chief effect upon the sympathetic nervous system; the most pronounced early effect of the poison of catarrhal diarrhœa is as a local irritant.

It now devolves upon the bacteriologist to isolate the microörganisms present in the various forms of summer diarrhœa, and upon the chemist to study the putrefactive products of these germs as they are grown in various media. There has already been considerable activity in this line of work among bacteriologists, but until the appearance of the monograph of Escherich,[1] a little more than a year ago, we knew nothing positively or accurately concerning the normal bacterial vegetation in the intestines and stools of infants, nor of the effects of alterations in the food of the child upon these growths. Escherich has done his work so thoroughly that it will serve as a basis from which the pathological organisms may be studied, and we hope for some good results in the near future.

Hayem,[2] and his pupil Lasage, claim to have discovered and isolated the microörganism of "green diarrhœa." They also state that they have found in lactic acid a sure germicide in the treatment of this form of summer diarrhœa. However, it has not yet been demonstrated that the "bacillus of green diarrhœa," as the germ is called, has any causal relation to the disease, and the statement that the administration of seven or eight grains of lactic acid per day will cure a disease which is characterized by the great extent to which the lactic acid fermentation goes on in the intestine will require repeated corroboration before it is generally credited.

IV. *The bacteria which produce these diseases prove harmful by splitting up complex molecules and forming chemical poisons.*

The answer to the question, How do germs cause disease? has now, thanks to the labors of Selmi, Brieger, Hoffa, and others, been satisfactorily answered. They do so by elaborating chemical poisons, some of which are powerful in action, are rapidly absorbed, and manifest their effects upon the central nervous system, as in Asiatic cholera, and, as I believe, in the choleriform diarrhœa of infancy; others are less powerful and act primarily as local irritants, inflaming the tissues and leading to necrotic changes, as is most likely the case in the catarrhal diarrhœas of infancy. We now expect to find for each infectious disease its specific microörganism, which produces its own characteristic ptomaine. The ptomaines of tetanus, anthrax, and typhoid fever have been isolated, and I think that in tyrotoxicon we have the chemical poison or ptomaine of genuine cholera infantum. This substance is rapidly formed in milk when the germ is present and the conditions are favorable for its growth. Newton and Wallace, in investigating the outbreak of milk-poisoning at Long Branch in August, 1886, found that the milk drawn from the cows at noon became sufficiently poisonous within six hours to affect seriously those who partook of it; they also found that the toxic agent in the milk was tyrotoxicon. The microorganism which produces this ptomaine has not yet been isolated, but we know that the production of this poison is due to the action of a ferment, because a small quantity of poisonous cheese, cream, or milk added to good milk will soon render the whole poisonous, if it be kept at the proper temperature. While this germ has not been identified, we know something of its nature and growth. It does not develop below 60° F., and it is anaërobic.

The symptoms produced by this poison are very similar, if not identical with those observed in the choleriform diarrhœa of children. There is a sensation of constriction or burning in the throat, retching, vomiting, and frequent watery discharges, the first two or three of which may contain fecal matter, but the subsequent ones are serous, without fecal odor, and alkaline in reaction. When too large doses are not given and collapse does not come on speedily, there may be an elevation of temperature, but when the heart becomes very weak, the temperature may be subnormal. With very large doses, one grain or more, full-grown cats may be killed within thirty minutes. In these cases there is the most violent retching, but neither vomiting nor stool. After death the lungs are found congested, the circular fibres of the intestine are in places tightly contracted, and the stomach is generally free from any redness. By the continued administration of very small doses the vomiting and diarrhœa are kept up; the animal is unable to retain any food, loses flesh and dies from exhaustion, usually immediately after a severe attack of retching or vomiting.

I deem it unnecessary to detail here experiments illustrating the effects of this poison, as I have done this elsewhere. Moreover, this ptomaine has been obtained, and its effects described, by Newton, Wallace, Schearer, Wolff, Firth, and others.

In a condensed form, the following are the reasons for believing that tyrotoxicon is the exciting cause, in at least some instances, of choleriform diarrhœa in infants.

(*a*) This ptomaine results from the putrefaction

[1] Darmbakterien, 1886. [2] France Médicale, 59, 712.

or bacterial fermentation of milk. The disease is confined (with very few exceptions, which are easily explained) to children fed upon cow's milk, and is most prevalent among those classes which use milk most likely to be subjected to conditions which favor putrefactive decomposition.

[I would not have it understood from the above that tyrotoxicon is formed whenever milk ferments. It certainly is not produced in the ordinary souring of milk by the lactic acid ferment, as I have repeatedly shown by experiment.]

(*b*) Tyrotoxicon has been found in the milk given to a child immediately before the appearance of the symptoms of choleriform diarrhœa.[1]

My colleague, Dr. C. George, has reported to me an interesting case, which I must mention in brief here. He was called in great haste, on a very hot day, to see twins a few months old, who were reported as vomiting and purging for some hours. On his arrival he found one dead and the other suffering from symptoms which he immediately pronounced cholera infantum. He called for the milk upon which the children had been fed, and not liking the taste of it, he told the mother it had not been properly kept. She resented this, and in order to show that the milk was good, she drank a full tumbler of it. In a short time she also was vomiting and purging.

(*c*) The symptoms of the disease increase if the administration of milk is continued, and abate when milk is withdrawn from the food.

For the demonstration of the truth of this statement, Drs. Jacobi, Holt, and others, have given abundant testimony.

(*d*) The symptoms induced by the poison and those observed in the disease are identical.

(*e*) The post-mortem appearances are identical in the two cases.

Tyrotoxicon may be produced either outside or inside the body. The germ taken into the stomach of the child with milk finds present the two conditions which we know to be necessary to its growth, a proper temperature and the absence of free oxygen. That some of the anaërobic germs which occasion putrefactive changes in milk, do grow and multiply in the stomach, is demonstrated by the not infrequent presence of the butyric acid ferment in the vomited matters in certain cases of indigestion.

While I am thoroughly convinced that the catarrhal diarrhœas of infancy are bacterial in their origin, and that these bacteria produce chemical poisons or irritants, I feel certain that both the bacteria and ptomaines are different from those causing the choleriform diarrhœa. In the needed investigations concerning the causation of these diseases, there is a rich field of promise for both the bacteriologist and the chemist.

[1] THE MEDICAL NEWS, vol. l. p. 675.

V. *The most efficient preventive treatment of the summer diarrhœas will consist in giving more attention to the food, methods of feeding, and to the sanitary surroundings of children during the first two years of their lives.*

I do not propose at this time to go into an exhaustive discussion of infant feeding, but there are a few points inseparably connected with the matter in hand which must be touched upon at least. I cannot agree with Wegscheider,[1] who holds that the proteids of woman's milk are fit for absorption without the action of any digestive juice, but there can be no denial of the fact, of which we have so many proofs, both physiological and clinical, that the infant digests the milk of the mother or healthy wet-nurse more readily than it does cow's milk. Nor must the large amount of nitrogenous substances in the stools of breast-fed children mislead us into the belief that these are altogether portions of undigested milk. The nitrogen-containing substances in the normal stools consist largely of the secretions, or rather excretions, from the intestine. With the fats it is otherwise. It must be acknowledged that woman's milk usually contains more fat than can be utilized by the child. The amount of fat in the normal stool varies from eight or nine to more than fifty per cent. of the dry substance. Unchanged milk-sugar does not appear in the normal feces of breast-fed infants. This does not necessarily mean, however, that all of this food stuff has been absorbed, for the products of the decomposition of milk-sugar do occur in the excretions from the bowels.

Escherich has shown that a healthy child of ten weeks of age will take about one quart of undiluted cow's milk per day, while an equally well-nourished child of the same age, taking its nourishment from the breast, receives in the same time about 774 grams of milk. The first child receives 34.64 grams of proteid, and the second only 12.93 grams of the same food stuff. We thus see that the proteolytic activity of the digestive organs of the artificially fed child must be severely taxed, or a large portion of the proteids must wholly escape digestion. That no large amount of the proteid does escape change of some kind, is shown by the experiments of Forster and Uffelmann, which demonstrate that in the normal stool of the child fed upon cow's milk, only about one and five-tenths per cent. of the casein appears unchanged. This also does not show that all the casein is digested. How much of it is altered by the agency of bacteria we do not know.

Children fed upon cow's milk are more likely to be over-fed than those nursing from the breast, for two reasons. In the first place, the supply is not so easily exhausted; and, in the second place, the child obtains the food more easily, indeed, the milk is

[1] Die Normal Verdauung der Saunglings, 1876.

often poured into the child's stomach *ad nauseam*. To these might be added the fact that the child is often supplied with the nursing bottle when the busy mother would not stop her work to nurse it herself. Still, again, the system needs about so much water, and too many mothers and nurses forget that a little water might be relished at times even by a babe. This overloading of the child's stomach with proteids greatly increases the chances of digestive disturbances arising from putrefaction. Granting that all of the proteid, which is altered in the alimentary canal, is really digested and absorbed, still the excess is not needed, cannot be utilized by assimilation, and must do harm. Some one has said that "we live upon what we eat;" Meinert, I believe, has changed this, and said "we live upon what we digest;" I should beg to make another alteration, and say, "we live upon what we assimilate." Overfeeding, even when followed by complete digestion, can do only harm.

But supposing that the excess of proteids in the cow's milk is avoided by dilution with water, there still remain the differences in the chemical composition of the two kinds of milk, and the greater probability that the cow's milk is contaminated with dangerous bacteria.

Simon[1] found that the mucous membrane of the stomach of a child, which died soon after birth, readily coagulated woman's milk, but was without effect upon cow's milk. The same investigator found that after complete desiccation the casein of woman's milk is freely soluble in water. Bouchardat, Quevenne,[2] Meggenhofen,[3] and others, state that the casein of woman's milk forms soluble compounds with small amounts of acids, while the casein of cow's milk is coagulated by the same. Radenhausen[4] claims that there is no real casein in the milk of woman, and that the proteids exist as albumen, protalbumen, and peptone. Struve[5] finds in woman's milk about one-sixth as much insoluble casein, twice as much soluble casein, nearly three times as much albumen, and one-third more peptone than in cow's milk. Other chemists of equal reputation might be quoted, but while there are many minor differences, all agree substantially that the proteids of the milk of woman are more easily digested than are those of the milk of the cow.

I can see no reason why the casein of cow's milk should not be partially digested, partly converted into the soluble form at least, when used in the feeding of infants, especially with those of feeble digestion. However, I would object to complete artificial digestion for several reasons. In the first place the digestive organs, like all other organs of the body, would be enfeebled if relieved of their physiological duties. In the second place the too rapid absorption of peptones is harmful. Albertoni, of Genoa, and Schmidt-Mulheim, have independently shown that if peptones be injected directly into the blood, they are poisonous. Normally, it is a function of the liver to arrest and alter the products of proteid digestion in the stomach and intestine, but if a great quantity of ready-made peptones be poured into the stomach, they will be absorbed so rapidly that the liver may fail to perform this function fully. The feeding of completely digested food may be admissible for a time, in rare cases, where there is great debility, but its long continuance is irrational and unscientific. Certainly it is not the thing to do for healthy children. Again, Brieger has shown that artificial digestion of proteids is accompanied by the production of a poisonous base, which he has named peptotoxin. Whether this substance is formed in normal digestion or not, we cannot say. If so, it must be altered or eliminated by the liver.

As to the addition of some carbohydrate to cow's milk, I agree with Dr. Smith, that dextrin is the best form. I will not take the time to give my reasons for this at present.

In order to protect the child, as far as possible, from the harmful microörganisms which may be present in cow's milk, the greatest attention should be given to the care of this food. I have elsewhere given some rules for the handling of milk, and I have not seen any reason for changing them.[1]

As to the sanitary surroundings of the child in their influence in the production of summer diarrhœas, it is unneccessary for me to say anything to you. I only mention this point to show that I do not ignore it, and would not omit from the list of things to be done in the prevention of these diseases improvement in the sanitary conditions of dwellings and their surroundings.

I will now proceed to my last proposition.

VI. *In the curative treatment of the summer diarrhœas of infancy, the destruction of the bacteria which are causing the abnormal fermentation is a necessity.*

The truth of this statement will be admitted, I think by all, and a detailed discussion of it here would be out of place. I will only refer to the methods of destroying these germs in brief.

One of the surest methods of destroying the life of any plant or animal is to withdraw all the sources of food supply. Germs in the intestine of the child may be destroyed in this way. If they feed upon the constituents of milk, stop the administration of milk. Escherich[2] has shown by actual demonstra-

tion, that the bacteria normally present in the stools and intestines of the young fed upon milk disappear wholly and speedily when the administration of milk is stopped and a meat diet is substituted. A radical change in diet is one of the most certain methods of changing the nature of the bacteria which cause certain digestive disturbances. The struggle for existence is probably not without its effect even upon microörganisms. Some thrive abundantly in a given medium—indeed, they multiply so rapidly in many instances that they crowd other germs out of existence—but when the medium in which they exist is changed they find that the new conditions of life influence their rate of growth and reproduction, and if these new conditions are unfavorable to the old resident, he is displaced by an invader. Again, although the old germ may grow and multiply in the new medium, it may lose its virulence, it may no longer be able to elaborate the chemical poison or ptomaine, the production of which characterized bacterial activity in the first medium. Thus, Brieger has shown that the typhoid bacillus will grow and multiply, but will produce no typhotoxine, in solutions of peptone, while in beef-tea preparations it does produce this poison. As I have already stated, a small quantity of milk containing tyrotoxicon added to any quantity of good milk will soon render the whole poisonous; but, when added to beef-tea, or solution of egg-albumen, the amount of the chemical poison is not increased.

This I have found to be invariably the case in a large number of experiments which I have made, and it indicates either that the meat and albumen preparations will not support the life of the tyrotoxicon-producing germ, or that in these media the conditions of the life of the germ are so altered that it no longer produces a chemical poison.

We have labored to show that the bacteria which cause the summer diarrhœas of infancy find in milk the most favorable conditions for their growth, activity, and reproduction, therefore, when we wish to destroy these bacteria we certainly shall not continue to feed them upon milk. The prompt and complete withdrawal of all milk, of every kind of milk, even that of the mother, in the treatment of the summer diarrhœas of infancy, has been advocated for many years by eminent clinical teachers, and now the chemist and bacteriologist have shown that this recommendation is a good one, and have given a scientific explanation of it.

The withdrawal of all milk food should be the first step taken in the treatment of the summer diarrhœas of infancy, then other means may also be resorted to in order to hasten the destruction of the agents of the harmful fermentation. Epstein[1] stops the use of milk, washes out the stomach, sometimes employing an antiseptic wash, gives solutions of albumen as food and germicides as medicine. Holt[1] and others recommend cleansing the alimentary canal with a free dose of castor oil in the early stages. Washing out the large intestine is, also, sometimes resorted to.

I have made a few experiments in order to ascertain the value of certain germicides in the destruction of the germ which generates tyrotoxicon. Two ounce bottles were filled with milk, milk and ferment, and milk, ferment and some germicide, closed with glass stoppers, and kept in an air-bath at the temperature of the body for twenty-four hours, and the contents of the bottles were then tested for tyrotoxicon with the following results:

No. 1. Pure milk; no poison.

No. 2. Pure milk; no poison.

No. 3. Milk and ferment; poison in quantity.

No. 4. Milk and ferment; poison in quantity.

No. 5. Milk and ferment and one hundredth grain mercuric chloride; poison present.

No. 6. Same as No. 5.

No. 7. Milk and ferment and one twenty-fifth grain of mercuric chloride; no trace of the poison.

No. 8. Same as No. 7.

No. 9. Milk, ferment, and five grains of naphthaline; poison present in as great quantity apparently as in the bottles containing milk and ferment only.

No. 10. Same as No. 9.

No. 11. Milk, ferment, and five grains of sodium salicylate; poison not present.

No. 12. Same as No. 11.

No. 13. Milk, ferment, and five grains of resorcin; poison not present.

No. 14. Same as No. 13.

It seems from these experiments that 1 part of mercuric chloride to 24,000 parts of milk is sufficient to prevent the activity of the tyrotoxicon-producing germ, while 1 part of naphthaline to about 200 parts of milk is wholly without effect. This is not the first time that naphthaline has been found wanting. Seitz[2] found it without effect on the typhoid bacillus.

The sodium salicylate and resorcin were efficient in proportion of 1 part to about 200. In less quantities they were not, as was shown by some further experiments. There has been some dispute about the germicide properties of combined salicylic acid, Bucholtz standing almost alone in claiming for it such properties. He found sodium salicylate, when present to the extent of 0.4 per cent., preventing the development of bacteria; and it will be seen that in my experiments it was present to the extent of 0.5 per cent. However, I cannot be sure that it acted as sodium salicylate; it may have been partially or

[2] Die Ætiologische Bedeutung des Typhusbacillus, 1887.

even wholly decomposed by the traces of free lactic acid present.

The germicide value of resorcin is generally understood. Ehrig[1] has used a 1.5 per cent. solution of this substance in washing out the stomach in cholera infantum, but in two cases in which a little of the solution was left in the stomach, serious symptoms, accompanied by bloody urine, followed.

GUNSHOT WOUND OF THE ABDOMEN.

PERFORATION DIAGNOSTICATED BY RECTAL INSUFFLATION OF HYDROGEN GAS; LAPAROTOMY; DEATH FROM SEPTIC PERITONITIS.

By WILLIAM MACKIE, M.A., M.D.,
ASSISTANT-SURGEON TO THE MILWAUKEE HOSPITAL.

Viewed from a diagnostic standpoint, the following case is of the greatest interest. Occurring in the human subject, it confirms the infallibility of rectal insufflation of hydrogen gas as a diagnostic measure for the detection of visceral injuries of the gastro-intestinal canal in penetrating wounds of the abdomen. This was first proposed by Professor Senn (with whom I have been associated in his experimental researches), and demonstrated by him in animals before the Surgical Section of the American Medical Association, at the meeting held in Cincinnati, in May, 1888.

C. D., colored, aged twenty-seven, admitted into Milwaukee Hospital, May 11, 1888, at 11 P. M., for pistolshot (38 calibre) wound of abdomen, inflicted two hours previously. The symptoms present were: copious vomiting prior to admission, vomit tinged with blood, excruciating pain referred to umbilical region, abdomen flat on percussion from level of umbilicus to pubes; abdominal wall rigid, liver dulness normal, shock not marked. The wound of entrance was situated two inches to the left of the linea alba, and one inch below the costal arch; that of exit, in the left lumbar region close to the spine, and one inch above the iliac crest; general direction of bullet from above, downward and backward. The bullet had been removed from underneath the skin before he was brought into the hospital.

The patient was etherized, and rectal insufflation effected in the following manner: A four-gallon rubber bag, filled with hydrogen gas, was connected by rubber tubing with the long glass tube of an extemporized chemical wash-bottle, half filled with water. To the short glass tube, passing through the cork only, was attached, by rubber tubing, the rectal nozzle of an enema syringe. This bottle was introduced so that the rapidity of inflation could be judged of by the bubbling of the gas through the water. When the rectal nozzle had been introduced, slow, steady, and continuous pressure was made on the rubber bag. Under very slight pressure the gas commenced to bubble through the water. As inflation progressed, the abdomen, previously flat on percussion from the umbilicus to pubes, became resonant, and the area of liver dulness diminished from below upward. The inflation was continued until the abdomen became uniformly distended and tympanitic throughout. Still no gas escaped through the wound of entrance, although kept at the highest level. On firmly compressing the abdomen, there occurred an intermittent escape of gas mixed with blood through the wound of entrance. To demonstrate the presence of hydrogen by ignition of the escaping gas, matches were employed. These proved very unsatisfactory, for a burning match never once happened to be directly over the wound of entrance when the gas was escaping. The taper as used by Senn in his experiments had, in the hurry of preparation, been overlooked. The escape of gas from the wound of entrance positively proved that the gastro-intestinal canal had been injured, so that further attempts at ignition were superfluous.

Laparotomy by median incision.—When the peritoneal cavity was opened, the omentum immediately bulged into the incision, and, through its translucent structure, it was distinctly seen that it was lifted from the subjacent intestines by the gas which had escaped through the perforations into the peritoneal cavity. From a puncture made in it gas escaped; still the abdomen remained uniformly distended. As the incision was enlarged the transverse colon, greatly distended, escaped; followed by the small intestine, uniformly distended. Examination showed that the intra-abdominal hemorrhage was profuse, originating from the superior mesenteric vein at the root of the mesentery. This was arrested by ligation of the distal and proximal ends.

The distended condition of the colon and small intestine, coupled with the position of wound of entrance, indicated that the perforations must be situated high up; therefore the search was commenced at the stomach. The stomach was empty, and in it were found two perforations, one on the anterior and the other on the posterior surface near the cardiac end, and close to the omental attachment. The duodenum was free from gas, and, at the junction of the duodenum and jejunum, two perforations on the lateral aspect of the intestine were found. For some distance beyond these the small intestine did not contain gas; but as no perforations were found before the distended intestine was reached, I concluded that no more perforations could exist. Examination of the small intestine, while replacing, confirmed this belief. These perforations were closed by a continuous Lembert silk suture. There was no extravasation of stomach or intestinal contents. The other injuries found were one perforation of the transverse meso-colon and two of the mesentery. Patient died of septic peritonitis thirty-six hours after the receipt of the injury.

Post-mortem six hours after death.—(Prof. Senn present.) The sutures were removed from the abdominal wound which had not united, and rectal insufflation of hydrogen gas made to test the integrity of the gastro-intestinal canal. Very slight pressure was required to overcome the ileo-cæcal valve, for compression of the rubber storage-bag had hardly been commenced when the small intestine,

[1] Jahrbuch für Kinderheilkunde, 1887.

previously flaccid, began to distend and escape through the abdominal incision. Its further escape being prevented, the gas was forced through the entire gastro-intestinal canal. The abdomen was now opened by the usual post-mortem incision. The peritoneal cavity presented the appearances of diffuse peritonitis, most marked in the region of the stomach. The sutured perforations, securely closed, were found. With the intestines *in situ*, alternate compression of the cæcum and ileum produced a to-and-fro movement of the gas through the ileo-cæcal opening. This was in every instance accompanied by a distinctly audible blowing, gurgling sound, such as Prof. Senn has described as present on auscultating the ileo-cæcal region in his experiments on the human subject. Further examination revealed a slight, contused and lacerated bullet wound in the tail of the pancreas, and hemorrhagic infiltration of the retro-peritoneal connective tissue below the kidney, and corresponding to the wound in the posterior abdominal wall. About one pint of sero-sanguinolent fluid was found in the peritoneal cavity.

Remarks. — It was impossible to diagnosticate, from the symptoms, perforation of the gastro-intestinal canal. The position of the wound of entrance and the character of the vomit were presumptive of injury to the stomach. The normal area of liver dulness was opposed to the presence of intestinal gas in the peritoneal cavity. That no gas escaped at the time of injury into the peritoneal cavity, is to be inferred from the diminution of the area of liver dulness following insufflation, and the escape of gas on puncture of the omentum. The general direction of the bullet, and the position of the wound of exit pointed to injury of the descending colon or kidney; still both were intact. The symptoms of intra-abdominal hemorrhage were not so marked as to justify a laparotomy.

The escape of gas from the wound of entrance, after rectal insufflation of hydrogen gas, afforded positive evidence of perforation existing somewhere in the gastro-intestinal canal, and on this evidence alone was laparotomy performed. The perforations were so situated as to put this diagnostic measure to the severest test. It was found reliable, and further experience will prove that it is as infallible in the human subject as Senn has found it in animals. It never once failed.

In conclusion, we come to the medico-legal aspect of this case. The man who did the shooting has been committed for trial. The symptoms present were only presumptive of the existence of perforation, until rectal insufflation was made. Had an exploratory laparotomy been performed with the above fatal result, and no intra-abdominal lesions, sufficient to warrant such a grave operation, been found, the position of the surgeon would have been very embarrassing. The defense might affirm that the surgeon ought to be held responsible for the patient's death, and not the defendant. Naturally, this would deter one from operating; but if the surgeon can demonstrate by rectal insufflation of hydrogen gas, the presence of diffuse tympanites due to escape of gas through a perforation into the peritoneal cavity, even without the escape of gas through the external wound, he may rest assured that perforation exists somewhere in the gastro-intestinal canal, and he can then safely proceed to the necessary operative treatment without incurring any medico-legal responsibility.

ON THE USE OF HYDROGEN GAS TO DETERMINE THE SITE OF A FECAL FISTULA—WHETHER IN THE LARGE OR SMALL INTESTINE.

By WILLIAM J. TAYLOR, M.D.,
of Philadelphia.

In a case at present in the surgical ward of St. Agnes's Hospital, in the service of Dr. W. W. Keen, Dr. Sprissler, one of the resident physicians, suggested the use of hydrogen gas, as recommended by Dr. Senn in The Medical News of May 16, 1888, in order to determine the site of a perforation of the bowel, whether in the large or small intestine. A brief account of the case will, I trust, prove of some interest to the profession in connection with this novel subject.

The patient had a fecal fistula on the left side of the abdomen. The question as to whether a lateral or a median incision should be made depended upon whether the proximal opening was in the large or the small intestine. The distal opening threw no light upon this point. In order to determine the question, inflation of the bowel by hydrogen gas was used by Dr. Keen, since if the gas escaped by the fecal fistula before any gurgling occurred in the ileo-cæcal valve, it would prove that the opening was in the large intestine; if, however, the gurgling sound was heard as the gas passed through the ileo-cæcal valve, prior to its escape from the fistulous opening, it would be proof that the opening was in the small intestine.

Accordingly, a gallon of hydrogen was procured in a rubber bag, to which was attached the nozzle of an ordinary Davidson syringe. On inserting this into the rectum, and with a moderate pressure by the hand on the bag, in less than half a minute, and after the use of not over one-third of the amount of hydrogen, and before any gurgling was heard at the ileo-cæcal valve, gas was seen to bubble out from the fecal opening, and on bringing a lighted candle near it, it took fire. The mode of its taking fire was worthy of notice. The day was clear, and the sun shone brightly, so that the flame was scarcely visible, but the gas took fire with a slight explosive snap, which was perfectly characteristic and easily perceived.

A small exploratory opening was then made in the belly-wall only, and the fecal fistula was found

to arise from a carcinoma in the large bowel, and as the disease had progressed, evidently, far beyond operative relief it was considered advisable to desist from further operation.

DIPHTHERITIC PARALYSIS.[1]

By W. H. THOMSON, M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS NEW YORK UNIVERSITY MEDICAL COLLEGE; PHYSICIAN TO BELLEVUE AND ROOSEVELT HOSPITALS, NEW YORK.

Owing to its practical importance, I beg leave, before entering on the consideration of diphtheritic paralysis, briefly to refer to a subject which is naturally suggested by it, namely, the post-latent stage, as I would term it, of the acute infectious diseases. To the antecedent latent stage of these diseases, which intervenes between the reception of the infection into the body and the first manifestations of its activity, we have the term incubation applied. Upon this follows the stage of development which is described in our text-books in its symptoms and course, until the clinical picture ends with what is called the termination in recovery. That termination is taken for granted to coincide with the subsidence and disappearance of all the characteristic external signs of the disease itself, and with the restoration of the different bodily functions which have been disordered to their normal state. That another latent stage of the disease should follow upon the stage of development, specific to each disease in its characters, of equally specific processes and duration, is hardly ever suggested, and yet I have long thought that this is the case in each of the acute infectious diseases, so that a post-latent period must not only be predicated of them as necessary to their real course and always preceding true final recovery, but that in each the effects of the specific latent processes are often of as much practical importance so far as providing for them in the treatment of the patient is concerned, as any of the outward manifestations of the period of development itself. If this be true, then when certain disorders arise during the so-called convalescence of the patient, instead of regarding them as sequelæ, and, therefore, of a more or less accidental character, they should be regarded as much parts of the original disease as the eruption of an exanthem is so regarded and described. Thus we ought not to call scarlatinous nephritis a sequel of scarlet fever, for we have no right to forget that the child still has scarlatina and the kidneys are yet to be heard from, though the patient may have returned to play for two weeks after his apparently mild and temporary first illness.

The frequent severity also of many of these so-called sequelæ in comparison with the light symptoms of the stage of development, ought to suggest the surmise that instead of having only traces or after-effects in hand we have the original complaint itself yet in all its power, and that in these cases its most active workings are during the third, and not during the second period of the natural history of the disease. The seasonal character of many epidemics in this respect, such as the greater liability to nephritis in scarlatina in some years than in others, is but another confirmation that nephritis is as much a part of the disease as the eruption itself, and yet in all its characters it is as much a post-latent stage symptom, and proving therefore, that there is a post-latent stage, as the eruption is a symptom of the stage which succeeds that of incubation. The same may be said of the so-called relapses of typhoid fever; what they in fact indicate is that typhoid fever does not cease when the fever ceases, just as scarlet fever does not; it is really a longer disease than the thermometer measures, and bears in this a resemblance to ague. On the same grounds, I suspect that measles has a post-latent stage in the bronchial tubes, with a continuous process of alteration of the bronchial epithelium going on for some weeks, as specific as its cutaneous eruption is, and that some instances of true sequelæ, such as a life-long asthma, might have been prevented had the significance of the persistent bronchitis been understood as meaning that measles was yet there, rather than that we only had a complication of measles to deal with. Another manifestation of the post-latent stage of measles may be found in the ears, and that this is not a simple local accident, but due to a still present influence of the original disorder in the whole system, may be shown by an unexpected endocarditis, often as insidious and as apt to be overlooked as the otitis itself. The same may be said of such generally trivial disorders in their development stage as mumps and suppurative tonsillitis; after either of these complaints the ears should be watched in the one case and the urine in the other, for the hyperacidity of the latter is often the precursor of acute articular rheumatism. It is doubtful whether any case of ague, with only a single chill as its outward manifestation, can be truly cured under six weeks, as a record of the periodical daily changes in the urine will show. In fact, what we wish to maintain by these remarks is, that all diseases which depend upon an infection of the system by a self-multiplying agent are divisible in their life-history in the body into three stages, namely: 1. The pre-latent or incubative period; 2. The development or manifestation period; and 3. The post-latent period, which latter is not a sequel of the preceding two, but a necessary and integral stage of the whole process, with its own specific characters, and, therefore, its own specific dangers, probably in some cases, as we

[1] Read before the Neurological Section, New York Academy of Medicine, May 15, 1888.

shall mention further on, dependent upon the addition of new special elements in the morbid process.

Diphtheritic paralysis, therefore, is not by any means an isolated case of an infective disease apparently, but only apparently, getting well, because after all signs of it have disappeared, it may be for weeks, yet the patient suddenly presents symptoms of a formidable kind in his nervous system. The intensity of these symptoms also in many cases so much exceeds the preceding signs of diphtheria that I have had several patients brought to me in which no such antecedent was suspected. It is hence a post-latent stage development, for it rarely manifests itself till the second week after the ordinary course of the disease, in most cases not coming on till the third week, and in many not till the fourth week or even longer.

Diphtheritic paralysis is distinguished by the separate rather than the progressive character of its manifestations. Thus it often happens that while it is invading new tracts of nervous distribution it is leaving those which it has first visited, paralysis of the lower extremities, for example, coming on while the pharyngeal and laryngeal symptoms are rapidly improving. This superficial semblance with hysteria ends there, for, as will soon appear, no disease has less of the characters of the functional and more those of the organic paralyses than it manifests. On the other hand, in contrast with organic paralyses, it begins generally with just those signs with which the worst organic forms end—namely, with apparently bulbar symptoms. For a long time the early implication of the palate and pharynx was incorrectly ascribed to the local influence of the antecedent exudation in the throat, but this view is negatived not only by the fact that the paralysis bears no special relation to the extent or duration of the previous angina, but also by the fact that paralysis of the palate and dysphagia are the most common paretic symptoms in those patients where the original seat of the disease was not in the throat at all, but in some other part of the body. It would be difficult to cite a more complete palsy than the palate shows in some typical cases. It does not move from its passive pendant state during respiration, phonation, or deglutition, and as one of its chief functions is to close the posterior nares against fluids during deglutition, one of the first signs of diphtheritic paralysis appears in drinking. It is not only motionless, but also more generally insensitive to all impressions, including electrical excitation, than in this disease elsewhere. The voice is very differently affected in different patients with apparently the same degree of palatine paralysis. If it exists alone a nasal twang is most noticeable; but in one case of my own the vowel sounds were so much altered that the larynx was examined and coincident paralysis of the left vocal cord was found. In this case the superior laryngeal nerve, whose motor filaments supply the muscles of the epiglottis, was not involved at all, the epiglottis being in its normal position and normally sensitive; so that though the patient had extreme dysphagia, yet he never had an attack of choking.

As our present object, however, is not so much to enumerate the varied clinical manifestations of diphtheritic paralysis as to discuss its nature, we may remark here that the coincidence of motor and sensory paralysis in limited localities which are yet supplied from both sides of the brain and cord, would indicate that the lesion was peripheric and not central. It is true that we often have only a motor or only a sensory local paralysis in diphtheria, but in the palate it is frequently the reverse, both arches are equally relaxed and equally insensitive. The significance of this fact was overlooked on account of the wrong interpretation that we had here an example of a general deadening of the part by a specific local inflammation. The same palatine paralysis, however, occurring after a diphtheritic conjunctivitis, for example, ought to have suggested that a morbid process involving the peripheric nerves and not the nerve centres was the true explanation of the condition. On the other hand, some of the features of the next most common manifestation of diphtheritic paralysis, namely, that of the power of accommodation in the eye, are rather puzzling to explain on the hypothesis of peripheric rather than centric origin. The patients lose the ability to distinguish near objects and become far-sighted or presbyopic. Hence, in myopics the disorder is not so easily recognizable. But meantime the light reflex of the iris remains almost invariably intact, and, as in other examples of ophthalmoplegia interna, the loss of accommodation with preservation of the light reflex is a sign of a central lesion, it seems to be difficult to explain diphtheritic cycloplegia as due to a local affection of the ciliary muscle, except that in other paralyses of the third nerve, not diphtheritic, it is rare to find one limited to the ciliary branch alone. It is curious also that the power of contracting the pupil in efforts at accommodation is sometimes preserved and sometimes absent after diphtheria. In about half the cases of palatine palsy the limbs become in time involved, and the legs before and more extensively than the arms. The leg movements are quite unlike those of spinal paraplegia, and instead of being stiff and spreading are more like those of hysterical paralysis in dropping heavily to the floor. Less frequent are paralyses of the laryngeal muscles, those supplied by the superior laryngeal nerve being oftener involved than those of the vocal cords. In such cases the epiglottis remains open, inert, and insensitive, and the danger of choking is very great Paralyses of the muscles of the neck and of the trunk, so generally

spared in hemiplegia, are often so pronounced that the head cannot be held up nor the trunk balanced or moved. In a few, and necessarily dangerous cases, the intercostal muscles and the diaphragm become affected and respiration greatly impeded. In other instances, the muscles of the eyeball, most commonly the external recti, are implicated, and Gowers mentions a case of complete ophthalmoplegia externa affecting both eyes with bilateral ptosis. Sensory paralyses, on the other hand, are just as varied, and seem to bear no relation to the motor disturbances. Thus, Owen of London (*Lancet* of April 2, 1887), reports a case of severe paralysis of deglutition, then of the intercostals, and then complete paralysis of the diaphragm with great weakness of the heart, and finally on the forty-fourth day paralysis of the left external rectus and of some facial muscles. The patient recovered, but throughout there was no alteration of the cutaneous sensibility or any other sensory symptom. On the other hand, in a patient of my own there was a very annoying persistence of symmetrical paræsthesia for six weeks in the soles of the feet with singular sensations following any tactile impressions made on the dorsum, but without any true anæsthesia or analgesia, and no motor weakness whatever. It is significant, however, that when anæsthesia develops in the limbs it is much more pronounced as we approach the extremities, being greatest in the toes and in the tip of the fingers. Of the special senses, hearing is exempt, but both taste and smell, as might be expected from their palatine associations, are sometimes affected. The limitation of the field of vision in some cases which have paralysis of accommodation, has, doubtless, some relation to that disability, for the optic nerve itself almost invariably escapes. It is, however, very probable that the muscular sensory nerves are sometimes involved, even though the cutaneous sensory nerves escape, for diphtheritic ataxia, especially of the lower limbs, often so closely resembles locomotor ataxia that it might be easily confounded with it, but for the history of the case, and the absence of certain symptoms which we now proceed to mention.

The exemptions of diphtheritic paralysis are quite noticeable and peculiar. Besides the nerves of hearing and of sight just mentioned, we have a striking exemption of the vasomotor and trophic nerves. The skin of the paralyzed parts is neither glossy nor œdematous, nor mottled, nor the seat of ulcerations or eruptions. Occasionally we have a more or less transient atrophy of some muscles, as we might expect from some anatomical lesions to be mentioned, but the rule is that trophic changes are conspicuous by their absence. The electrical reactions are sometimes unchanged, oftener, however, when the motor disturbances have been prolonged, faradic excitability is much diminished or lost, and the muscle phenomenon of the reaction of degeneration is present. It is in these cases that we come the nearest to signs of centric implication in slight weakness of the sphincters of the bladder and rectum, especially of the former.

The most characteristic—that is to say invariable—change of diphtheritic paralysis is absence of the knee-jerk. This phenomenon not only accompanies the paralysis, but it belongs to diphtheria as a symptom by itself; for, according to Bernhardt, it occurs in about two-thirds of all cases of diphtheria which have no paralysis of any kind. The existence of a post-latent stage in this disease is thus demonstrated, even if we did not have diphtheritic paralysis, for, according to Bernhardt's observations, its most usual time of development in non-paralytic cases is in the second month, though it sometimes begins at the end of the first. Prof. R. L. McDonnell, Physician to the Montreal General Hospital (THE MEDICAL NEWS, October 15, 1887), however, has published records of eighteen cases of diphtheria admitted into his wards, in ten of whom the knee-jerk was absent on the day of their admission, and while they were suffering from the first symptoms of the disease. His first case was that of a previously healthy boy who had just returned from a visit to a friend when he had an attack of supposed quinsy, and now merely complained of feeling weak. There was nothing to point to the preëxistence of diphtheria except a slight discharge from the nose, and the absence of the knee reflexes. There were at his home four children, three girls and a boy, between the ages of eight and sixteen. Isolation was attempted, but it was too late, for three of the four children took the disease. The patient eventually suffered from great debility, with regurgitation of food, and his voice became quite nasal. The knee-jerk did not become normal for four months. The sisters were admitted to the hospital, where one died, the other two lost the knee reflexes immediately, and subsequently had diphtheritic paralysis. Dr. McDonnell supposes that early loss of the reflex is a pretty sure indication of the advent of paralysis, for, of the ten cases above mentioned, two died, four developed nervous symptoms while yet in the hospital, but of the remaining four no satisfactory report could be obtained of their condition after they left the hospital. Of the eight patients, however, whose knee-jerk was unaffected on admission, paralysis appeared in one, two died, and of the rest no history could be obtained. From these data he concludes that, 1. In a considerable number of cases the knee-jerk is lost from the beginning of the disease, and thus affords a valuable means of diagnosis of the nature of the throat affection; and 2. That absent knee-jerk at the beginning has no influence on the prognosis.

This observation is certainly worthy of being generally tested in acute cases of diphtheria, for it does

not seem to correspond to the experience of others who have found this symptom only in what I term the post-latent stage of the disease. It is not impossible that it was characteristic of the epidemic in Montreal during the time when the observations were made, for we often find seasonal peculiarities in the epidemics of diphtheria as in other epidemics, such as exceptional liability to nephritis in scarlatina, or to intestinal hemorrhages in typhoid fever.

The fact, however, remains that this symptom is of such constant occurrence in diphtheria, and is so significant in itself, from its relation to other nervous diseases, of the nature of the morbid process in diphtheritic paralysis, that it takes the first rank in the consideration of the true pathology of the affection. Dr. Angel Money, in his work on *Diseases of Children*, and also in the discussion on "Diphtheritic Paralysis" in the London Clinical Society, Sept. 1887, speaks of an initial exaggeration of the knee-jerk in many cases as preceding its total loss, thus resembling the same phenomenon in other diseases when it is indicative of the primary nervous irritation which precedes the stage of paralytic exhaustion. I think, however, that this condition must be very exceptional, and suggestive of some exceptional inflammatory element in the parts implicated, for in my opinion, inflammation, either central or peripheral, has nothing to do with true diphtheritic paralysis.

To sum up the conclusions as to the pathology of diphtheritic paralysis from its clinical features alone, before we go further:

1. We would infer that diphtheritic paralysis is due to a peripheric and not centric nervous disorder, because it is so difficult to conceive of the central nuclei being primarily affected in many cases of diphtheria, without their closely contiguous or associated nerve centres becoming also involved, as they are in all other nervous affections where the centres in question are affected. Thus, to take the motor nerves of the palate. According to Vulpian's experiments on dogs, supported by Horsley's and Beevor's experiments on monkeys, the azygos uvulæ and the palatine muscles generally are supplied with motor filaments from the spinal accessory nerves, and not from the motor branch of the fifth, as usually taught. But considering the close association of the nucleus of the spinal accessory with the vagus, on the one hand, and with the laryngeal and cervical muscle nerves on the other, it is hard to see how a case of bilateral paralysis of the palate, if of centric origin would not simultaneously give us symptoms connected with some out of a very extensive array of closely associated motor movements. The facts are, however, that when laryngeal or cervical disorders manifest themselves, it is not simultaneously with the palatine paralysis, but not until long afterward, and generally in a most capricious manner, if contiguity of the centres be supposed to have anything to do with the causation of the disorder. The same may be said about the paralysis of accommodation. If it be of centric origin, as already mentioned, it is difficult to explain why the other branches of the third nerve escape in diphtheria, when they rarely do so in anything else; and here again, while paralysis of the internal rectus has been frequently reported in diphtheria, it does not occur usually until the accommodation paralysis has got well, and as a very late symptom of the case. Moreover, we do not find here the usual associations of third nerve paralysis, such as that of paralysis of the superior rectus with the levator palpebræ. In fact, one of the great characteristics of diphtheritic paralysis is, that it seems to disregard centric associations on principle, as when it attacks the motor branches of the superior laryngeal without involving the recurrent laryngeal, and *vice versâ*.

2. We would conclude from the clinical facts of diphtheritic paralysis, that it is not due to any inflammatory affection of peripheric nerves, that is, not to a true neuritis. I would here anticipate a reference to the pathological anatomy of diphtheritic paralysis, by saying that I do not regard that anatomical change in nerve fibres to which the term parenchymatous neuritis is applied, as a neuritis at all, in the sense that it is caused by a true inflammatory process; rather I regard it as a primary degeneration of the nerve elements quite distinct from inflammation. *Interstitial* neuritis, on the other hand, is the only true neuritis, as it is accompanied by cell infiltration, etc., characteristic of all inflammatory processes, and while nerve degeneration does occur from interstitial neuritis as a result, it is not the primary or the essential process of the affection. Thus alcoholic peripheral neuritis is a neuritis, but the diphtheritic change is no more so than Wallerian degeneration is a neuritis. Now the great clinical feature of neuritis is pain; and absence of pain is the distinctive feature of diphtheritic paralysis. Not but that a true neuritis and nerve pain or tenderness do occur in diphtheria; they do sometimes, but, as I believe, from an independent purulent infection, as we will soon mention.

3. That from the start diphtheritic paralysis is characterized by paralysis of reflex impressions. This of itself is conclusive against a primary inflammatory element; and, moreover, that view is further supported by the absence of signs of inflammation of the vasomotor nerves, which are so sensitive to inflammatory irritation. This early abolition of reflex movements is not only shown in the patellar reflex, but elsewhere even more strikingly. Thus there is not in the body a more wide-awake "reflex" region than at that important switch where the tract of deglutition crosses the tract of respiration. In the treatment of epilepsy, for example, I pay a great

respect to the reflex susceptibilities of that district from the palate down, till the larynx is well cleared, for it is doubtful how much the habit of rapid reflex excitation, by allowing children to eat fast, has to do both with causing and with keeping up epilepsy. But it is just here that diphtheritic paralysis shows its most signal deadening of reflex action. Often not the slightest attempt at gagging will follow the most prolonged titillation of the palsied palate, and the epiglottis, when affected, may be fingered without the least protest.

As to the pathological anatomy of diphtheritic paralysis, we owe to Déjerine the first conclusive demonstration that this affection has for its anatomical basis a change similar in all its essential features to the changes found in multiple neuritis from any cause. In a recent publication by this distinguished investigator, he describes the segmentation of the myeline, the multiplication of the nuclei in the sheath of Schwann, and the disappearance of the axis-cylinder without any signs of interstitial inflammation, as typically developed in a case of diphtheritic paralysis, as in any case of descending Wallerian degeneration. A similar observation is carefully reported by Mendel, in a case of general ophthalmoplegia, where the nerve centres presented no morbid appearance whatever; although the alterations in the nerves to the eyeball muscles were profound. (Gowers, *Dis. Nerv. Syst.*, p. 1231.) On the other hand, a case reported by Paul Meyer, in Virchow's *Archiv*, Bd, lviii. Heft 2, shows that in long-standing cases the process travels up the nerve trunk for a short distance and then skips, as it were, to the root, and then passes into the horns of the gray matter. Meyer, in distinction to most observers, found both the anterior and posterior horns involved, though the former more extensively, and he comes to the conclusion that the diphtheritic agent poisons the nervous textures indiscriminately, both centric and peripheric, so that there is no reason to regard the one as secondary to the other. This, however, is too broad a deduction to make from a single case, in view of the fact that in other diseases characterized by peripheral neuritis, centric changes are sometimes found associated with it. Indeed, it is antecedently probable that extensive lesions involving either region of nerve distribution may often affect the other, so as occasionally to render it difficult to decide which is the primary seat of the process.

Buhl, Gowers, and other writers describe signs of interstitial inflammation of the nerves in some cases. Thus Buhl reports having found evidence of congestion, and even hemorrhage, about the anterior nerve roots. In one case he found the nerve sheaths infiltrated with bodies which he describes as occurring also in great numbers in the false membranes in the throat. Practical bacteriologists are the only ones who can decide the relationship to pathology of such bodies, but in view of the tendency of late researches to reduce most of the alleged specific forms to a single, widely spread organism, we may infer that we have in this case also the same *streptococcus pyogenes* which has done duty as the erysipelas coccus of Fehleisen, the pneumonia coccus of Weichselbaum, the scarlatina coccus of Klein, the diphtheria coccus of Löffler, etc.[1] As far as our present knowledge extends it seems that wherever there is an external focus of ulcerative and suppurative processes, and notably in such a rich bed of lymphatics as the tonsils present, the general system may become infected by absorption both of micrococci and of poisons generated in the inflamed parts, some of which give rise to internal inflammations of various kinds, including neuritis, but further or more definitely than this it is not easy to go.

Muscular degenerations, as might be expected, accompany in varying degrees, however, the nerve lesions of diphtheria. Granular and fatty changes of the muscle fibres have been found irregularly distributed, not only in the same part of the muscle but in different parts of the same fibre. Such alterations have been demonstrated most in the palate, but also in other regions, and especially in the heart. This organ, however, suffers from more than one condition in diphtheria, namely, in the early and in the post-latent stages of the disease. Sudden cardiac failure in the early stage is doubtless due to entirely different causes from cardiac weakness coming on many days afterward in association with late throat and trunk paralyses. In some instances again distinct myocarditis has been demonstrated.

Finally the interesting question presents itself, What is the special agent present in the system which causes diphtheritic paralysis? In the first place it can hardly be the original infective material which is *the* cause of diphtheria, because that belongs plainly to the class of agents which occasion communicable diseases; in other words, it is a living self-multiplying organism. Nothing else can ever cause a communicable disease. For many years I have been accustomed to restrict the term virus to such agents, in distinction from the term poison, which, whether of mineral, vegetable, or animal origin, can never reproduce itself nor ever communicate a disease. It must act always according to quantity, while a virus acts only by growth. Now diphtheritic paralysis is no more catching than any other paralysis. It occurs only after there is nothing more to catch from the patient, generally weeks after the infective agent has done its work. On the other hand our knowledge of the action of the micro-

[1] Prof. E. Crookshank, Distribution of Streptococcus Pyogenes. Lancet, Jan. 21, 1888. Also G. Moos, Bacterial Invasion of Inner Ear in Diphtheria. Archiv. Otology, vol. xvii, No. 1, trans. by Dr. H. A. B. Macauley, New York.

organisms is sufficiently advanced now for us to know that some of them evidently cause disease by generating definite poisons or ptomaines which are absorbable into the blood, and then act there just as other poisons act, some of them as even arsenic does, causing multiple neuritis of a disseminated and yet selective kind. This renders it quite conceivable that a ptomaine may follow upon the changes which the diphtheritic process sets up in the organism, and thus produce all of its characteristic symptoms. The special tendency of diphtheritic inflammation to cause necrotic and gangrenous lesions lends a further support to this surmise.

The late appearance of the symptoms, however, seems to be in harmony with some of the more recent additions to our knowledge of the life history of microörganisms, especially of the saprophytic kind. In the Presidential Address at the last meeting of the British Microscopical Society, Dr. Dallinger gives a very interesting summary of the successive changes which a piece of animal tissue has to go through before it is finally resolved into its component inorganic materials. First begins bacterium termo and does its work with an amazing multiplication of its own form and, moreover, with definite chemical changes as the result of that work. In the course of a week or more, dependent upon the period of the year, there is a rapid succession of spiral forms, such as *spirillum volutans*, *spirillum undula*, and lastly, *bacterium lineola*. After these have done their work and disappeared with further changes in the material, appear two new forms, *cercomonas typica* and *monas dallingeri*, both simple oval forms, but the former has a flagellum at both ends of the long axis of its body, while the latter has a simple flagellum in front. When these have done their work, two new striking forms, *tetramitus rostratus* and *polytoma uvella*, make their appearance, to be followed in turn by *heteromita rostrata*, and *dallingeria drysdali*, the latter the most powerful in its decomposing power of all.

As Dr. Dallinger says, the most important of all ferments, that by which nature's dead organic masses are removed, is one which there is evidence to show is brought about by the successive vital activities of a series of adapted organisms, which are forever at work in every region of the earth.

We may here remark that as the processes of nature are never wholly exceptional, but often are reproduced in many different, yet analogous forms, as in the long known succession in the processes of saccharine fermentation, first to alcoholic, then to acetous changes, so it becomes quite conceivable in view of such facts as these to infer that the working of the diphtheritic organism may prepare, in certain cases, the way for some subsequent process in the body by another organism, when the conditions for its growth have been fulfilled by the antecedent presence of the diphtheritic agent, and that it is during this subsequent process that the poison which works such mischief on the nervous mechanism is produced. As regards diphtheria, this surmise is rendered more probable by the remarkable account of Boissarie cited by Gowers, of an epidemic in a certain district of Paris, where there occurred a series of cases of severe diphtheria, and at the same time a series of cases of paralysis of the palate, eyes, trunk, heart, etc., perfectly like that which occurs after diphtheria, and accompanied by albuminuria. The remarkable fact is that in these cases of primary palsy there was no history of preceding sore throat, and in several of them distinct diphtheria followed the paralysis, which lessened during the throat affection, indicating that the poison of the paralytic disease was of a different origin from the virus of the diphtheria, and hence it is likely that its producer can, under certain circumstances, exist and form its specific ptomaine without having the diphtheritic agent to prepare the way for it. The late researches of Pitres and Villiard on peripheral neuritis occurring after typhoid fever, with instances of the same paralysis of the palate, and of accommodation occurring after that disease as after diphtheria, further lend color to the surmise that we may have an independent origin from some successive organism of the paralyzing poison, which develops, generally, only after diphtheria, but may also after typhoid, and, perhaps, after other fevers, or occur independently, as in Boissarie's cases.

I have but a few observations to make as to treatment. The ordinary course of diphtheritic paralysis is toward spontaneous, though slow, recovery, and, hence, as in chorea and other affections which get well with or without treatment, it is difficult to gauge the influence of the remedies which are recommended. There are certain consequences, however, of the interruption of function by the paralysis of particular muscles which give rise to dangers of their own. Both for frequency and for seriousness, paralysis of deglutition with insensitive epiglottis takes the lead. The patient is not only liable to lose strength rapidly from the difficulty of feeding him, but as we might expect from the close association of the action of the œsophagus with the heart, cardiac failure is to be dreaded as well. Here, as in other tracks of diphtheritic paralysis, I have found the recourse to strychnia and to electricity very disappointing. The faradic current, used as a general cutaneous irritant to the chest, may assist, reflexly, to stimulate the nerves of respiration, as Duchenne recommends it to the back of the chest in paralysis of the muscles of expiration, but I have not been able to assure myself that either the constant or the interrupted current is of much service when locally applied to the palate or throat passages. Instead, I have found that topical irritants seem occasionally to be quite

effective. In palatine and pharyngeal paralysis I begin early with brushing the parts every few hours with a paste of black pepper and honey, and the effect seems to me much more permanent than the ordinary transitory impression of electricity toward awakening the lost, but vitally important, reflex excitability of the parts. Parenchymatous neuritis should always be treated by stimulants, for it is essentially a condition of loss of vitality from the first, and hence in paralysis of the limbs, trunk, etc., I have the parts enveloped twice a day in a pack of infusion of capsicum of the strength of a drachm of the powder to a pint of boiling water, the application to last from ten to twenty minutes. Of medicines, the tr. phosphor., teaspoonful t. i. d., if the kidneys are free, is my favorite.

In accumulation of mucus in the bronchi in respiratory paralysis, there is no reason why the posture treatment, which does so much good in cases of bronchial palsy, should not be tried here. The patient should be let down on his hands from the bed with head down and encouraged to cough, and frequently a short recourse to this measure will result in expelling a quantity of suffocative fluids from the trachea with great relief to the respiration for some time. Cardiac complications require special attention. For the failure which threatens life during the diphtheria itself, alcohol should be given in heroic doses, as recommended by Jacobi, but digitalis never. I shall not soon forget the effect I once witnessed of the administration of this drug in a young man who was sinking from heart failure in the first week of the disease, when I reluctantly yielded to his physician's request to sanction its administration, for every visible artery pulsated after it, just as in cases of extreme aortic regurgitation. When the heart is involved in the later paralysis, the possible presence of myocarditis should not be forgotten. I think that iron, and the explanation of iron as a remedy—oxygen, are our chief resources against this condition. The patient should be kept prone, and as often, or as much as possible, in the open air.

UNILATERAL ANOPHTHALMUS—WITH A CASE.

By JAMES K. YOUNG, M.D.,
ASSISTANT SURGEON, ORTHOPÆDIC DISPENSARY, UNIVERSITY HOSPITAL; CLINICAL ASSISTANT, WILLS OPHTHALMIC HOSPITAL.

The subject of anophthalmus is one of interest alike to the student of teratology and ophthalmology—to the one it is another example of a very constant rule—to the other it is an exception to the histological process with which he is familiar. The monoculus of cyclopia, occurring both in the human subject and lower animals as the result of fusion in an acephalous monster, early attracted attention, and soon received a proper explanation.

Exceedingly numerous also in literature are cases of microphthalmus, in which the eye has been arrested at some particular period of its development, without either atrophy or disease, so that although perfect, perhaps, at birth, its size is diminutive in proportion to the surrounding parts.

Anophthalmus, more properly anophthalmus bilateralis, or complete absence of eyes, was first described in 1609, in Monstrorum Historia, since which time numerous cases have been recorded.

Anophthalmus unilateralis, a much rarer deformity, consisting in the complete absence of an eye, the other remaining perfect or microphthalmic, was first described by Klinkosch,[1] a Bohemian surgeon, in 1766, since which time about 22 cases have been recorded. The term anophthalmus unilateralis would seem to serve better to distinguish these cases from the monoculus of cyclopeæ, than the term monophthalmus, given by some writers. More recently (1881), Dr. E. Hocquart[2] has written an able article on cryptophthalmos—in which in the dissected cases (4) a rudimentary eye was discovered—apparently arrested at the period of formation of the lens.

Observers generally have described the anophthalmus bilateralis as much more common than the unilateralis; and Collins[3] in reporting his case (bilateral) collected 30 of the former, and 12 of the latter, which corresponds to the proportion given by most systematic writers. To these 31 cases might be added 6 others: those of Neary,[4] Radzwzewski,[5] Skrebitzky,[6] and H. Magnus[7] (2 cases), and Stjeminski.[8]

Case.—W. H., male adult, fifty-two years, married, of English birth, presented himself at the clinic of Dr. A. Douglas Hall at Wills Ophthalmic Hospital, suffering from a traumatic abrasion of the left cornea. There was no history of deformity in the family, consanguinity of parents, or maternal impression. On examination the right eyeball was found entirely absent, there being only a small fibrous mass at the bottom of the orbit. The lids and cilia were well formed, but collapsed, and the palpebral fissure shortened. The lachrymal gland and canals were absent. The orbit was remarkably well formed, and gave the appearance of having lost its contents by enucleation.

In the left eye the tutamina oculi were normal, and the eyeball well formed. There was, however, a coloboma of the lower inner segment of the iris, and also of the choroid. The lens and ciliary body were intact, and vision was good.

The peculiarities of the case are the development of the orbit, and the association of coloboma of iris and choroid in the other eye.

[8] Vest. ink. oftalmol., Kieff, 1881, vi. 364.

The literature on the subject of unilateral anophthalmus is meagre. To the 12 collected cases of E. T. Collins, the writer desires to add 11 more collected from accessible literature, those of Klinkosch,[1] Rudolphi,[2] V. Walther,[3] Peringer,[4] Hirschberg,[5] Godley,[6] v. Reuss,[7] v. Arlt,[8] Haederath (2),[9] and Chisholm.[10]

From a study of all these cases (12), including the writer's, certain peculiarities were observed.

The age at which they came under observation varied from birth to fifty-two years, of which three were stillborn.

In the 4 cases in which the sex was given, 2 were males, and 2 females. The family history was not recorded in any.

Of other deformities, 3 were monsters, one of which (Klinkosch) had a deformity of the skull and contents on both sides: the hemispheres were not separated, and the ventricles were formed into one large sac filled with water. In another the optic, olfactory, and third, fourth, and sixth nerves were absent. The palpebral fissures of five were described as smaller and shrunken, in one the lids were absent, and two had cysts in the lower lid.

The orbits were described as small in two, and deformed in one, and one contained a large cyst—the remains of the sclerotic, and two others, remains of bulbs.

In two cases the lachrymal apparatus was entirely absent. In 6 out of the twelve cases the other eye was microphthalmic, of varying degrees—one of which contained also a cyst, the size of a walnut, and one (the writer's) had coloboma of iris and choroid.

The earlier writers attributed this defect to congenital hydrops oculi, by which the eye burst, and finally atrophied, but that the more recent explanation, based on embryological facts, is correct, does not admit of a doubt.

This is particularly well shown in the reports of the post-mortems (9) of bilateral cases collected by E. T. Collins,[11] in which not the least trace of an eyeball, or anything resembling it, could be found. "Not in any case was the optic nerve found to enter the orbit; in one it ended in a cone shape at the optic foramen, in another in a fibrous filament, and in five the chiasma was absent. What had happened," he says, "was this, that no primary optic vesicle had budded out from the anterior primary encephalic vesicle, or, having budded out, had failed to form a secondary optic vesicle."

The remarkable development of the appendages, which are derived from the epiblastic and mesoblastic layers; the cases of so-called cryptophthalmus bilateralis, before referred to; and the association of anophthalmus with microphthalmus, and coloboma of the iris and choroid, are all interesting in themselves, and add additional weight to the correctness of the theory.

MEDICAL PROGRESS.

Acute Poisoning from Quinine.—Rosenbusch, in a recent number of the *Przeglad Lekarski*, reports a case of acute quinine poisoning, which he had observed in the hospital of Prague. After the administration of 15 grains of the sulphate of quinine the patient was attacked with shivering, tinnitus aurium, severe headache, cold and pains in the extremities, palpitations, and vomiting, with great prostration. An hour later the patient became unconscious, the temperature rose to 103.5° F., the pulse was 158 and compressible, the pupils contracted, but reacting to light, the tongue dry. The skin of the face and the whole body presented a uniform redness, resembling that of scarlet fever, and composed of many small confluent patches. The likeness to scarlet fever eruption was the more striking as the neck and the thigh were very deeply colored. Respiration was difficult. Castor oil, caffein, and cold compresses to the head and the cardiac region were ordered. On the following day the temperature was only 97° F., the pulse 108, with considerable arterial tension. The patient had a restless night and was delirious; the bowels acted toward morning, the rash became paler, the pupils regained their normal size, the tongue became red and coated with yellow patches. Sensations of tearing and trembling in the extremities were complained of. Bromide of sodium was given. The rash and all the other symptoms described disappeared in two days, and only a slight pigmentation of the skin remained. The patient had stated that, five years ago, he had a similar attack after taking two powders, each containing 7½ grains of sulphate of quinine. On that occasion the rash disappeared the next day. Dr. Rosenbusch points out that this case is specially interesting by reason of the high temperature, which had never before exceeded 101.5° F.; also on account of the great resemblance of the rash to that of fever, from which at first it could hardly be distinguished. The absence of throat symptoms and the sudden occurrence of a diffuse and uniform blush over the whole body were the chief features which differentiated the affection from scarlet fever.—*British Medical Journal*, May 5, 1888.

Glycerine as a Laxative.—Novatny is quoted by the *Centralblatt für die gesammte Therapie* for May, 1888, in his report of two hundred cases in which he used glycerine, per rectum, as a laxative. The dose was from thirty to forty-five minims; the effect was generally pro-

duced in from one to two minutes; in a few cases two or three hours elapsed before defecation ensued. Novatny considers the effect produced to be due to the increased peristalsis, extending to the small intestine, producing increasing secretion and fluid stools.

Oxide of Zinc in Infantile Diarrhœa.—M. Dupré stated at the Société Médicale de Reims that oxide of zinc is by far the most effectual remedy in infantile diarrhœa. It should be prepared as follows:

R.—Sublimized oxide of zinc . .	gr. 55
Bicarbonate of soda . . .	gr. 25
Tincture of krameria . . .	20 drops.
Plain syrup	30 "

A teaspoonful of this preparation is given every half hour until vomiting and diarrhœa have ceased. The first teaspoonful stops the vomiting, and the third or fourth the diarrhœa. In the few cases in which this treatment fails in entirely checking the disease, it gives great relief and prevents complications. From 1884 two hundred and thirty-four cases, all of which occurred during the months of July, August, and September, were treated by oxide of zinc, and among these only eight deaths were registered, the death-rate being thus only 4.7 per 100.—*British Medical Journal*, April 28, 1888.

Intra-muscular Injection of Mercury in Syphilis.—The *Medical Press* of April 25, 1888, writes, that the inconveniences to which mercury administered by the mouth is apt to give rise, and the uncertainly which exists as to the precise amount that is being absorbed, have led certain practitioners to resort to injection into the tissues, as a more reliable and, withal, a more convenient method of exhibiting the drug. The earlier attempts in this direction were not attended with the success that had been anticipated, inasmuch as they gave rise to so much pain and such untoward sequelæ as to render continuous treatment impossible. Since others, however, undeterred by the suffering in which they were not called upon to participate, carried their investigations further, it was found to be possible to administer the drug in this way without the untoward results which attended its employment in the first instance. In a paper read before the Medical Society of London, Mr. Astley Bloxam gave the results of a very extensive experience with the different preparations that have been suggested. The preparation which, in his hands, has proved the most uniformly successful and free from inconvenience, is a solution of *sal Alembroth*, containing perchloride of mercury and chloride of ammonium, ten drops of which are equal to a third of a grain of the perchloride. This he injects deeply into the muscles of the buttock. The proceeding is said not to be very painful, though as to this the opinion of some of the patients would be desirable, and no abscess has ever been known to follow. Its advantages are, that the stomach is not deranged, that one injection a week is sufficient to keep the patient under the influence of the drug, and that the disease may be cured with some seven or eight grains of the salt, spread out over a year or eighteen months.

An Interesting Case of Lead Poisoning.—The Paris correspondent of the *British Medical Journal* writes that at the meeting of the Surgical Society on February 9th M. Duguet described a case of lead poisoning. The patient' a woman, aged thirty-eight, was employed in a factory where colored cardboard boxes are made by machinery. Her business was to gum small bands of paper 0.15 centimetre long on these boxes, which were intended to hold reels of cotton. These paper bands are colored red and orange on one side, being gray on the other side, which is covered with gum. In taking up these bands, which are packed in layers, the patient was obliged to wet her finger with her tongue each time, and slip off each band, of which the red and orange side is placed uppermost, with her finger. The gray side of the band had then to be licked, and the band gummed on the box. The patient had frequently gummed as many as 5000 of these bands in one day. She stated that all her companions (eight or ten) who did the same work, all became pale and thin, and suffered from colic. Those who were employed in pasting on blue-colored bands of paper were not affected with any morbid symptoms. The red and orange bands of paper were analyzed by M. Gur. The residue of the paper, when burnt, gave all the reactions of salts of leads. Each band contained about 12 milligrammes of metallic lead. This form of lead poisoning has not been described before. M. Monod suggested that the case should be reported to the Préfect de Police.

The Antiseptic Treatment of Pharyngeal Diphtheria.—Huchard employs the following method of treatment:

The application to diseased surfaces of an alcoholic solution of bichloride of mercury, 1 to 1000. Irrigation with boric acid solution, 1 to 100. Internally the administration, hourly, of teaspoonful doses of

Sodii benzoat.	ʒ 2½.
Aquæ menth. piper.,	
Aquæ destillat.	āā ʒ 10.

Alcoholics, coffee, and nourishing foods should be given, and the air of the room antisepticized by a spray of the antiseptic substance found least irritating.—*Revue de Thérapeutique*, April 15, 1888.

An Epidemic of Various Eruptions following Vaccination.—The Report of the Royal Bureau of Hygiene at Berlin for 1888 (*Veröffentlichungen des Kaiserlichen Gesundheitsamtes*, 1888, No. 3) contains an interesting account of peculiar cutaneous eruptions which accompanied the use of vaccine virus from three heifers, in the vaccine farm at Eberfeld. This farm was in apparent good order; it had been inspected regularly, and its officials were reliable and skilful. Among a large number of successful vaccinations occurred skin eruptions, many of them contagious, among those children and adults vaccinated with the lymph from certain three heifers. The presence of any especial disease in the animals was not recognized. The eruptions were a contagious impetigo, a contagious pemphigus, urticaria, and herpes, accompanied by pruritus. In some cases pustules formed about the original pustule, resembling auto-inoculation. Among children several deaths occurred; in one of these cases post-mortem examination revealed a subscapular abscess, with sero-sanguinolent fluid in the pleural sac. Considerable constitutional disturbance followed the occurrence of the eruptions; contagion seemed to be promoted by schools, and the occurrence of the harvest. By order of the Government the vaccine farm was temporarily

suspended; all instruments and appliances were destroyed, the buildings most thoroughly disinfected, and the heifers destroyed. Vaccine lymph subsequently produced at this farm was excellent in its results. The physician-in-charge sent a specimen of lymph to Berlin for examination. The microscope showed isolated bacilli, and numerous micrococci which multiplied in chains and did not liquefy gelatine. No control experiments, by inoculation, were made.

Wine of Ipecac by Inhalation.—Murrell reports in the *Medical Press* of April 25, 1888, six cases of various affections of the lungs which were greatly benefited by inhalations of wine of ipecac, in spray. He concludes that most successful results are obtained from the employment of the ipecacuanha spray in cases of chronic bronchitis and bronchial catarrh. In fibroid phthisis there is often a marked improvement, even when no constitutional treatment is adopted. A single inhalation will sometimes restore the voice in cases of hoarseness due to congestion of the vocal cords. It is a matter of little importance whether the spray be given with a handball spray apparatus or with a small steam vaporizer. In either case the spray must be warm and the patient should not go out for some minutes after inhaling. Care should be taken te see that the spray really enters the chest and is not stopped by the arching of the tongue against the wall of the mouth. The best results are obtained by using the spray for about ten minutes, three or four times a day. In the majority of cases of winter cough relief will be obtained in ten days.

Creolin, Internally.—Spaeth, of Frankfurt, in the *Münchener medicinische Wochenschrift* of April 10, 1888, gives the following formula which he has found useful in prescribing creolin internally:

Creolin.	ʒ 3.
Tragacanth. pulv.	gr. 30.
Spirit. dilut.	♏ 30.
Glycyrrhizæ pulv.	ʒ 6.
Muc. gum. acac.	q. s.

Ft. pil. 200 in num.

Dose.—One pill, two or three times daily.

The Dangers of Saccharin.—The Paris correspondent of the *Medical Press*, of April 25, 1888, writes, that in introducing a discussion on this subject, M. Worms said that the most interesting application that he made of this remarkable product was that of enabling those who suffer from glycosuria the possibility of eating sweetened aliments without the fear of increasing their malady. But he found that saccharin was not very well borne by the patients to whom he gave it. Out of four treated, only one was able to continue its use, the others suffering from gastric disturbance. Consequently he considered there would exist a certain amount of danger to the public if the drug were to be extensively used by grocers, confectioners, etc., in the sweetening of their products, as twenty grains of saccharin have a sweetening power equal to nine ounces of white sugar. M. Dujardin said he had not met with the accidents mentioned by his colleague; he gave as much as 120 grains to a dog without witnessing any ill effects; consequently saccharin was not toxic. However, it could not be considered as an aliment, because it was found after ingestion in the urine unchanged. He agreed with M. Worms on the necessity of examing the subject more fully, and especially in a commercial point of view, as if this product of tar were to be used by the trades mentioned a very serious prejudice would be caused to one of their most important national industries.

The Disinfection of Apartments.—Krupin has recently experimented in the Alexander Barrack at St. Petersburg upon various methods of disinfecting rooms. He found that the ordinary disinfection practised by chlorine gas is inefficient; anthrax spores left in a room so treated were uninjured. The best method of disinfection, from the standpoint of efficiency, convenience, and cheapness, for bedding, clothing, and rooms of the sick, is steam of corrosive sublimate solution one per cent; walls and furniture should be washed with this solution, or one composed of equal parts of corrosive sublimate 1 to 100, and carbolic acid five per cent. Disinfection by this method does not expose a subsequent occupant of the room to danger.—*Deutsche medicinische Wochenschrift*, April 26, 1888.

Suture of a Wound of the Liver.—The *Riforma Medica*, of April 25th, states that Professor Postempski recently stitched up an incised wound of the liver. The operation, which is said to be the first of the kind ever performed, took place in the Ospedale della Consolazione at Rome on April 18th. The abdomen was opened, and the edges of the wound, which was situated in the left lobe, and which was 2¾ inches in length, and ¾ inch in depth, were brought together by two catgut sutures, applied by means of extremely fine needles. The hemorrhage, which had been very free, was at once checked when the wound in the liver-substance was closed. On April 23d, four days after the operation, the patient's temperature was normal, and he was doing well. Professor Postempski will publish the case in detail in due course.—*British Medical Journal*, May 5, 1888,

Cocaine in Diseases of the Genito-Urinary Organs.—Fenwick, in the *Lancet* of May 5, 1888, concludes as follows on this subject; If pain in any part of the body be due to a *slight* nerve irritation of an unimportant character, a cocaine injection into the urethra will rapidly relieve it. If, on the contrary, the pain is due to severe nerve irritation, a cocaine injection will not relieve it. These facts open a large field in the differential diagnosis of the causes of pain, as well as the just estimation of the amount of pain experienced by neurotics and others. I have used it largely in the diagnosis of urinary diseases. For instance, in cases of renal pain, if a urethral injection of a 20 per cent. solution of cocaine immediately relieves a pain in the kidneys, I diagnose a transient or unimportant cause for that pain, such as congestion, uratic urine or grit, colonic pressure, &c. If, however, the renal pain is uninfluenced by such an injection, I give a more guarded prognosis, and this has been several times verified by the subsequent passage of small stone, or, as in one case, by the development of a renal carcinoma. There are also various vesico-urethral diseases, in which cocaine thus used proved of diagnostic value, as in glans pain, urethral pain, suprapubic pain, &c. Lastly, there is every reason to believe that

it will prove of value as a prophylactic agent in warding off, by inhibition, the untoward effects of reflex renal flooding after operations upon the bladder and urethra. I have used the drug with this object for a couple of years, and I hope soon to be able to bring forward physiological as well as clinical evidence upon this point.

Albuminate of Iron.—*The Bulletin Général Thérapeutique* of April 30, 1888, gives the following formula for the preparation of albuminate of iron:

Egg albumen (dried),	gr. 45
Cinnamon water	ʒ 7½

Dissolve and add:

Liquid perchloride of iron	ʒ 3
Distilled water	ʒ 10

Mix; add aqua ammonia ♏ 15, shake well and filter. The resulting liquid should be aromatic, reddish-brown, and alkaline. It may be given in milk, or any desired article.

The Incompatibilities of Antiseptics.—Boxall reports experiments to determine the incompatibility of various antiseptics in the *British Medical Journal* of April 28, 1888, and concludes as follows:

The moral conveyed by the experiments is obvious: avoid as far as possible the admixture of anti-septic agents and their contamination with lubricants and with soap when incompatibility exists. For instance, in employing corrosive sublimate it is advisable to use the same solution for disinfecting the hands (carefully avoiding contamination with soap) and for cleansing instruments[1] as for irrigating the parts, to employ a mercurialized lubricant and to use alembroth dressings. If for any reason it becomes requisite to substitute one antiseptic agent for another, a second should be chosen which is not incompatible with the first, and the same precautions should be observed throughout the series.

The above observations deal with one phase only of the subject. I am content to leave to more able hands the elaboration of further details. The second question—the chemical nature of the bodies produced—is for the chemist to answer; the third point—the antiseptic value of these bodies—still remains for the germiculturist to determine. When these points have been settled and acted upon, less scepticism as to the value of antiseptic agents may be looked for. The fault lies not so much with the antiseptics themselves as with the unscientific method in which they are often employed.

Alcohol as a Digestive Tonic.—In a discussion on the use of alcohol at the recent Congress of German Physicians at Wiesbaden, von Jaksch, in speaking of alcohol as a digestive tonic, said that alcohol is of positive value in those cases where no pronounced anatomical alteration of the stomach is present, and also no great alteration in the quantity or quality of its secretions. In neurasthenic patients, where a tonic and hypnotic effect is desired, beer is advised. For the promotion of digestion, light red and white wines are best. For stimulation, alcoholics of high percentage are indicated. Von Jaksch, and all who took part in the discussion, were decided in their expression regarding the necessity of limiting the use of alcoholics in accordance with the indications stated.—*Deutsche medicinische Wochenschrift*, April 26, 1888.

[1] Here, again, a caution is requisite, for copper and steel, unless nickel-plated, are apt to decompose the solution and to cause precipitation of the mercury in a free state.

Micro-organisms in Vichy Water.—Some elaborate investigations, which have been undertaken by Dr. Frémont, have apparently resulted in the discovery of a number of microörganisms in the mineral waters of Vichy. The microscopic bodies vary according to the source of the water, and some are said to possess the property of acting upon food substances and assist in the transformation of the latter into peptones. A Commission has been appointed, consisting of several noted scientists, to inquire into the alleged discovery, and, upon the whole, we cannot but feel some satisfaction that this is the case. The result of their researches will certainly be watched with interest by those whose convictions on the utility of Vichy waters are beyond cavil; for we may presume that most persons who patronize these waters would prefer to leave the peptonization of their food to the ordinary arrangements of digestion, and would object to the intrusion of microörganisms to a wholesale extent, whatever the effect might be. Reflective minds, however, may find in this record the germ of a large therapeutic earthquake. It may be that the utility of Vichy waters has hitherto depended upon the microörganisms they contain, and extending this hypothesis to other medical agents, it may be the case that each drug has a germ which thrives and develops in the blood only when the drug is given. Thus to make an extravagant suggestion, it may be, after all, the fact, that the action of drugs depends directly upon germ life.—*Medical Press*, April 18, 1888.

Soluble Iodo-tannate of Mercury, for Hypodermatic Use in Syphilis.—Nourry, of Paris, has found the following combination productive of a salt easily soluble for injection in the treatment of syphilis:

Hydrarg.	gr. ⅛
Iodini	gr. $\frac{2}{20}$
Acid. ratanhiæ tannic.	gr. ⅗
Glycerin. pur.	♏ 15

This injection is not followed by pain, abscess or induration. Its absorption is very rapid; in forty-eight hours after taking the quantity stated, violent salivation and gastric disturbances may occur. The ordinary injection of this compound should, therefore, not be more than one-half a Pravaz's syrings (seven minims) of the solution.—*Bulletin Général de Thérapeutique*, April 30, 1888.

The Development of the Pharynx in the Embryo.—Piersol, in a preliminary communication to the Medical Society of Würzburg, reports researches upon the development of the pharynx in mammals which show that the pharyngeal space is developed before the branchial arches; that an external and internal pocket, or cavity, form, which subsequently form three, and from which epithelial tubal masses are developed. The middle ear and Eustachian tube are developed from the different divisions of the pharyngeal space. The thymus and thyroid gland are also developed from the divisions of the pharyngeal space. A detailed account of his researches will appear in the *Zeitschrift für Wissenschaftliche Zoologie*.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JUNE 9, 1888.

THE MICROBE OF DYSENTERY.

CHANTEMESSE and WIDAL report the discovery of a specific bacterium in dysentery (*Progrès Médical*, April 21, 1888). Working in Cornil's laboratory, they have studied five cases of tropical dysentery and have found the same microbe in the lesions and stools of a fatal case and in the stools of four others. The bacteria were found in colonies in and between the tubular glands of the intestine, in the lymph glands, and spleen. The organisms develop rapidly at the ordinary temperature, thriving on all the usual culture media. They are bacilli, with rounded ends and somewhat thicker in the middle than toward the extremities. They grow luxuriantly in sterilized water from the Seine. Fed to guinea-pigs, pure cultures produce intestinal inflammation and necrosis, the stomach itself being affected. The lesions are more marked when the gastric contents are rendered alkaline. Intraperitoneal injections cause death in two or three days with peritonitis, pleuritis, and pericarditis. The liver is affected in these animals, necroses with colonies of bacilli being found in the portal areas. All the lesions in the experimental cases furnished pure cultures of the bacillus.

From these facts, and the absence of the bacillus in the feces of healthy men, Chantemesse and Widal feel justified in claiming specific properties for this bacillus.

Although the observations they have made are too few in number to bring absolute proof, they are of interest as being the first in which so much has been accomplished. Numerous other investigators have described microörganisms in dysentery, but none, up to this time, have succeeded in cultivating them. Further developments will be awaited with interest.

SPONTANEOUS AND EXPERIMENTAL TYPHOID FEVER IN ANIMALS.

WHETHER typhoid fever occurs naturally in our domestic animals, and whether it can be produced experimentally, are questions which have received most contradictory answers. Veterinarians are by no means agreed on the first point. There is a disease in the horse characterized by swelling and ulceration of the Peyer's glands and enlargement of the spleen, but the recent observations of SERVOLLES and of LEBAT would indicate that with superficial resemblance the affection is etiologically distinct. Anatomically the lesions are very similar, and in the current number of Virchow's *Archiv*, SEMMER has described several cases in horses and dogs. The statements bearing upon the experimental production of the disease are also at variance. While Klein, Klebs, Gaffky, and others obtained negative results, Birch-Hirschfeld, Fränkel, and Simmonds, and Michal and Todor have produced in rabbits, mice, and guinea-pigs a disease with enteric symptoms and swelling of the spleen. In the *Lyon Médical*, No. 14, 1888, PERREY gives the result of some observations upon this question which are of value, as no lesions were produced by the injection of material directly into the duodenum, nor, in a horse, by the introduction of cultures directly into the jugular vein. Nor were positive results obtained in the case of six animals which were fed for many days with potatoes upon which were growing pure cultures of the typhoid bacillus. He holds that the artificial disease has never the true picture of human typhoid, but is rather a septicæmia induced by the penetration of the bacilli.

INEFFICIENT QUARANTINE.

THE great responsibility resting upon the health officer who guards a city and, through it, an avenue to the whole country against the introduction of contagious or infectious diseases from foreign ports, is never more fully recognized than when through his error of judgment or incapacity persons suffering from such diseases are allowed to pass quarantine without recognition or restriction. An error of this kind at any time may lead to extended propagation of disease, with all its ulterior evil consequences.

From information reliably obtained, it seems to be undisputed that the recent occurrence of smallpox in Philadelphia can be traced to a case of varioloid imported on one of the transatlantic steamers which arrived at this port on February 1st of this year; and it is almost as clear that this case was sufficiently suspicious in its manifestations to have been detected by ordinary skill and care. But it was not, and hence the spread of the disease. Moreover the mistaken diagnosis of cases of disease not requiring quarantine, and the consequent useless detention of vessels arriving in port, furnish additional ground for fearing that the people have not the benefit of that experience and vigilance which they have the right to expect in the administration of the important office of Port Physician.

It is incumbent upon the appointing power to select for this responsible position a man possessing undoubted qualifications, especially as the duty of intercepting disease brought to the country through this port is entrusted to his care for a greater portion of the year, and its skilful and intelligent performance is absolutely essential to the protection of the health of the whole country. The best quarantine regulations are fruitless without judicious and efficient execution; and it therefore behooves the Governor of Pennsylvania, in view of the serious allegations which have been brought to public notice, to make careful investigation into the manner in which the duties of the office have been discharged by the present incumbent.

ON Thursday, the 31st ult., a fire broke out on the upper floor of the Medical Hall of the University of Pennsylvania, and destroyed the Histological and Pathological Laboratories. The Wistar and Horner Museum suffered a good deal from water, and many valuable specimens were destroyed by falling plaster and by careless handling in removal. Many books in the Stillé Library were badly damaged by water. The losses are fully covered by insurance. The necessary repairs can readily be completed before the opening of the next session, and we learn that designs have been prepared for a complete rearrangement and enlargement of the histological and pathological laboratories.

THE public of Philadelphia has sustained a severe loss in the death of Miss Alice Fisher, who nearly four years ago was appointed by the Board of Guardians to take charge of the Training School for Nurses at the Philadelphia Hospital. Only those familiar with the inner history of that institution can appreciate the changes which have been effected under her judicious direction. The good work which she has accomplished has stimulated other hospitals of the city, and training schools have been established at the Pennsylvania, Episcopal, and University Hospitals. By no means the least important lesson of Miss Fisher's too brief life in this community has been the demonstration of the fact that the profession of nursing affords an ample, as well as a most suitable, field for women of the highest culture and intelligence.

IT is proposed to begin at once the erection of a Maternity Hospital for the University of Pennsylvania on the grounds of the University Hospital, to consist of a main central building and two wings. Sufficient money is on hand to complete the erection of one wing, and it is confidently expected to finish the whole building at an early date.

AT the recent examination held in Toronto by the Ontario Medical Council, 241 students presented themselves for the primary examination (anatomy, chemistry, physiology, and materia medica), of whom 125 passed and 116 were rejected. At the final or pass examination, which alone entitles a doctor to practise in the Province, of 167 candidates, 97 passed and 70 were rejected.

THE Maine Medical Association will hold its thirty-sixth annual meeting at Portland, Me., on Tuesday, Wednesday, and Thursday, June 12, 13, and 14, 1888, under the presidency of Dr. F. C. Thayer, of Waterville.

THE Association of American Institutions for Idiotic and Feeble-minded Persons will hold its twelfth annual session at the Rossio House, Toronto, Canada, on Monday, June 18, at 3 o'clock P.M., moving to Orillia on the following morning. By resolutions of previous sessions, the following reports will be called for: "On Causation of Idiocy," etc., superintendents reporting from their earliest received cases. "On Status of the Work before the People and Legislatures of the various States." "On Development and Progress of the Institutions represented." "Improvements in School Training and Hospital Care introduced during the past year." "Clinical reports of special cases." A number of interesting papers have been promised.

The Board of Pharmacy of Brooklyn, New York, has taken official action tending to restrict the sale of "Rough on Rats." It has issued a circular to all pharmacists in that city, stating that, according to trustworthy analyses, the dangerous article contains ninety percentum of arsenic, and directing that all sales thereof hereafter made by them must be in strict accordance with the statutory rules governing the dispensing of poisons. This action we regard as worthy of commendation and imitation, for, while it cannot, of course, prove prohibitory of its purchase by persons bent on self-murder, it will cause druggists and housewives to be more circumspect than formerly in the handling of the deadly compound.

Dr. Gersung, of Vienna, Assistant to Billroth, has performed the novel operation of transplantation of nerve from rabbit to man. The patient was Dr. von Fleischl, Professor of Physiology at the University of Vienna, who suffered from neuroma in the stump of his right thumb amputated sixteen years before, in consequence of an injury received while making a post-mortem examination. The sciatic nerve of a rabbit was inserted in the interval of the resected median, and held by suture. The operation, which was done under chloroform about two months ago, has resulted in a marked subsidence of the neuralgic distress, and sensibility is becoming reëstablished in the part. It should further be stated that the distinguished patient had been the subject of amputations, resections, and other surgical procedures for the constantly recurring neuromata that promptly developed after every operation except this latest one done by Dr. Gersung.

The Chair of Hygiene, at Netley, made vacant by the death of Dr. de Chaumont, is about to be filled by the appointment of Dr. J. A. Marston, Deputy Surgeon-General. He has already temporarily occupied the chair during the illness of his predecessor, last summer.

Sir William Jenner, having retired from the presidency of the Royal College of Physicians, received from the present officers of the College the highest token of respect, in a visit of gratulation from the President, Senior Censor, Registrar, and Dr. Quain. Sir William expressed his gratification at their visit, and remarked that his rule in life had been never to do more than one thing at a time: first, as an investigator; secondly, as a teacher; thirdly, as a practitioner.

The following item, purporting to be a cable dispatch from Paris, appeared in the daily press: "An officer was sent to arrest a man, known as the 'Wizard of Montmarte' for the illegal practice of medicine. The wizard was reputed to be an ignorant quack. On the appearance of the officer, the wizard produced a diploma and avowed himself a doctor of the Paris faculty, with full right to practise medicine. He further stated that, although he had distinguished himself at his examinations, he had starved as a regular practitioner, but that having set up as a quack, he had made his fortune, and had now amassed a capital of $80,000. The people had avoided him as a doctor, but rushed to him as a quack."

REVIEWS.

The Rules of Aseptic and Antiseptic Surgery. By Arpad G. Gerster, M.D., Professor of Surgery at the New York Polyclinic, Visiting Surgeon to Mount Sinai Hospital and the German Hospital, New York. 8vo. pp. 326. New York: D. Appleton & Co., 1888.

The author starts with the proposition that owing to the strides made within the past few years consequent upon the general adoption of Listerian principles, nearly all English text-books are inadequate to the wants of modern students. We think he has achieved a high measure of success in his laudable effort to render clear and distinct the underlying principles which govern the practice of all surgeons professing to employ aseptic or antiseptic measures, but which too often appear to the majority of practitioners as "an incongruous chaos of seemingly contradictory and often incomprehensible details, arbitrary and varying according to the predilections or whims of this or that teacher."

Dr. Gerster, with commendable candor, admits that the methods of wound treatment herein explained are, to a certain extent, still undergoing changes, yet it is undoubtedly true that just in proportion to the clearness with which the *principles* are understood is the rarity of changes in the *methods* of achieving asepsis and antisepsis. In his endeavors to render easily comprehensible the adaptation of the principles to various classes of cases, he has minutely detailed innumerable operations, many of which we think had better have been omitted, except that the author would have had to occupy a less prominent position, but then, *that* would have perhaps allowed of a clearer demonstration of the principles of asepticism and antisepticism unencumbered with a mass of notes of essentially similar cases.

Beginning with a succinct account of what is meant by sepsis and asepsis, the treatment of aseptic wounds is first considered with the proper dressings, instruments,

and essentials for public and private practice. Ten minutes' perusal of this section will convince any unprejudiced reader that with but little trouble aseptic methods are as easy of application in private practice as in a well-appointed hospital. While agreeing in the main with the author, why, may we ask, is capillary drainage ignored both in theory and practice, a method which we have proved to be effective in many major and minor operations?

"Soiled wounds" are next treated of, when the differences between "aseptic" and "antiseptic" methods are explained and illustrated. Special rules regarding the treatment of accidental wounds, and special applications of the aseptic method as illustrated by scores of cases, complete the first portion of the work.

"Antisepsis," which, paraphrased, means the treatment of suppuration, is next taken up and fully illustrated by cases.

"The Aseptic and Antiseptic Treatment of Tuberculosis," "Gonorrhœa, its Antiseptic Treatment," and "Syphilis, Aseptic and Antiseptic Treatment of its External Lesions," are the remaining topics discussed by Dr. Gerster.

Agreeing unreservedly with the author that "It cannot be successfully denied that *the surgeon's acts determine the fate of a fresh wound, and that its infection and suppuration are due to his technical faults of omission or commission*," we cannot but hope that this book will be widely read and most thoroughly digested. Many years of extended experience of the principles taught in this work have convinced us of the absolute truth of the above statement. The book is admirably printed on superfine paper; the illustrations, so-called, in most instances show next to nothing and might have been omitted without injury to the work.

The Treatment of Hemorrhoids by Injections of Carbolic Acid and other Substances. By Silas Y. Yount, M.D., Physician to St. Elizabeth's Hospital, Member of the American Medical Association, Member of State Medical Society, and Member of the Tippecanoe County Medical Society. Second Edition. 8vo. pp. 102. Lafayette, Ind.: Echo Music Co., 1888.

At the outset we must take exception to the author's unwarranted assumption that it requires special knowledge, teaching, and training—especially by the perusal of works like the present—to treat piles successfully, for we know that any hospital surgeon of average experience is far better fitted to treat such diseases than the so-called rectal specialists. This may seem severe language, but when the author takes the unscientific position that *all* varieties of internal hemorrhoids are to be treated by weak solutions of carbolic acid, ignoring the fact that in most persons, after fifty years of age *bleeding* ceases and the rectal prolapse is the chief occasion of complaint, while prolapse will recur so long as the tumors remain, our strictures will commend themselves, at least in a measure. Still further, careful perusal of the work by any of our readers will, we are sure, cause them equally with us, to decide that no necessity existed for the production of this book when such excellent works as those of Allingham, Van Buren, and Kelsey's were already in the hands of the profession.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section on Pædiatrics.

Stated Meeting, May 23, 1888.

The President, J. Lewis Smith, M.D., in the Chair.

Professor Victor C. Vaughan, of the University of Michigan, Ann Arbor, read a paper on

EXPERIMENTAL STUDIES ON SOME POINTS CONNECTED WITH THE CAUSATION AND TREATMENT OF THE SUMMER DIARRHŒAS OF INFANCY.

(See page 621.)

Dr. W. D. Booker, of Baltimore, read a paper on

A STUDY OF THE MICROÖRGANISMS IN THE STOMACH AND INTESTINES IN THE SUMMER DIARRHŒA OF INFANTS.

It has been ascertained, he said, that in the intestinal tract of all milk-fed infants in health there are constantly present, and in large numbers, two species of bacteria, viz., the *bacterium lactis aërogenes* and the *bacterium coli commune*. These were designated as the obligatory milk-feces bacteria, as distinguished from the inconstant bacteria which are found under various circumstances. The latter are aërobic for the most part, and, as a rule, are somewhat more numerous in the feces of infants fed on cow's milk than in the feces of sucklings.

He had separated twenty-three varieties of bacteria from the dejecta of eighteen children affected with different forms of summer diarrhœa, a description of which is given in a paper read by him before the Section on Diseases of Children of the Ninth International Medical Congress. He finds that the diarrhœal feces contain mostly a different bacterial vegetation from the healthy feces, having a much larger number of varieties than the latter.

During the past winter he has studied the changes perceptible to the naked eye and the microscope produced by these bacteria upon milk, and especially upon milk and bile mixed in different proportions. Bile does not apparently destroy the bacteria found in diarrhœal discharges, and cultures can be obtained from pure bile after being inoculated and kept for days in the thermostat. Some of the varieties of bacteria show diminished activity in milk when bile is added, others increased activity. In milk colored green by a large quantity of bile, or light yellow by a small quantity, one variety gives to the mixture a bright yellow color. This variety is found frequently in the diarrhœal feces. Some varieties give to the milk and bile mixtures a brown color, some a white or whitish-yellow, and one variety a gray color. Some of the varieties cause a disappearance of the oil globules in the milk, with a deposit of granular matter; some varieties do not affect them.

Dr. L. Emmett Holt read a paper on

MICROSCOPIC EXAMINATION OF THE STOMACH AND INTESTINES IN THE SUMMER DIARRHŒA OF INFANTS.

The cases were divided into three classes, according to the duration of the disease. This in 82 fatal cases was as follows:

(1) Those lasting four days or less, 10 cases.
(2) Those lasting from four to ten days, 31 cases.
(3) Those lasting over ten days, 41 cases, or one-half

the whole number. The average duration of this class was about three weeks.

In the *first class* the microscopical examination was the least satisfactory. Post-mortem changes took place rapidly in the intestines in hot weather, and unless autopsies were made six hours after death, no significance could be attached to the alterations of the epithelium, which were almost the only changes.

In the *second class* there were found, with considerable uniformity, degenerative changes in the epithelium of the tubules of the intestine, those in the stomach being less constant. There was marked infiltration of the solitary follicles of the colon, and, to a less degree, of the small intestine, with similar changes in Peyer's patches. The solitary follicles had ruptured in many places, but there were no ulcers. There were no important changes in the submucous coat, except a sprinkling of new cells in its superficial portion.

In the *third class* well-marked lesions were found in the intestine, usually involving all the coats. Those in the colon, consisted of infiltration of the mucous membrane with new cells, in great numbers, obliterating many of the simple follicles; the submucous coat was crowded with round cells quite to the muscular coat, sometimes even invading this. There were superficial ulcers involving the mucous membrane only, and deeper ones reaching quite to the muscular coat, but none invading this coat had been met with. These were follicular in their origin. The most marked changes in the mucous membrane were found near these follicles. The lesions were not uniformly distributed, nearly healthy follicles being found quite near those which were completely disorganized.

In the large intestine, the cæcum, sigmoid flexure, and upper part of the rectum, were the portions in which the most advanced lesions were met with. In the small intestine the changes were usually limited to the lower part of the ileum, and were not nearly so marked as in the colon. Peyer's patches were swollen and often ruptured, but no ulcers of any moment had been seen about them, nor about the solitary follicles here. In a few instances patches of false membrane were seen in the colon.

The changes in the stomach in these protracted cases were not constant, there might be lesion of extensive gastritis, or the stomach might be almost normal.

The paper did not discuss the subject of the microorganisms found in the tissues. The writer's own investigations are as yet incomplete, and the reports of others are conflicting and indecisive. We can be pretty certain that at the end of three weeks lesions of a good deal of importance exist in the intestine. A glance at the size and depth of these follicular ulcers enables one to understand the chronic, rebellious course of these cases, the frequency of relapses, and the importance of local treatment by injections, if we would treat the lesion at all.

The paper was illustrated by a number of drawings, showing the various lesions of the disease.

DR. J. LEWIS SMITH said that, at his request, a well-known chemist had made a series of experiments for the purpose of ascertaining what effect, if any, the different germicidal agents now coming into vogue in the treatment of summer diarrhœa had on the process of digestion, and he said it was a point of some practical importance to know that these agents do not appear to retard digestion to any extent that would lead us to hesitate on this account to employ them.

DR. GEORGE B. FOWLER referred to the myriads of bacteria found in the intestines, and said that the pathological ferments are all organized, while the physiological forments are all unorganized. Still, the latter are fully capable of developing active poisons, as shown in the case of xanthin, etc. He had always regarded the gastric juice as possessed of valuable antiseptic properties, so that it stood on guard, as it were, to render more or less inert poisonous organisms entering the system by the mouth. Many high authorities also teach that the bile has an antiseptic value.

DR. A. CAILLÉ said that the practical outcome of the evening's discussion was about as follows: If we admit the bacterial origin of the summer diarrhœa of infants, we must admit that its principal cause is to be found in milk; and if this is acknowledged, we are forced to the conclusion that the ordinary methods of preparing and preserving milk are altogether faulty. At the February meeting of the Section on Pædiatrics, he had called attention to the apparatus devised by Dr. Soxhlet, of Munich, by means of which the preparing and feeding of sterilized milk can be carried out in any family. In his article on the subject Soxhlet said: "During the process of milking particles of manure and other forms of dirt get into the milk, and during transportation and general handling fermentation sets in; so that much of our milk is really unfit for consumption before it gets into the stomachs of infants and children. Mother's milk, on the contrary, is taken directly, and would undoubtedly be equally contaminated and frequently injurious to infants if it suffered the same manipulation."

Since the February meeting a New York firm, at his suggestion, had begun to manufacture and were now ready to supply an apparatus similar to that of Soxhlet, consisting of a tray holding ten feeding-bottles with combination stoppers, and a pot to boil them in. These, together with extra bottles, a tin dipper for warming the milk immediately before feeding, rubber nipples, and a cleansing brush are all packed in a box ready for transportation. In using the apparatus each bottle is filled to within one-half inch of its neck with the food prepared according to the age of the infant, and a perforated rubber stopper pressed well into the neck of the bottle. The bottles are then set in the tray, and the tray in the pot containing water up to the neck of the bottles, and the water is brought to the boiling point. After the water has boiled for ten minutes each bottle is hermetically closed by pressing a glass stopper down through the perforated rubber stopper. After the boiling has continued for ten minutes more the tray is lifted out and set aside to cool; after which it should be kept on ice or in a cool place until all the milk has been used. Milk prepared in this way can be kept sweet and pure for any required length of time.

The apparatus, Dr. Caillé went on to say, can be purchased for four dollars, but as this is probably too expensive for the poor, he would recommend that a mother unable to buy one should get six or eight bottles provided with the combination stopper, and boil the milk prepared for her infant in them.

DR. A. SEIBERT said that he had no doubt that the proceedings of this evening would constitute a stepping-

stone toward the attainment of a really scientific knowledge of the origin of summer diarrhœa. He was gratified to find that Professor Vaughan had also arrived at the same conclusion as himself, that 60° Fahrenheit is the boundary line beyond which the fermentation of milk commences.

DR. J. E. WEEKS said that a year ago he had made a series of experiments in regard to the action of different agents on the pus germ. He found that salicylate of sodium is inert, while salicylic acid is actively germicidal; and he believed, therefore, that Professor Vaughan was right in concluding that in his own experiments the salt becomes changed, and that its germicidal value is really due to the salicylic acid that is liberated. Naphthalin he found germicidal in rather strong solutions, while bichloride of mercury stands very high. Nitrate of silver also stands high.

PROF. VAUGHAN said that in his own experiments it was probable that the lactic acid present set some of the salicylic acid free from the sodium salicylate. In Dr. Weeks' experiments, there being no such agent present, the salt would naturally remain unchanged. As to the practical use of germicides in the treatment of summer diarrhœa, the dose of the bichloride of mercury required would be about one twenty-fifth of a grain, and as this seemed rather large for young infants, it would, no doubt, be safer to give five grains of salicylate of sodium, which was the dose of this agent required for the purpose desired.

The Chairman having inquired whether it is a fact, as supposed by some, that calomel becomes changed into the bichloride of mercury after being taken into the system, Dr. Vaughan replied that this is undoubtedly the case with a certain proportion of the amount taken, and it seemed probable to him that the change is especially likely to take place when the calomel is given in small doses.

NEWS ITEMS.

The Congress of American Physicians and Surgeons at Washington.—THE AMERICAN PHYSIOLOGICAL SOCIETY has issued the following preliminary list of papers to be read at the meeting to be held in Washington, D. C., on September 18, 19 and 20, 1888.

On the Therapeutic and Forensic Aspects of Hypnotism. By Dr. G. Stanley Hall.

On Enzymes Comparable with Papain, found in certain fruits of temperate climates. By Dr. G. L. Goodale.

On the Knee-jerk Phenomena. By Dr. H. P. Bowditch.

On the Nature of the Knee-jerk. By Dr. W. P. Lombard.

On the Effects of Varying Rates of Nerve Stimulation upon the Character of Muscular Movements. By Dr. H. P. Bowditch.

Growth and Death. By Dr. C. S. Minot.

The Cells of the Cortex Cerebri. By Dr. C. S. Minot.

The Uterus During Gestation. By Dr. C. S. Minot.

On the Temperature Limits of the Vitality of the Mammalian Heart. By Dr. H. N. Martin.

Histological Changes Produced in Ganglion Cells by Stimulation. By Dr. H. H. Donaldson.

On Fever. By Dr. Isaac Ott.

On the Distribution of Bacteria in Drinking Waters and Public Buildings. By Dr. W. T. Sedgwick.

The Origin and Regeneration of Blood Corpuscles. By Dr. W. H. Howell.

On Certain Ptomaines. By Dr. V. C. Vaughan.

On the Physiological Action of Uranium Salts. By Dr. R. H. Chittenden.

On Myosin and Certain of its Decomposition Products. By Dr. R. H. Chittenden.

On the Influence of Acetanilide or Antifebrin on Proteid Metabolism. By Dr. R. H. Chittenden.

THE AMERICAN CLIMATOLOGICAL SOCIETY announces the following programme:

The President's Address. By Dr. A. L. Loomis, of New York.

The Relation of High Altitudes to Germ Disease. By Dr. S. A. Fisk, of Colorado.

Is Climate an Etiological Factor in Graves' Disease? By Dr. R. G. Curtin, of Philadelphia.

An Environment Experiment Reported. By Dr. E. L. Trudeau, of Saranac Lake.

Definite Results Obtained by the Climatic Treatment of Disease. By Dr. A. Y. P. Garnett, of Washington.

Invalids Suited for Treatment at Colorado Springs. By Dr. S. E. Solly, of Colorado.

Influence of Semi-Tropical Latitudes on Types of Disease. By Dr. John Guitéras, of Charleston.

Discussion: The Relative Importance of Different Climatic Elements in Treatment of Phthisis. *Referee*, Dr. E. T. Bruen, of Philadelphia; *Co-Referee*, Dr. V. Y. Bowditch, of Boston.

Observations on the Use of Terebine. By Dr. D. M. Cammann, of New York.

Climate and Bright's Disease. By Dr. J. C. Wilson, of Philadelphia.

Discussion: The Mineral Waters of the United States; Therapeutic Value as Suggested by their Chemical Composition. By Dr. A. C. Peale, of Washington.

Their Therapeutic Value in Gastro-Hepatic Diseases. By Dr. Wm. Pepper, of Philadelphia.

In Urinary and Arthritic Diseases. By Dr. A. H. Smith, of New York.

In Malarial Diseases. By Dr. J. C. Van Bibber, of Baltimore.

Report on Mineral Springs. By Dr. C. C. Rice, Chairman, of New York.

Interpleural Pathological Products; their Cause, Significance, and Special Relationship to Pulmonary Phthisis. By Dr. J. R. Leaming, of New York.

Conditions which Tend to Render the Atmosphere of a Locality Aseptic. By Dr. J. T. Whittaker, of Cincinnati.

Discussion: Influence of Altitude on Cardiac and Pulmonary Diseases. *Referee*, Dr. F. Donaldson, Sr., of Baltimore; *Co-Referee*, Dr. J. J. Levick, of Philadelphia.

Climatic Characteristics of Texas. By Dr. Morse K. Taylor, U. S. A., of San Antonio.

Therapeutic Differences of Mountain and Sea Air. By Dr. W. H. Geddings, of Aiken.

Indications and Contra-indications for Altitude in Treatment of Phthisis. By Dr. F. I. Knight, of Boston.

Discussion of the Nasal and Neurotic Factors in Etiology of Asthma. *Referee*, Dr. F. H. Bosworth, of New York; *Co-Referee*, Dr. E. L. Shurly, of Detroit.

Therapy of Climate. By Dr. I. H. Platt, of Lakewood.

Therapy of Ocean Climate. By Dr. A. L. Gihon, U. S. N.

Climatic Characteristics of Roan Mountain, Eastern Tennessee. By C. J. Kenworthy, of Florida.

Notes of Summer in Switzerland. By Dr. D. B. St. John Roosa, of New York.

An Epidemic of Cerebro-Spinal Meningitis in Central New York. By Dr. W. T. Ford, of Utica.

Further Contributions to the Study of Consumption among the Indian. By Dr. W. Matthews, U. S. A.

The American Society of Microscopists will hold its next meeting at Columbus, Ohio, August 14, 1888.

The British Medical Association.—The fifty-sixth annual meeting of this Association will be held this year at Glasgow, on August 7th and three following days. The President-elect is Professor W. T. Gairdner, M.D., LL.D. The Address in Medicine will be delivered by Dr. Clifford Allbutt, of Leeds: the Address in Surgery by Sir G. H. B. Macleod, M.D.; and the Address in Physiology by Dr. J. G. M'Kendrick. A special address on "Recent Investigations in Surgery" will be given by Dr. W. Macewen.

Professsr Virchow.—The Emperor of Germany has conferred upon Professor Virchow the honor of the Red Eagle of the second class.

Medicine and Politics in Alsace.—By a decree of the Governor of the Department, the Société de Médicine de Strasburg has been dissolved; in other words, the authorization which is required by law for all meetings of more than twenty persons has been withdrawn. No reasons are given for this rigorous decision, and the disappearance of this venerable society has given rise to general expressions of regret.—*British Medical Journal*, May 26, 1888.

Fire in a Chemical Laboratory.—Fire in the laboratory of Dr. A. R. Leeds, of the Stevens Institute, Hoboken, N. J., recently caused damage to the extent of $5000.

An Anthropometric Laboratory.—Mr. Francis Galton has described his ideal of an anthropometric laboratory as a place where a person may have any of his various faculties measured, and where duplicaties of his measurements may be preserved as private documents. Besides the ordinary simpler apparatus, such an institution should contain instruments for psycho-physical research, for determining the efficiency of each of the various senses and certain mental constants. Instruction might be afforded to those who wish to make measurements at home, together with information about instruments and the registration of results. A library would contain works relating to the respective influences of heredity and nurture. It might also fulfil a welcome purpose as a receptacle for biographies and family records.—*Popular Science Monthly.*

Water Pollution a Thing of the Past.—The *Sanitary News* hopefully believes that with the cremation of garbage and precipitation of sewage, accomplished facts, water pollution will be a thing of the past.

Pharmaceutical Reform in Germany.—Revelations in a criminal trial at Strasburg last week disclose the prevalence of great abuses in the dispensing of drugs in at least one part of the Teutonic empire. In the late autumn of last year Dr. Flocken, a general practitioner, was in attendance on two patients suffering from rheumatoid arthritis, and in both cases, by some inexplicable mistake, he prescribed the extract instead of the tincture of colchicum. The unfortunate sufferers were thus made to take in each dose of this powerful depressant about ten times the maximum allowance, and they soon died of colchicum-poisoning. In both cases the prescription, in the absence of the apothecary, Greiner, was made up by his assistant, Wolf, and, without apparent misgiving, delivered to the messenger. Worse, however, is yet to follow. Dr. Flocken, on learning the fatal consequences of his ignorance or negligence, contrived to get back the prescriptions, destroyed them and the remainder of the medicines, of which he also got possession, removed the labels from the bottles, and in concert with Greiner, suppressed the prescription-book. For this a new book was substituted, and in it were entered the old prescriptions, all rewritten, including the two which prescribed the extract instead of the tincture of colchicum. After a two days' trial, Dr. Flocken, Greiner, and his assistant, Wolf, were all found guilty; the second assistant, Anders, being acquitted. Dr. Flocken was sentenced to six months' imprisonment, in which the month he had spent in prison before his trial was counted; Wolf, as the dispenser of the two fatal draughts, to three months; and Greiner, the master apothecary, who aided and abetted the falsifying of the prescription-book, to two weeks. Considering the gravity of the case, the sentences of the three are by no means too exemplary.—*Lancet*, May 26, 1888.

The "Moxie" Nerve Food.—The *American Analyst* for May 15, 1888, states that it has caused this preparation to be analyzed, finding it wholly inert. Publication of this fact resulted in a suit for damages by the proprietor of "Moxie," which was decided for the defendant, the plaintiff paying all costs.

Antiseptic Ammunition.—A useful suggestion is being carried out by the Netherland Government, by which provision will be made for supplying each soldier, during the time of war, with a cartridge containing some antiseptic dressings. Each cartridge will be made of convenient size, namely, about three inches in length, by two in width, and will be secured at one end with a safety pin. The dressing contained in each will consist of a bandage, about three yards long, and two pieces of gauze, all of which have been rendered antiseptic by a sublimate solution. Hence, in the event of wounds being received a ready means would be at hand for the immediate application of antiseptic dressings. Soldiers, in the case of slight injuries, would probably at once avail themselves of the dressings, and the latter could not fail to be of much use to the surgeons. The idea is well worthy of the attention of the military authorities in this country, and might even with advantage be adopted, as it has been for years past in the German army. In the wars in which, during the past few years, we have been engaged in tropical climates, the early application of antiseptics to the wounds received by the men was admitted to be a matter of the utmost importance by the

army medical officers attached to the forces.—*Medical Press*, May 9, 1888.

Adulteration of Cod-liver Oil.—Professor Peel, of St. Petersburg, reports an adulteration of cod-liver oil with fifty per cent. of mineral oil, and although it contained this large amount of mineral oil suspicion was not aroused by the appearance or taste. The stools of patients had the odor of petroleum, and this led to the discovery.—*American Journal of Pharmacy*, May, 1888.

Antidotes for Poisons.—The *American Journal of Pharmacy* for May, 1888, writes that a general antidote for poisons is a mixture composed of equal parts of calcined magnesia, wood charcoal, and hydrated oxide of iron, with a sufficient quantity of water. It is, as a harmless and simple remedy, applicable in such cases when the nature of the poison is unknown.

As an antidote for iodoform, BEHRING recommends a twenty per cent. solution of bicarbonate of sodium.

Imagination in Men and Women.—An interesting experiment was made by Dr. Durand, in reference to the relative power of imagination in the two sexes. He gave to one hundred of his hospital patients a dose of sweetened water, and shortly afterward entered the room, apparently greatly agitated, saying he had by mistake administered a powerful emetic. In a few minutes four-fifths of the subjects were affected by the supposed emetic, and were mainly men, while every one of those not affected were women.—*The Popular Science Monthly*, June, 1888.

Season and Disease.—While it appears from the records of English health officers that some diseases have special seasons in which they are most likely to prevail, it is not shown that occasional variations in temperature have much influence in the matter. Scarlet fever is at its minimum from January to May, and at its maximum in October and November. Diphtheria is more evenly distributed through the year, and is most dangerous a little later than scarlet fever. Measles and whooping-cough seem to be somewhat aggravated by cold weather, but are most fatal in May and June. Hot weather is adverse to smallpox, and favorable to disorders of the bowels, particularly in children.—*The Popular Science Monthly*, June, 1888.

Medical Education in England.—A committee of the English Medical Council has been appointed to consider the best means of increasing the practical element in medical education. Although the strictly scientific parts of medicine are taught as they never have been taught before, it is conceded that there has been a falling off in the practical part, and that the new graduate, although more learned in minute anatomy, chemistry, and physiology than his predecessors, is less apt at recognizing and treating common diseases.—*The Popular Science Monthly*, June, 1888.

Chocolate Chewing Gum and Paraffine.—Two confectioners in Glasgow have been fined £3 each, under the Adulteration of Foods Act, for selling a sweetmeat called chocolate chewing gum, and containing 42 per cent. of paraffine wax. It was stated for the respondents that the confection was manufactured in Lincoln, and that it was bought by children for the purpose of chewing and then making crackers. Dr. Russell stated that the paraffine wax was insoluble in any of the fluids, and indigestible, and might so irritate the stomach as to cause convulsions in children of tender years. The sheriff said the article had a misleading name, and as children might purchase it for eating, the trade must be put down.—*British Medical Journal*, April 21, 1888.

An Explanation.—Messrs. Wm. R. Warner & Co., request us to state that they have no connection with the firm of H. H. Warner & Co., of Rochester, who make "Safe Remedies" and other patent medicines.

NOTES AND QUERIES.

THE MODIFIED LITHOTOMY STAFF.

To the Editor of THE MEDICAL NEWS,

SIR: Referring to the communication of Nathan R. Smith, M.D., of Baltimore Md., May 7, 1888, in your issue of the 12th inst., I desire to state that in 1877 I assisted at an operation for lithotomy successfully performed by Professor Alan P. Smith (son of the late Professor Nathan R. Smith) upon a Justice of the United States Supreme Court, the grooved lithotomy staff, devised by Professor Nathan R. Smith, being used.

Professor Smith's lithotomy staff is the instrument *par excellence* —the operator having entered the point of his knife in the groove of the staff may proceed with mathematical certainty to the bladder. The staff was first used many years ago by Professor Nathan R. Smith. Yours, respectfully,

SOLON B. STONE,
A. A. Surgeon U. S. Army.

POST HOSPITAL, FORT MISSOULA, M. T.,
May 28, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING JUNE 2, 1888.

CRAIG, F. C., *Passed Assistant Surgeon.*—Detached from Naval Hospital at Norfolk, and ordered to the Naval Hospital at New York

WENTWORTH, A. R., *Assistant Surgeon.*—Detached from U. S. S. "Galena," and ordered to the Naval Hospital at Norfolk.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING JUNE 2, 1888.

DEVAN, S. C., *Passed Assistant Surgeon.*—Granted leave of absence for ten days, May 29, 1888.

CARRINGTON, P. M., *Passed Assistant Surgeon.*—Granted leave of absence for five days, May 29, 1888.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LII. SATURDAY, JUNE 16, 1888. NO. 24.

ORIGINAL LECTURES.

THE ADDRESS IN OBSTETRICS.

Delivered before the Pennsylvania State Medical Society, June 6, 1888.

BY THEOPHILUS PARVIN, M.D.,

PROFESSOR OF OBSTETRICS AND THE DISEASES OF WOMEN IN THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

ADDRESSING myself directly to the present study I propose, not a catalogue of the chief, still less of the numerous articles pertaining to obstetrics and diseases of women published within the year, but a brief presentation of a few of the more important subjects relating to these departments, considered within that time.

ELECTRICITY IN OBSTETRICS AND IN DISEASES OF WOMEN.

The induction of premature labor[1] by the constant current has been tried in seven cases by Brühl, and the results show that this means has a very limited application. It may entirely fail in exciting uterine activity, and even where this effect is produced it must usually be supplemented by other means to cause complete dilatation of the os uteri; moreover, the effect is only secured by several applications.

A very distinguished authority in therapeutics[2] has recently suggested that post-partum hemorrhage should be treated by the faradic current instead of by ergot, friction of the abdominal walls, and other reflex stimuli intended to secure uterine contraction. The suggestion is a valuable one, and yet few obstetricians have the necessary apparatus at hand; and even if they had, probably most cases of post-partum hemorrhage would be arrested by compression of the uterus, and by evoking its contracture by means of the hand and by hot water injections, before an application of faradism could be made.

Electricity for the destruction of the life of the fœtus in ectopic gestation was first tried by Bachetti, in 1857, and the experiment was successful. The operator employed two needles, penetrating the cyst, and connected with an electro-magnetic apparatus; it may be questioned whether the double puncture of the gestation cyst was not the efficient agent. To Dr. J. G. Allen, of Philadelphia, is due the credit of having first successfully used the faradic current for this purpose—this was in 1869—and he thus originated what may be justly termed the American method of treating this grave condition. Several successful cases have since been reported, some of them in the practice of very eminent American obstetricians, such as Thomas, Reeve, and Garrigues, in which Dr. Allen's method was employed. The most recent of these cases was reported by Dr. Van de Warker at the last meeting of the American Gynecological Society. So far, I believe, no fatal result to the mother has occurred when the interrupted current was used. Such fortunate exemption has not always followed the employment of the constant current. Dr. Janvrin, in 1866, reported a case of death, and last year a like result occurred in the practice of Dr. Percy Boulton.[1] The patient of the latter was supposed to be about eight weeks pregnant, three needles were passed into the tumor, and their ends, projecting from the vulva, were connected with the positive electrode of a thirty-cell battery, and a flat sponge connected with the negative pole was put upon the thigh, being moved about from place to place during the six minutes the current was applied. The woman died twenty days after. It is somewhat remarkable that the electrolytic treatment of extrauterine pregnancy is attributed by the author to American physicians; and he states that in a future case he would prefer applying the faradic current, a conclusion he might have reached without his sad experience with electrolysis, had he read the usual practice successfully pursued in this country.

But surely the day is coming, if not already here, when an extrauterine pregnancy, as soon as recognized, will be treated by abdominal section. The brilliant results which Mr. Tait has had in operating immediately after rupture of the gestation cyst in such cases, has opened the way for this important advance. In this city there have been within a year at least two successful operations, one by Dr. Joseph Price, and the other by Dr. Charles B. Penrose, made early in extrauterine gestation and prior to the rupture of the cyst.

Apostoli[2] has recently reported a case of hydrosalpingitis successfully treated by the galvanic current. Two applications were made at an interval of thirteen days, the strength of the current at the first being one hundred and at the second one hundred and forty milliampères; the current was continued for five minutes at each sitting, a steel capillary trocar the size of a needle of Pravaz's syringe was thrust the distance of one centimetre into the most prominent part of the swelling in the vagina, and connected with the negative pole, while the positive pole was connected with his well-known application to the abdominal wall. Apostoli claims that galvanopuncture is a valuable means, accomplishing a double object in such cases: 1. It aborts a phlegmasia in the beginning and arrests an inflammatory process; 2, it permits ready evacuation of a fluid in consequence of the separation of the resulting slough, provided this cyst is united to the vaginal cul-de-sac.

But it must be obvious that such method of evacuating a pelvic serous collection, no matter whether tubal, or in the connective tissues, or peritoneal, has nothing to com-

mend it over the aspiration advised by Hardon in the early stage of inflammation of the connective tissue, or the incision and drainage employed by Laroyenne and Blanc.[1] Some of the cases reported by Blanc in his interesting monograph were believed by him to be hydrosalpinx. Let me turn aside for one minute to refer to Dr. Hardon's method of treating so-called pelvic cellulitis. In such inflammation he states that the first stage, that of serous infiltration, lasts usually not more than forty-eight hours, and believing that the inflammation may be aborted by removing this serum, he introduces an aspirator needle into the inflamed tissue, and withdraws all the fluid he can, when a puncture is made at another point and suction employed, and thus the process repeated at other parts of the tumor. He asserts that by this practice the pain is relieved, the fever ceases, and rapid convalescence follows. Certainly the results he has had speak strongly in favor of his method.

Returning from this digression, in the electrical department of the diseases of women in the Jefferson Medical College Hospital,[2] some very satisfactory results have been had from the use of the interrupted, and of the constant current. Thus, one patient suffering with cervical stenosis and anteflexion, and very painful menstruation, was cured by faradism; previously dilatation, while the patient was anæsthetized, was twice resorted to, once by myself, with only temporary benefit. Within the last five months cases of retroflexion, subinvolution, and old inflammatory deposits in the connective tissue adjacent to the uterus have been treated by the constant current, all of them being relieved, and some of them permanently cured; the strength of the current employed in these cases was ten to twenty-one milliampères, and it was continued for ten minutes, the application was made once in three or four days.

But probably the most important contributions to the use of electricity in diseases of women are those relating to the treatment of uterine fibroids by the methods advised by Apostoli. Foremost among these contributions must be placed Apostoli's, presented at the last meeting of the British Medical Association, and published in the *British Medical Journal* of October 1, 1887. In that paper the distinguished author states that from July, 1882, to July, 1887, he has had under his care 273 patients with fibromata or hypertrophy of the uterus in some manifest degree, and upon these he has used 4246 applications of the continuous current of electricity. In 95 per cent. of the cases in which his advice was fully acted upon, permanent benefit resulted. Keith, Sir Spencer Wells, and Playfair have visited Apostoli at Paris, and after carefully studying his method and its results, have become convinced of its value. Surely their course is to be commended rather than that of a London surgeon who condemns without personal investigation, and declares that he has never tried the Apostoli method, and being a surgeon, does not intend to, thinking it may be more properly left to the obstetric physician. Mr. Keith,[3] writing in December, 1887, states "that hysterectomy is an operation that has done more harm than good, and its mortality is out of all proportion to the benefits received by the few." He further states, "I have never been in favor of hysterectomy, simply because its death-rate is so high, and because it is performed for the removal of a tumor that rarely kills. So strongly do I now feel upon the subject that I would consider myself guilty of a criminal act were I to advise any patient to run the risk of her life—and such a risk—before having given a fair trial to this treatment"—that is, the electrical—"even were I sure that the mortality would not be greater than that which hysterectomy has given me in my private cases—under 4 per cent." At the time this was written he and his son had, within five months, applied electricity "in strong, accurately measured doses" in 100 cases chiefly of fibroid tumors, the number of applications being more than 1200; the results were very encouraging. More recently Skene Keith[1] has reported 7 cases of uterine fibroids thus treated.

Steavenson, though less enthusiastic than Apostoli, or even than Keith, uses the following language:[2] "I do not think that the electrolytic treatment will supplant the necessity for abdominal section or removal of the uterine appendages in such cases as those in which these operations would be appropriate, but I do think that in the use of electricity we have a means of treating fibroid tumors which is superior to any we have formerly employed, short of their entire removal. I have treated a large number of cases, and in nearly all the symptoms have been removed, in many the tumors have decreased in size, and in some the decrease has been considerable." Dr. A. Victoria Scott[3] states, as the result of her experience, that the symptoms of pain and hemorrhage cease, that the general health is improved, and that in all cases treated for a period of two months or longer, there has been a sensible diminution in the size of the tumors. Dr. Franklin H. Martin, in a paper presented at the last International Congress, claimed that the Apostoli treatment is free from danger, is painless, stops hemorrhages, diminishes the tumors, and alleviates neuralgic pains. Villa, on the other hand, gives[4] scant commendation to the method; among other things adverse to the electrotherapic treatment, stating that many of the patients thus treated for a long time by different physicians, among these Dr. Apostoli, have claimed the radical operation. It might be added, Apostoli frankly says that seven patients of his did leave him to have hysterectomy done, and that they are all dead.

I think, in considering the various testimonies that have been given upon the subject, we may safely adopt the words of Aveling,[5] always temperate, and usually wise in his utterances: "If electricity relieves pain, hemorrhage, and bulk of tumor, the three urgent symptoms for which hysterectomy is performed, and the patient is thus symptomatically cured, is it not worth trying?"

PUERPERAL ECLAMPSIA.

Puerperal eclampsia has occupied no inconsiderable space in the periodical professional literature of the past year, but probably no very important contributions have been made to the etiology or to the therapeutics of the

[1] Atlanta Medical and Surgical Journal. De l'Inflammation Peri-uterine Chronique, Paris, 1887.

[2] This department is conducted by Drs. Davis and Scholl, to the latter of whom I am indebted for the above statements.

disease. In regard to the former, the theory so ingeniously and ably urged by Dr. King, has not been generally accepted. According to this theory, "disturbances in the renal circulation are produced chiefly by pressure of the gravid uterus upon the abdominal aorta or its branches, or upon the vena cava or its branches, or upon both or all of them, in consequence of the child and womb not maintaining during pregnancy their normal lateral obliquity above the pelvic brim." The theory fails to explain the occurrence of eclampsia early in pregnancy, and the increased liability from great distention of the uterus, as in plural pregnancy. Moreover, if descent of the fœtal head into the pelvic cavity in the latter weeks of pregnancy, which is the rule in primigravidæ, causes the interference with the circulation referred to, the disease ought to be much more frequent. A Dublin obstetrician, some fifty years ago, stated that there was little danger of eclampsia if the fœtal head did not present. Since cephalic presentations vastly predominate over all others, the importance of this observation is quite plain.

While in the great majority of cases of eclampsia albuminuria is present and has preceded the attack, there still remain a large number in which there is no renal disorder, and these are properly termed reflex, the primary source of irritation being in most instances uterine, though in some it may be vesical; for example, the bladder being distended with urine; such source of convulsions was long ago pointed out by La Motte and by Portal.

A very interesting fact is stated by Herman[1] as to the difference between the albumin escaping in the urine in eclampsia, and in Bright's disease; in the former it is mainly paraglobulin, and in the latter serum-albumin.

So far as therapeutic means are concerned, in addition to those with which the profession is so generally familiar, such as bleeding, chloroform, chloral, and morphia, abroad many practitioners have successfully employed pilocarpine, and in this country veratrum viride was strongly advocated both at the International Medical Congress, and at the American Gynecological Society. In referring to the value of the latter remedy, as claimed by American practitioners, a writer in a British medical journal[2] rather ungraciously remarks: "To prevent disappointment, however, it is right to say that American women appear to respond to drug treatment more readily and certainly than English women."

Some cases of eclampsia treated by inhalation of oxygen have been reported last year, but the results do not seem to establish for this remedy an important position.

THE TREATMENT OF PLACENTA PRÆVIA.

The treatment of placenta prævia is still a subject of no little discussion, obstetricians not having yet adopted by common consent one method as the best, probably because there is no such single way to be followed to the exclusion of every other. Dr. Barnes, very justly as I think, condemns some of the methods employed as disregarding the life of the fœtus. The craniotomists as opposed to the Cæsareans, occasionally refer to the sentimentalism of the latter, when they urge their favorite operation on the ground of saving the life of the child, even though the mother should run a greater risk than if it were sacrificed. But a similar manifestation of feeling seems to be forgotten by some in their mode of treating cases when the placenta is prævia. Le Page, for example, says:[1] "The chances for the child's life, I therefore contend, should not be a factor in the treatment." The same opinion has been avowed in more than one of our American medical societies.

In what has been termed the recent method of treating placenta prævia, that is by bimanual podalic version, as advocated especially by Lomer, Hofmeier, and Behm, the fœtal mortality has been very great, that of the last reaching 83.4 per cent. Of course, the mortality is still greater, if we adopt the rule laid down by Le Page: "At whatever period of utero-gestation after mid-term we become aware of the existence of placenta prævia, we shall serve the best interest of our patient if we at once bring to a conclusion a condition of things fraught with the utmost danger." Yet in the same paper the author states: "Hemorrhage during parturition is not inevitable, nor does loss of blood invariably take place during gestation." The last statement evidently condemns the one immediately preceding, as an invariable rule of practice. I do not believe the majority of obstetric authorities claim that in all cases of placenta prævia the pregnancy must be at once ended; certainly Churchill, Depaul, and Spiegelberg did not so teach. Following such teaching, and that of others equally famous, as well as the light of experience and sound reason, as I believe, I said in my work upon obstetrics, referring to the management of cases of placenta prævia in pregnancy: "If loss of blood be slight, and especially if the fœtus be not yet viable, the expectant plan is indicated." One gentleman, for whose obstetric knowledge and ability I have the highest respect, exclaims: There is no expectant treatment of placenta prævia. And another gentleman, discussing the question in a medical society, and doubtless never having read what I did say, charges me with absolute advocacy of expectant treatment, not specifying the conditions in which it was advised, and graciously attributes such recommendation to my ignorance. By those words as first uttered I still stand, insisting that we have no right to sacrifice the life of the child when the mother's is not in jeopardy. But should the hemorrhage be serious, let the pregnancy be ended, whether the child is viable or not. Further, after that viability has been reached, if the placenta be deeply situated, whether the implantation be central or only lateral, the induction of premature labor is indicated, furnishing not only the best security for the mother's, but also the best chance for the child's life, My advocacy of this practice dates many years back. Thanks to the couveuse and gavage, the time when the fœtus becomes viable may now be placed in the seventh month, and not at its end, as has hitherto been done. Now in the great majority of cases of placenta prævia hemorrhage does not occur prior to this time; and, hence, there is in most cases a protection of the child's life until it is capable of continuing after delivery, should it escape the perils of birth. The question therefore is, How can delivery be effected so that there is a fair chance for the child's life without imperilling that of the mother? Zweifel,

recognizing the deplorable mortality, in regard of the fœtus, attending podalic version as usually done, suggests that the obstetrician, instead of introducing his finger or two fingers on one side of the os, for the purpose of making version, should pass them anteriorly, for there they can enter the uterus further, and with less violence to the placental attachment, and thus a conservative influence be secured in reference to the child: this suggestion may be of value.

All of the three chief methods when labor is complicated by hemorrhage in placenta prævia, are essentially only different ways of applying a tampon; the bleeding is arrested by pressure from the vagina when the classic tampon is used; from the cervico-uterine canal either in case of the hydrostatic dilator, or in that of the drawn-down limb of the child; it is evident, from statistics, that the last method of tamponing is not the best for the life of the child. If we conjoin with the pressure from the hydrostatic dilators of Barnes, his method of partial detachment of the placenta—the physiological reasons for this have been so well presented by him that it is unnecessary, even if there were time, to call attention to them now—we probably have attained the best method of treating placenta prævia after labor has begun, and the vaginal portion disappeared, so far as the interests of both mother and child are concerned; the child's life is less imperilled, in part because prompter delivery can thus be effected. In some cases, probably the method of Dr. Davis, with which the members of the Society are familiar, and which has furnished such good results in his hands, could be well employed.

ANTISEPTICS IN OBSTETRIC PRACTICE.

The prophylactic employment of antiseptics in obstetric practice has justly occupied considerable attention during the past year. After this subject has been so much discussed, and its importance so strongly urged, and the value of these agents in lessening not only childbed mortality, but also childbed morbidity, especially in hospital practice and after instrumental deliveries, has been so conclusively demonstrated, the following statement,[1] made in one of our medical societies about a year ago, reads like an anachronism: "I have not taken pains to disinfect instruments to be used in obstetric practice, and have not had many cases of puerperal metritis."

Kascharoff[2] has devised a bath-tub, in which warm, sterilized water is placed, and the woman's hips and genitals are placed so that they are completely covered by the water during the performance of obstetric operations, and thus infection prevented. He recalls the fact that Aitken, an English obstetrician, in 1784, advised that the Cæsarean operation should be performed under water, believing that then it could be done with less risk than in contact with the air. Such an apparatus as Kascharoff's might possibly be used in hospitals, but could not be employed by the obstetrician in general practice; besides, there are more convenient ways of rendering obstetric operations aseptic.

In considering the prophylaxis of puerperal septicæmia at the last meeting of the British Medical Association, Playfair presented a series of rules for monthly nurses, one of them being that the vagina of the puerpera should be syringed out twice a day with an antiseptic solution. Few obstetricians, no matter how firm believers in antiseptics, will accept this rule of practice; such injections, in case the condition of the woman is normal, are meddling, and may be mischievous.

The dangers from intrauterine injections in obstetric and in gynecological practice, have been the subject of recent study by Maginn.[1] So far as such dangers occur in the puerperal state, they may be guarded against by proper precautions. In the first place, obstetricians have used unnecessarily strong solutions of corrosive sublimate; probably a solution of 1 part of the salt to 5000 of water will meet the requirements of almost every case in which such injections are needed. Next, the solution should never be used cold, but either warm or hot. The injection must be made gently, and free exit of the fluid from the uterus secured. After the corrosive sublimate solution has been used, the uterus is to be washed out by water sterilized by boiling. Nevertheless, if there is a peculiar susceptibility to mercurial action, or in case of renal disease, the ordinary injection should be replaced by a solution of carbolic acid.

CÆSAREAN SECTION.

Probably no more important advance in obstetrics has been made within the last few years than in the method of performing the Cæsarean operation; what is now known as the improved operation has given results in Germany so satisfactory that possibly the day is at hand when craniotomy upon the living fœtus will be very rarely performed, if done at all. If the promise of the hour is fulfilled, the operation will soon count as large a percentage of cures in this country as it has recently in Germany. In New York there have been four successful operations, all within a year, I believe, three of these done by Lusk, and one by Garrigues; in Philadelphia, Dr. Howard Kelly has recently had two successful cases; in Chicago one by Dr. Jaggard, in Toledo one, and in Baltimore one, have been successful.

I am indebted to Dr. Harris for the following table of all the Cæsarean operations done in the United States up to the present month:

Cæsarean operations in the United States			169
Old style			150
Sänger method			19
Women saved under old operation			56
" " " Sänger method			9

GENERAL ADVANCES.

Did time permit, I would like to refer to some most important papers upon extra-uterine pregnancy, such as those of Breisky,[1] Werth,[2] Hart and Carter,[3] and others; to the subject of puerperal septicæmia as considered by Barnes,[4] Byers, Madden, and others, Runge,[5] Leopold,[6] and Galabin,[7] and others; to the operative treatment of puerperal purulent collections in the abdomen, as presented by Besnier[7] and Baldy;[8] to the complications of pregnancy by typhoid fever, to the use of ergot during or after labor, to the valuable lectures by Dr Priestley on the "Pathology of Intra-uterine Death;" to the present status of Alexander's operation, an operation that receives little countenance even in England, and still less in Germany; to the cure of retroflexion of the uterus by substituting another malposition—that is, making it immobile by attachment to the abdominal wall—an operation suggested by Sims[9] twenty years ago, and first performed by Koeberlé, in 1877, and an operation which, though now advocated by some brilliant surgeons, will probably not survive a score of years, but be consigned to "innocuous desuetude;" to the subject of hysterectomy for malignant disease, and various other topics.

A recent paper upon exploratory laparotomy by Dr. Baldy furnishes both instruction and warning. Dr. W. S. Stewart has devised an obstetric forceps with parallel branches; time only will test its value. Nevertheless such an instrument presents some advantages over the ordinary one with crossed branches, advantages which the Lyons school of obstetricians have especially urged, but which have not been generally recognized.

OVARIOTOMY AND SALPINGOTOMY.

Abdominal sections to remove the ovaries, or the tubes, or both, have been attended by so slight mortality in the hands of Battey, of that great master in abdominal surgery, Lawson Tait, not to mention other famous names at home or abroad, and in the practice of what I may call the Philadelphia Dispensary School of Surgeons, and the results of the operations have been in many cases so satisfactory, is there not great danger of such operations being too frequently performed, and are the specimens removed carefully examined by competent pathologists, who conclude that structural changes justify their removal? Nay, is there not danger that men without experience, without previous apprenticeship to a competent master, deceived by the glamour of brilliant statistics, and ambitious of fame as operators, will decide upon and perform these operations when there is no necessity for them, and no benefit follows them, or they are fatal? Sad stories of such events are occasionally whispered, and their warning against rash operations should be heeded. Reverdin[10] has recently stated that castration for nervous diseases ought never to be done unless the patient is examined while anæsthetized, and the ovaries are found to have undergone structural change; it is added that among all the cases of castration of women for nervous diseases, very many have not resulted favorably. If this last statement be true in Paris, is it not probable it is also true in this country?

It cannot be denied that there is a growing belief in the professional mind that these operations are too frequently resorted to; and, therefore, their indications ought to be clearly established, and the presence of the latter conclusively demonstrated, before a woman is subjected to what otherwise is an odious mutilation which may have very injurious consequences, even if her life is not sacrificed in the operation. The dentist may pull a wrong tooth, but an artificial one can make good the loss; the surgeon may needlessly sacrifice a limb, but the mistake is not irreparable, for an artificial one may take its place. But there is no such substitution possible for ovaries unnecessarily removed—the loss is remediless—and, therefore, the greater heed necessary to prevent so grave, if not criminal, an error. Possibly there is a tendency on the part of some to underestimate the value of these organs, and bringing to their charge various pains and aches, either in them or elsewhere in the corporeal domain, in head or in toe, and functional misbehavior or mental disorder, or convulsive disease, try, convict, declare worthy of death, and execute with the rapidity characteristic of a court martial in war times. But is it a slight matter to deprive a woman of organs upon which her sex depends? I recall the words of the most brilliant of American obstetric teachers, the late Dr. Charles D. Meigs,[1] who in referring to woman, said: "Her ovary is her sex, and she is peculiar because of it, and in order that she might have this great, this dominant organ planted within the recesses of her body." I read in Maudsley,[2] when he speaks of the influence of the sexual organs in the development of the boy: "These evolutional effects, that of the functional development of the reproductive organs upon the mind, do not take place when such development is prevented by their removal before puberty. The minds of eunuchs are mutilated like their bodies; they are said to be cowardly, envious, liars, utterly deceitful, destitute of social and moral feelings; with the deprivation of sexual feeling, they are deprived of all the mental growth and energy which it inspires directly or remotely. How much that is it would be hard to say; but were man deprived of the instinct of propagation, and of all that mentally springs from it, it is probable that most of the poetry, and perhaps all the moral feeling would be cut out of his life."

Now is it probable that a woman can have during the reproductive period of her life, in some instances the operation has been done quite early in that period, her ovaries removed without greater or less changes in her mental and moral condition? What those changes are have not yet been studied, save in a very superficial manner, and our knowledge will probably remain imperfect for many years. Peradventure, some of the pages of this scarcely opened book may be read in hospitals for the insane, in courts of justice, and by coroners' juries over the bodies of suicides.

I have heard an eminent neurologist say that if men's testicles were removed for the same reasons that lead some operators to extirpate women's ovaries, there would be a very large number of eunuchs. Admitting, then, the necessity for these operations thus made common to each sex, there may be compensations. Romeo and Juliet may disappear, but the problem of Malthus can no more vex political economist or philanthropist, and an important step toward the desirable and inevitable completion of human history, according to Schopenhauer, when the will to live, which especially expresses itself in reproduction, ceasing, the human race will pass into a dreamless sleep which knows no waking.

ORIGINAL ARTICLES.

THERAPEUTICS OF DIPHTHERIA.[1]

BY A. JACOBI, M.D.,
CLINICAL PROFESSOR OF DISEASES OF CHILDREN IN THE COLLEGE OF PHYSICIANS AND SURGEONS OF NEW YORK.

DIPHTHERIA is a contagious disease. Severe forms may beget severe or mild forms. Mild cases may beget mild or severe cases. There is probably no spontaneous origin of diphtheria, any more than there is a spontaneous origin of cholera or scarlatina. What has been called follicular amygdalitis (or "tonsillitis") is diphtheria in many, perhaps most, instances. It is seldom dangerous to the patient, because the tonsils have but very little lymph communication with the rest of the body. But the diphtheritic variety of follicular amygdalitis also is contagious. This mild variety is that from which adults are apt to suffer. It made me proclaim the warning that there is as much diphtheria out of doors as there is in doors; as much out of bed as in bed. With this variety the adult is in the street, in business, in the school-room, in the railroad car, in the kitchen and nursery. With this variety, parents while complaining of a slightly sore throat, kiss their children. Wherever it is suspected, it ought to be looked after. Where it is seen, it ought to be isolated and treated, less perhaps for the sake of those who are sick, than of those who are in serious danger of being infected. This is the more necessary, as this form is apt to last long and give rise to repeated attacks. But it is not only the mild variety which is liable to last long. Serious, undoubted cases are also apt to last for weeks, and some of them months. As long as they do persist, they are contagious.

These reminiscences and quotations from former writings must justify the preëminent place I claim for preventive treatment.

Those sick with diphtheria, severe or mild, must be isolated. If barely possible, the other children ought to be removed from the house. This can but rarely be done in the homes of the poor, in the densely populated districts. A great charity is still waiting for its consummation, viz., that of erecting buildings, dormitories and playrooms for those who ought to be temporarily exiled from their infected homes. A suggestion of mine, before the New York State Medical Society, at its meeting of 1882, resulted in the erection of the Willard Parker Hospital of New York, for the benefit of those suffering from scarlatina and diphtheria. The erection of a sufficient number of temporary homes would be a still greater blessing to the poor, and a greater protection to the public at large. If it be impossible to send the well children away, let them remain outside the house, in the air, as long as feasible, and with open bedroom windows during the night, in the most dis-

part of the house; during the winter, on a lower floor. Their throats must be examined every day, and their rectal temperatures taken by the mother, so that the physician may be called on the occurrence of but slight changes. The few minutes spent in this way are amply repaid by the safety they may accomplish. The attendants upon cases of diphtheria must have no intercourse with the well children; though a brief visit of the physician may not render him sick, or dangerous to others, a long exposure affects him or a nurse, to a greater or less degree.

The well children of a family in which there is diphtheria, must not go to school or church. Schools must be closed when a number of pupils have been attacked; or, better still, when there is an epidemic, though it may not yet have affected the school children to a great extent, the teachers ought to be taught how to examine throats, and directed to do so every morning, and send home those children who are suspected.

When an attack of diphtheria has made its appearance, it is well enough to examine the hygienic condition of the house, with its deteriorating influences on the general health of the inmates, and to look after the source of the case in the persons of friends, attendants and help. A family with children ought to insist upon the occasional inspection of the throats of their servants; those with chronic pharyngeal catarrh must not be hired. A seamstress or laundress, coming for an occasional day's work, sick nurses, children's nurses and cooks, ought to be examined from time to time, the more so, the more such people are, for obvious reasons, inclined to conceal slight troubles. The opportunities for infection are so numerous that it is impossible to sail absolutely free from it. It is easy to imagine how many cases of diphtheria are liable to be disseminated by teachers, shopkeepers, restaurants, barbers and hairdressers.

In times of an epidemic, every public place, theatre, ball-room, dining-hall and tavern ought to be treated like a hospital. Where there is a large conflux of people, there are certainly many who

[1] Read, by invitation, before the Philadelphia County Medical Society, May 23, 1888.

carry the disease. Disinfection ought to be enforced at regular intervals. In this respect I can but repeat what I said in my treatise (p. 172) and Pepper's *Cyclopædia* (I. 697). Public vehicles must be treated in the same manner, after a suspicious case has been carried; that it should be so when a case of smallpox has happened to be conveyed in them, appears quite natural. Livery stable keepers, who would be anxious to destroy the germs of smallpox in their coaches, must learn that diphtheria is as dangerous a passenger as variola, and what is correct in the case of a poor hack is more so in that of a railroad car, whether emigrant or Pullman. I have seen many cases coming to and leaving the city in them. They ought to be thoroughly disinfected in times of an epidemic, at regular intervals, for the highroads of travel have always been those of epidemic diseases. Still, can that be accomplished? Will not railroad companies resist a plan of regular disinfections, because of their expensiveness? Will there not be an outcry against this despotic violation of the rights of the citizen, the independence of the money bag? Certainly there will be, exactly as there was when municipal authority commenced to compel parents to keep their children from school when they had contagious diseases in their families, and when smallpox patients were arrested because of their endangering the passengers in a public vehicle, or taken to a fever hospital for the protection of their neighbors. In such cases, it is not society, or the State, that tyrannizes the individual; it is the individual that endangers society.

To what extent the infecting substance may cling to surroundings is best shown by the cases of diphtheria springing up in premises which had not seen diphtheria for a long time, but had not been interfered with; and best, perhaps, by a series of observations of auto-infection. When a diphtheritic case has been in a room for some time, the room, bedding, curtains and carpets are infected. The child is getting better, has a new attack, may again improve, and is again stricken down. Thus I have seen them die; but also improve immediately after being removed from that room or house. If barely possible, a child with diphtheria ought to change its room and bed every few days.

To other rules of protection and disinfection, both private and public, including the prohibition of public funerals, I allude only for the purpose of referring to the admirable rules published by the National Board of Health, in its *Bulletin* No. 10, of September 6, 1879, and copied in my treatise on diphtheria, New York, 1880, and my article on diphtheria, in Pepper's *System of Practical Medicine*, vol. i. p. 698.

Prevention can accomplish a great deal for the individual. Diphtheria will, as a rule, not attack a healthy integument, be this cutis or mucous membrane. The best preventive is, therefore, to keep the mucous membrane in a healthy condition. Catarrh of the mouth, pharynx and nose must be treated in time. Many a chronic nasal catarrh, with big glands round the neck, requires sometimes but two or three regular salt-water injections (1 : 130) into the nose, and gargling if the children be large enough to do so. The addition of one per cent. of alum will often be found useful. This treatment, however, must be continued for many months, and may require years. Still, there is no hardship in it and no excuse for its omission. The nasal spray of a solution of nitrate of silver, 1 : 500 or 1000 will accelerate the cure, and not infrequently has a treatment which was considered obsolete when I was young been of great service to me. It consists in the internal administration of the tincture of pimpinella saxifraga. It is certainly an efficient remedy in subacute and chronic pharyngitis and laryngitis. I generally give it to adults, diluted with equal parts of glycerin and water, a teaspoonful of the mixture every two or three hours, with the proviso that no water must be taken soon after.

Large tonsils must be resected in times when there is no diphtheria. During an epidemic every wound in the mouth is liable to become diphtheritic within a day, and, if feasible, such operations ought to be postponed. The scooping of the tonsils, for whatever cause, I have given up since I became better acquainted with the use, under cocaine, of the galvano-cautery. From one to four applications to each side, or to the post-nasal space, are usually sufficient for every case of enlarged tonsils or lacunar amygdalitis. It is advisable to cauterize but one side at a time, to avoid inconvenience in swallowing afterward, and to burn from the surface inward. Cauterization of the centre of the tonsils may result in swelling, pain and suppuration, unless the cautery is carried entirely to the surface; that means to say the scurf must be on, or extend to, the surface. Another precaution is to apply the burner cold, and heat it *in situ*.

Nasal catarrh and proliferation of the mucous and submucous tissues may require the same treatment, but in my experience the cases which require it are less frequent than those in which the tonsils need correction.

The presence of glandular swellings around the neck must not be tolerated. They and the oral and mucous membranes affect each other mutually. Most of them could be avoided, if every eczema of the head and face, every stomatitis and rhinitis, resulting from uncleanliness, combustion, injury or whatever cause, were relieved at once. A careful supervision of that kind would prevent many a case of diphtheria, glandular suppuration, deformity or phthisis.

For its salutary effect on the mucous membrane

of the mouth, chlorate of potassium or sodium, which is still claimed by some to be a specific, or almost so, is counted by me amongst the preventive remedies. If it be nothing more, it is in a case of diphtheria an adjuvant. It exhibits its best effects in the catarrhal and ulcerous condition of the oral cavity. In diphtheria, it keeps the mucous membrane in a healthy condition, or restores it to health. Thus it prevents the diphtheritic process from spreading.

Diphtheria is seldom observed on healthy, or apparently healthy, tissue. The pseudo-membrane is mostly surrounded by a sore, hyperæmic, œdematous mucous membrane. Indeed, this hyperæmia precedes the appearance of the diphtheritic exudation in almost every case. The exceptions to this rule consist of those cases in which the virus may take root in the interstices between the normal tonsillar epithelia, pointed out by Stoehr but a few years ago. Indeed, many cases of throat disease occurring during the prevalence of an epidemic of diphtheria are but those of pharyngitis, which, under favorable circumstances, may develop into diphtheria. These throat diseases are so very frequent during the reign of an epidemic, that in my first paper on diphtheria (*Amer. Med. Times*, August 11 and 18, 1860) I based my reasoning on 200 cases of genuine diphtheria and 185 of pharyngitis, without a visible membrane.

These cases of pharyngitis, and such of stomatitis and pharyngitis accompanying the presence of membranes, are benefited by the local and general effect of chlorate of potassium. The surrounding parts being healthy or returning to health, the membrane remains circumscribed. The generally benign character of purely tonsillar diphtheria, which is apt to run its full course in from four to six days, has in this manner contributed to secure to chlorate of potassium the reputation of being a ready, *the*, remedy in diphtheria. The dose of the salt must not be larger than fifteen grains for an infant a year old, not over twenty or thirty for a child from three to five years, in the twenty-four hours. An adult should not take more than one and a half drachms daily. These amounts must not be given in a few large doses, but in repeated doses and at short intervals. A solution of one part in sixty will allow a teaspoonful every hour, or half a teaspoonful every half hour, in the case of a baby one or two years old.

It is not too late yet to raise a warning voice against the use of larger doses. Simple truths in practical medicine do more than simply bear repetition; they require it. For though the cases of actual chlorate of potassium poisoning are no longer isolated, and ought to be generally known, fatal accidents will still occur even in the practice of physicians. When I experimented on myself, with half ounce doses, thirty years ago, the results were some gastric and intense renal irritation. The same were experienced by Fountain, of Davenport, Iowa, whose death from an ounce of the salt has been impressively described in Alfred Stillé's *Materia Medica*, from which I have quoted it in my treatise on diphtheria. His death from chlorate of potassium induced me as early as 1860 to prohibit large doses. In my contribution to Gerhardt's *Handbuch der Kinderkrankheiten*, vol. ii., 1877, I spoke of a series of cases known to me personally. In a paper read before the Medical Society of the State of New York in 1879 (*Med. Record*, March 15th), I treated of the subject monographically, and alluded to the dangers attending the promiscuous use of the drug, which has descended into the ranks of domestic remedies; and, finally, in my treatise (New York, 1880), I collected all my cases and the few then recorded by others. Since that time, the recorded cases have become quite numerous, and but a few days ago a few new ones were related before the Practitioners' Society of New York. The facts are undoubted, though the explanations may differ. The probability is that death occurs from methæmoglobinuria produced by the presence of the poison in the blood; though Stockvis, of Amsterdam, has tried, by a long series of experiments, to fortify my original assumption that the fatal issue was due to acute nephritis.

The attempts at forming indications for the treatment of patients with diphtheria—I refuse to say treatment *of* diphtheria, based upon the preconceived or acquired idea as to the nature and causes of diphtheria, are all futile. We know that many cases are undoubtedly of local origin; but there are those in which we require no other proof of its original infectious character than the fact that there is a period of incubation. But all that is indifferent, in view of the fact that the cases we are called upon to treat are, as a rule, or have become, both local and constitutional. It is these we have mostly to deal with.

There is no better proof of the non-existence of a specific in diphtheria than the fact that the pharmacopœia has been exhausted to find one, and new remedies, legitimate and illegitimate, are all the time being recommended as panaceas. While there are certain indications resulting from the characteristics common to all, every case must be treated on general principles, which must be applied to the prominent individual features. When there is a high temperature in the beginning, it requires all the tact of a good physician to judge of the advisability of reducing it by antifebriles, such as sponging, warm bathing, cold bathing, antipyrin, antifebrin, or the subcutaneous use of the carbamide of quinia. Convulsions may demand active treatment, such as chloroform inhalations, or chloral hydrate internally or by the rectum. Vomiting or other cerebral symp-

toms may ask for liquids, or smaller or larger doses of opiates. A very quick and feeble pulse may require a few large doses of a heart stimulant, digitalis, strophanthus or sparteine, in the very beginning.

Renal complications are frequent, and occur at an early time. The majority of cases terminate favorably; in some, a large amount of albumin will be eliminated in the course of a few days, and disappear shortly. But whether your individual case will be of that nature, you do not know, and, in time of danger, nothing must be taken for granted. Milk or farinaceous diet, plenty of water or, better, Poland, Bethesda, Seltzer, Apollinaris or Vichy, warm bathing, warm feet, a few good doses of calomel, a number of hourly or two-hourly, small doses of opium (which are better than those of digitalis and nitro-glycerin) will often prove beneficial. If a diffuse nephritis, such as is more frequently met with in scarlatina, be the result, it impairs the prognosis, and requires further treatment, conducted on general principles.

To what extent *local treatment*, if it be possible to employ it, is effective, can best be seen on external diphtheritic surfaces: thus the cutis denuded by vesicatories, the inguinal regions sore with intertrigo, the vagina, circumcision wounds or tracheal incisions. I have tried almost everything which has been recommended for these conditions, but am most pleased with the effect of iodol or iodoform powdered, or one part with eight or ten of vaseline. Powders of subnitrate of bismuth, boric acid or salicylic acid, with fifteen or twenty-five times its quantity of starch, have not given me the same satisfaction.

The treatment of *diphtheritic conjunctivitis* requires also nothing but local treatment. It consists in the application of small ice-bags or iced cloths, which must be changed every few minutes, and the frequent instillation of a saturated solution of boric acid, with or without atropia.

The *local treatment* of pseudo-membranes of the fauces is a subject of great importance. To look upon them as an excretion which needs no interference is incorrect. If it were possible to remove or destroy them, it would be a great comfort; but they can be reached only in certain places, and just in those in which they do the least harm. Pseudo-membranes on the tonsils are the least dangerous, for their lymph communication with the rest of the body is very scanty. Thus, almost all forms of tonsillar diphtheria are amongst the most benign, at least as long as the process does not extend. Most cases of the kind run their mild course in from five to seven days, and it is just these which have given rise to the many proposals of tearing, scratching, cauterizing, swabbing, brushing and burning. They are cases which do not show the harm done. The fact is, that neither the galvano-cautery, nor carbolic acid, nor tannin and glycerin, nor perchloride or subsulphate of iron can be applied with leisure and accuracy to the very membrane alone, except in the cases of very docile and very patient children. In almost every case, the surrounding epithelium is getting scratched off or changed, and thus the diphtheritic deposit will spread. Besides, the membrane of the tonsil is changed surface tissue, as it always is wherever the epithelium is pavement, and not deposited upon the mucous membranes, from which it might be easily detached. Whatever is done must be accomplished without violence of any kind. If nasal injections be found advisable, they can be made to wash the posterior pharynx and the tonsils sufficiently, so as to render the special treatment directed to the throat absolutely useless. Besides, it is easier, and meets with less objection, and gives rise to less exhaustion than the forcible opening of the mouth. This is of very great importance, as I shall show in connection with the local treatment of the nasal cavity. Where it is possible to make the local applications without difficulty, the membrane may be brushed with tincture of iodine several times daily, or a drop of rather concentrated carbolic acid. Of powders, I know only one, the application of which is not contraindicated, viz., calomel. Even this may irritate by its very form. Everything dry irritates and gives rise to cough or discomfort. Whatever has, besides, a bad taste or odor, such as sulphur, iodoform or quinia, must be abhorred.

For the purpose of dissolving membranes, papayotin or papäin has been employed. It is soluble in twenty parts of water, and may be injected, sprayed or brushed on. I have used it in greater concentration, in two or four parts of water and glycerin, in the nose, throat and, through the tracheotomy tube, in the trachea. One of the irrepressible drug manufacturers and advertisers pushes the claims of some modification of the drug which he calls papoid. For the same purpose, trypsin is preferred by others. The mode of its application appears to be the reverse of indifferent. But lately I have seen, in the practice of one of our best-known practitioners, papayotin applied in powder, which resulted in constant irritation of the throat, while the patient otherwise was convalescent. The pharyngeal hyperæmia and slight exudation disappeared when mild alum washes were substituted.

Steam.—Its inhalation is useful in catarrh of the mucous membranes, and in many inflammatory and diphtheritic affections. On mucous membranes, it will increase the secretion and liquefy it, and thus aid in the throwing off of the pseudo-membranes. Its action is the more pronounced the greater the amount of muciparous follicles under or alongside a cylindrical or fimbriated epithelium. Thus it is that tracheo-bronchial diphtheria, so-called fibrinous bronchitis, is greatly benefited by it. Children affected with it I have kept in small bath-rooms for

days, turning on the hot water, and obliging the patient constantly to breathe the hot clouds. Several such cases I have seen recover with that treatment. Atomized *cold* water will never yield the same result. Nor have I seen the patent inhalers do much good.

Still, where the surface epithelium is pavement rather than cylindrical, and but few muciparous follicles are present, and the pseudo-membrane is rather immersed in, and firmly coherent with, the surface —for instance, on the tonsils and the vocal cords, the steam treatment is less appropriate. On the contrary, moist heat is liable in such cases to favor the extension of the process by softening the hitherto healthy mucous membrane. Thus it takes all the tact of the practitioner to select the proper cases for the administration of steam, not to speak of the judgment which is required to determine to what extent the expulsion of air from the steam-moistened room or tent is permissible.

Steam can be properly mixed with medicinal vapors. In the room of the patient, water is kept boiling constantly, over the fireplace, provided the steam is prevented from escaping directly into the chimney, on a stove (the modern self-feeders are insufficient for that purpose and abominations for every reason), over an alcohol lamp, if we cannot do better, not on gas if possible, because of the large amount of oxygen which it consumes. Every hour a tablespoonful of oleum terebinthinæ, and perhaps also a teaspoonful of carbolic acid, is poured on the water and evaporated. The air of the room is filled with steam and vapors, and the contact with the sore surfaces and the respiratory tract is obtained with absolute certainty.

The secretion of the mucous membranes is sometimes quite abundant under the influence of steam, but still, like that of the external integuments, increased by the introduction of water into the circulation. Therefore, drinking of large quantities of water, or water mixed with an alcoholic stimulant, must be encouraged. Over a thoroughly moistened mucous membrane the pseudo-membrane is more easily made to float and macerate.

It was for this purpose that pilocarpine, jaborandi, was highly recommended. Guttmann recommended it as a panacea in all forms of diphtheria. There is no doubt that the secretion of the mucous membrane is vastly increased by its internal application, and by repeated subcutaneous injections of the muriate or nitrate of the alkaloid, but the heart is enfeebled by its use. I have seen but few cases in which I could continue the treatment for a sufficient time. In many, I had to stop it because, after some days of persistent administration, I feared for the safety of the patients. Thus, as early as the meeting of the American Medical Association, at Richmond, eight years ago, I pointed out the exaggerations in the statements of Guttmann. There will be but exceptional cases in which pilocarpine will be tolerated long enough to do good. It is one of the remedies by which we may cure our case and will kill our patient.

Diphtheria of the nose is apt to terminate fatally, unless energetic treatment is commenced at once. This consists in persevering disinfection of the mucous surface. The disinfecting procedure must not be omitted long, because of the general sepsis resulting from rapid absorption from the surface, which is supplied with lymph ducts and small superficial bloodvessels to an unusual extent. Disinfectant injections must be continued every hour, for one or more days. If they are well made, the consecutive adenitis, particularly that about the angles of the lower jaw, is soon relieved and the general condition improved. But there are cases in which not the lymph bodies are the main gates through which constitutional poisoning takes place, but the bloodvessels only. In the incipient stage of such cases, the discharge from the nostrils is more or less sanguineous; in them, the bloodvessels, thin and fragile, carry the poison inward with great rapidity.

In a few cases injections are unsuccessful. They are those in which the whole nasal cavity is filled with membranous deposits to such an extent as to require forcible treatment. Sometimes it is difficult to push a silver probe through it. That procedure may be repeated, the probe dipped in carbolic acid, or wrapped in absorbent cotton moistened with carbolic acid of 50 or 60 per cent. After a while injections alone will suffice. But now and then, the development of pseudo-membranes is very rapid; a few hours suffice to block the nostrils again, and the difficulty is the same.

The liquids which are to be injected must be warm and fairly mild. Solutions of chloride of sodium, two-thirds of one per cent., saturated solutions of boric acid, one part of bichloride of mercury, 35 of chloride of sodium, and 5000 of water, more or less, or lime-water, or solutions of papayotin, will be found satisfactory. From the selection of these remedies, it is at once apparent that the object in view is partly that of washing out, and partly of disinfecting. I have not mentioned carbolic acid, which may be used in solutions of one per cent. or less. Its employment requires care, for much of the injected fluid is swallowed, and proves a danger to children of any age, but mostly to the young.

Most of the syringes I find in my rounds are abominations. The nozzle must be large, blunt and soft. After having recommended for many years the common hard-rubber ear syringe, the sharp end of which was cut off, I now use always a short stout glass syringe with soft rubber mounting in front.

When the children cannot, or must not be raised,

I employ the same solutions from a spoon or a plain Davidson atomizer. These applications can thus be made while the children are lying down, every hour or very much oftener, without any or much annoyance. The nozzle must be large, so as to fit the nostril. A single spray on each side will generally suffice. I am in the habit of covering the common nozzle with a short piece of India-rubber tubing.

For a day or two, these injections of fluids or spray must be made hourly. It is not cruel to wake the children out of their septic drowsiness; it is certain death not to do it.

Injections of the nose are oftener ordered than judiciously made. Hundreds of times have I been assured that they had been made regularly, hourly, for days in succession. Still there was a steady increase of glandular swelling and sepsis. I never believe a nurse to have made them regularly unless I have seen her doing it. They *will* run up their syringe vertically and not horizontally; the fluid *will* return through the same nostril. On the successful injecting or spraying of the nares hangs every life in cases of nasal diphtheria. I have long learned to look upon a neglect to tell at every visit how to make an injection as a dereliction of duty. This may appear a trifling way, but it is a safe one. The nurse must be made to tell you that at every injection the fluid returns through the other nostril, or through the mouth, or is swallowed.

The procedure is simple enough, and need not take more than half a minute for both nostrils. A towel is thrown over the child's chest up to the chin, and the child gently raised in bed by the person who is to make the injection. This person, sitting on the bed, steadies the patient's head against her chest, while somebody else holds the patient's hands. The syringe is introduced horizontally by the person sitting behind the patient, and gently emptied. No time must be lost in refilling, and attending to the other side. When pain is complained of in the ears, more gentleness is required, or the spray, or pouring in from a spoon, or minim dropper even, has to take the place of the injection.

Many sins are committed in even doing this simple thing. The unfortunate little one is made to see all the preparations, and is worried and excited, and the necessary gentleness in the proceedings is neglected. The cases reported by me before the Section on Theory and Practice in the New York Academy of Medicine, in a discussion on the local treatment of diphtheria, read as follows:[1]

"There were two trained nurses, and two children of six and four years. When I saw the little four-year-old, the other was dead. Where did he die? His head between the knees of the trained nurse. They had been told that Dr. Jacobi ordered nasal injections to be made every hour in such cases. Every hour the unfortunate boy was lugged out of bed, protesting and fighting, and wearing out his little strength in his battle against two trained brutes; had his head rammed between the knees of one of them, who was herself comfortably seated on a chair, while the other did the rest; and thus the boy was murdered. When I heard that fearful story from the smiling lips of that person, I begged and pleaded, and showed her how to do it gently. A week afterward, the doctor told me that the little girl died between the knees of one of the smiling creatures; and neither of them is in the State prison."

What is the concentration in which antiseptic injections should be used? For twenty-five years and more, while employing irrigations and injections frequently, I had used quite weak solutions, and felt assured of their efficacy. All at once (when the gospel of bacteria was being preached) it was claimed that weak solutions were useless and a snare, because antiseptics, and particularly carbolic acid, would not destroy bacteria and bacteria-poisons, except in such doses and concentrations as would necessarily destroy blood and tissues first. I felt dismayed, but still continued in my heretic ways, hoping that improved knowledge would finally harmonize theory and practice. So it happened. In *The American Journal of the American Sciences* for January, 1881, T. Mitchell Prudden proved that a solution of one-sixteenth of one per cent. of carbolic acid prevents the emigration of white blood-corpuscles under circumstances otherwise favorable to inflammation, and Koch found that though bacteria are not easily killed, their growth is stopped by a solution of one part of carbolic acid in 850, and their activity by one in 1200. These effects are all that is required for practical purposes; thus the frequency of applications is justified by both necessity and safety.

Diphtheritic adenitis, the swelling of the cervical glands near the angles of the lower jaw, to which I have alluded as an ominous symptom, points to nasal and nasopharyngeal infection. The treatment consists in disinfection of the absorbing surfaces.

Direct local treatment of the glands, if not entirely useless, is, at all events, of minor importance and efficiency. Applications of one part of carbolic acid to ten of alcohol irritate both surface and patient more than they can do good. Inunctions may do some good by friction (massage); inunctions with some absorbable material in them may do a little better. The common iodide of potassium ointment is useless; iodide of potassium in three or five parts of glycerine is more readily absorbed; the same in equal parts of water, with a little animal fat, and six or eight times its quantity of lanolin, gives an ointment which is readily absorbed. Iodine is found in the urine within a few hours. Iodoform may be utilized in the same way. Injections of

[1] New York Medical Record, 1887, p. 403.

iodoform in ether, which I suggested some time ago, are too painful. Mercurial inunctions, those of blue ointment, require too much time for any effect to take place. Oleates are too irritating locally; a lanolin ointment would prove more satisfactory. After all, however, the readiest method of reducing the swelling of the glands, and improving the prognosis accordingly, is that of cleansing and disinfecting the field of absorption. The rare cases of suppuration in these glands require incision and disinfection. They are, however, as ominous as rare. There is but little pus, as a rule, but one or many local deposits of disintegrated gland cells and gangrenous connective tissue. The incisions must be extensive; the scoop and concentrated carbolic acid must be freely used. In these cases, hemorrhages may occur, some of them very difficult to manage. I have seen some of them terminate fatally. In these, carbolic acid must be avoided. Compression, actual cautery and acupressure have rendered good service. Solutions of iron must be avoided, for the scurf formed is a shield behind which deleterious absorption is constantly going on in such wounds, as it does in the uterus.

Besides sepsis, the great dangers in diphtheria are heart failure and strangulation. The latter has its own indication, to which I shall not allude to-day. Heart failure exhibits itself sometimes quite suddenly, but, as a rule, it is foreshadowed by a gradually increasing frequency, weakness of heart-beats and pulse, and the equal length of the intervals between the feeble systole and diastole, and diastole and systole. This equality is always a dangerous symptom. Heart failure is due to myocardial changes, besides the influences common to every fever. These may depend on the influence of the septic decomposition of the blood, and the ill nutrition of the heart-muscle depending thereon, or the direct diphtheritic changes of the tissue, or both. These changes and dangers set in, sometimes, at a very early period. Thus, whatever enfeebles must be avoided. Patients must be spared every unnecessary activity. They must remain in bed, without excitement of any kind, take their meals, and evacuate their bowels in a recumbent or semi-recumbent position; crying and worrying must be avoided; the room kept airy, and rather dark, so as to encourage sleep if the patient be restless. In no disease, except, perhaps, in pneumonia, have I seen more fatal results from sudden changes of posture, or from exertion. Unless absolute rest be enforced, neither physician nor nurse has done his or her duty.

The threatening feebleness of the heart yields a positive therapeutical indication. In no disease is the danger greater from the side of the heart, in no disease is the indication for sustaining and strengthening the heart more positive from the very beginning. Digitalis, strophanthus, sparteine, besides camphor, alcohol and musk, must not be postponed until feebleness and collapse have set in. It is possible or probable that they will appear; and it is certain that a cardiac stimulant will do no harm. It is safe and advisable to use them at an early date. That is particularly necessary when antipyrin or antifebrin is given. A few grains of digitalis, in a palatable and digestible form, may, or must, be given daily. When a speedy effect is required, one or two doses of from two to four grains are not too large, and must be followed by smaller ones. When it is justly feared that the effect of digitalis may be too slow, I give, with or without the former, sulphate of sparteine. An infant a year old will take one-tenth of a grain four times a day, as a matter of precaution, and every hour or every two hours, in an emergency.

Of at least the same importance as cardiac tonics are alcoholic stimulants. The advice to wait for positive symptoms of heart failure and collapse, before the life-saving apparatus is employed, is bad. There are cases which get well without treatment, but we do not know beforehand which they will be. No alleged mild case is safe until it has recovered. When heart failure sets in—and often it will occur in apparently mild cases, our efforts are too often in vain. Thus, alcoholic stimulants ought to be given early, and in large quantities, though amply diluted. There is no such thing as intoxication or danger from it, in septic diseases. A few ounces daily may suffice, but I have given ten ounces of brandy or whiskey daily, to save children who had done badly with three and four.

Coffee is a good stimulant for the heart. Camphor may be employed to great advantage for the same purpose. From five to twenty-five grains may be given daily, as camphor water, or in a mucilaginous emulsion, which is easily taken. It does not upset the stomach as ammonium carbonate is liable to do. When a rapid effect is aimed at, it may be employed subcutaneously in five parts of oil, which is milder and more convenient than ether.

But the best internal stimulant, in urgent cases, is Siberian musk, in powders, or with mucilage. When required at all, it ought to be given in sufficient doses and at short intervals. When ten or fifteen grains, administered to a child one or two years old, will not accomplish, within three or four hours, a return of a more satisfactory heart's action, the prognosis is very bad.

Besides exhaustion at the height of the disease, we have paralysis during convalescence, or intense anæmia long after apparent recovery. This anæmia may be general, or is local, and then mostly cerebral.

Diphtheritic paralysis, though of different anatomical and histological origin, yields in all cases a certain number of identical therapeutical indications. These are: The sustaining of the strength of the

heart by digitalis and other cardiac tonics. A child of three years may take daily, for a month, three grains or its equivalent; for instance, one grain of the extract. This is an indication on which I cannot dwell too much. Many of the acute, and most of the chronic diseases of all ages do very much better by adding to other medications a regular dose of a cardiac tonic. It is true that it is a good practice to follow the golden rule to prescribe simply, and, if possible, a single remedy only, but a better one to prescribe efficiently. A prescription paper with a single line on it looks well, but a readily convalescent or well man looks better.

Besides, there are some more indications: Mild preparations of iron, provided the digestive organs are not interfered with. Strychnia or other preparations of nux at all events. In ordinary cases, a child of three years will take an eightieth of a grain three or four times a day. Local friction, massage of the throat, of the extremities and trunk, dry or with hot water, or oil, or water and alcohol; and the use of both the interrupted and continuous currents, according to the known rules, and the locality of the suffering parts, find their ready indications. The paralysis of the respiratory muscles is quite dangerous; the apnœa resulting from it may prove fatal in a short time. In such cases, the electrical current used for very short periods, but very frequently, and hypodermatic injections of sulphate of strychnia in more than text-book doses, and frequently repeated, will render good service. I remember a case in which these and the occasional use of an interrupted current, and occasional artificial respiration by Silvester's method, persevered in for the better part of three days, proved effective.

Chloride of iron.—I am still, as I was in my first paper on diphtheria, in 1860, an advocate of the internal use of chloride of iron. Its mode of administration I have not changed much these twenty years. At a public lecture delivered before a New York audience, by an European authority, whose name has lately appeared a little more prominently in the newspapers than an American physician would wish, I was highly praised for giving a few drops of the tincture of the chloride of iron a few times a day. This eulogy I have always tried not to deserve, for the efficient method of its administration is not that. The chloride of iron is an astringent and antiseptic. Its contact with the diseased surface is as important as is its general effect; therefore, it must be given frequently, in hourly or half hourly doses, even every twenty or fifteen minutes. An infant of a year may take forty-five or sixty grains a day, a child of three or five years one hundred and twenty or one hundred and eighty. It must be mixed with water to such an extent that the dose is half a teaspoonful or a teaspoonful; a drachm in four ounces allows half a teaspoonful every twenty minutes. No water must be drunk after the medicine. As a rule, it is well tolerated. There are some, however, who will not bear it well. Vomiting or diarrhœa is a contraindication to persevering in its use, for nothing must be allowed to occur which reduces strength and vigor. A good adjuvant is glycerin; better than syrups. From ten to fifteen per cent. of the mixture may consist of it. Now and then, but rarely, it is not well tolerated either. When diarrhœa sets in, glycerin must be discontinued. Still, these cases are rare; indeed, the stomach bears glycerin very much better than the rectum. In the latter, the presence of a small dose of glycerin is known sometimes to produce large evacuations, a result appropriated and utilized by an advertising nostrum monger.

In connection with this remedy, I wish to make a remark of decidedly practical importance. I know quite well that recovery does not always prove the efficacy of the remedy or remedies administered. But I have seen so many bad cases recover with chloride of iron, when treated after the method detailed above, that I cannot rescind former expressions of my belief in its value. Still, I have often been so situated that I had to give it up in peculiar cases. These are such in which the main symptoms are those of intense sepsis, I should say such in which the iron and other rational treatment was not powerful enough to prevent the rapid progress of the disease. Children with naso-pharyngeal diphtheria, large glandular swelling, feeble heart and frequent pulse, thorough sepsis, and irritable stomach besides, those in which large doses only of stimulants, general and cardiac, can possibly promise any relief, are better off without the iron. When the circumstances are such as to leave the choice between iron and alcohol, it is best to omit the iron and rely on stimulants mostly. The quantities required are so great that the absorbent powers of the stomach are no longer sufficient for both.

Nor is iron sufficient or safe in those cases which are preëminently laryngeal. To rely on iron in membranous croup means waste and danger.

Mercury.—The first volume of *A System of Practical Medicine by American Authors*, which appeared in 1885, contains in an article on diphtheria, written in 1884, the following remarks on page 705:

"Not all cases of diphtheria are septic or gangrenous, nor are all the cases occurring during an epidemic of the same type. Some have the well-pronounced character of a local disease, either on the tonsils or in the larynx. The cases of sporadic croup, met with in the intervals between epidemics, present few constitutional symptoms, and assume more the nature of an active inflammatory disease, very much like the sporadic cases of fibrinous tracheo-bronchitis. These are the cases in which mercury deserves to have friends, apologists and even eulo-

gists. Calomel, 0.5–0.75 gramme (grs. viij–xij), divided into thirty or forty doses, one of which is taken every half hour, is apt to produce a constitutional effect very soon. Such, with minute doses of one milligramme (gr. $\frac{1}{60}$th) or more of tartar emetic, or ten or twenty times that amount of oxysulphuret of antimony, have served me well in acute fibrinous tracheo-bronchitis. But the mucous membrane of the trachea and bronchi is more liable to submit to such liquefying and macerating treatment than the vocal cords. The latter have no muciparous glands like the former, in which they are very copious. And while the tracheal pseudo-membrane, though recent, is apt to be expelled through a tracheal incision at once, that of the vocal cords takes from six days to sixteen or more for complete removal. Still, a certain effect may even here be accomplished, for maceration does not depend only on the local secretion of the muciparous glands, but on the total secretion of the whole surface, which is in constant contact with the whole respiratory tract. Thus, either on theoretical principles, or on the ground of actual experience, men of learning and judgment have used mercury in such cases as I have detailed above, with a certain confidence."

"If ever mercury is expected to do any good in cases of suffocation by membrane, it must be made to act promptly. This is what the blue ointment does not. In its place I recommend the oleate, ten or twelve minims of which may be rubbed into the skin along the inside of the forearms or thighs, or anywhere else, every hour or two hours, when those surfaces become irritated. Or repeated doses, such as mentioned before, will be useful, or hypodermatic injections of corrosive sublimate, in one-half or one per cent. solution in distilled water, four or five drops from four to six times a day or more, either by itself or in combination with the extensive use of the oleate, or with calomel internally. Lately, the cyanide of mercury has been recommended very strongly. I hardly believe that it will work more satisfactorily than any other equally soluble preparation. Within the past few years, the internal administration of bichloride of mercury has been resorted to more frequently and with greater success than ever before.

"My own recent experience with it has been encouraging, and so has that of some of my friends. William Pepper gave one thirty-second of a grain of corrosive sublimate every two hours in a bad form of diphtheritic croup, with a favorable result. But in this very bad case, desperate though it was—child of five years, respiration 70, pulse 160, large membrane, 'evidently from the larynx,' had been expelled before the treatment was commenced on the seventh day of the disease. The solution ought to be given in solution of 1 : 5000, and in good doses. A baby, a year old, may take one-half grain every day many days in succession, with very little, if any, intestinal disorder, and with no stomatitis. A solution of the corrosive sublimate in water is frequently employed of late as a disinfectant. It acts as such in a dilution of 1 in 20,000. As healthy mucous membrane bears quite well a proportion of 1 : 2000 or 3000, any strength between these extremes may be utilized. A grain of the sublimate in a pint or more of water, with a drachm of table salt, will be found both mild and efficient. As a gargle and nasal injection, it will be found equally good. But it has appeared to me that frequent applications give rise to a copious mucous discharge; hourly injections into a diphtheritic vagina become quite obnoxious by such oversecretion, which ceases at once when the injections are discontinued. Thus, when it is desirable not only to disinfect, but also to heal the diseased surface, the injections with corrosive sublimate appear to yield a result inferior to less irritating applications."

These remarks of 1884 constitute what I consider a great progress over the statements of my treatise on diphtheria, 1880, which are more cautious and negative. Extensive experience with the remedy increased my favorable opinion of its efficiency to such an extent as to induce me to publish a number of cases and conclusions in the *Medical Record* of May 24, 1884.

They have been amply justified by the observations of the last four years, so that I am fully prepared to commit myself to the following statements: My conviction of the utter uselessness of internal medication in laryngeal diphtheria, membranous croup, is strongly shaken. The mortality of 90 or 95 per cent. of the cases not operated upon has no longer existed these five or six years, in my observation. The above figures were by no means taken from small numbers. For, since 1860, I have tracheotomized more than 500, perhaps 600, times, have assisted in as many more operations, and seen at least a thousand case of membranous croup which were not operated upon at all. During the last six years, I have seen no less than 200 cases, perhaps many more. Amongst them recoveries have not been rare. In the practice of no less a man than O'Dwyer, I have seen two cases of general and laryngeal diphtheria in the same family, which got well without any operative procedure. Such recoveries have taken place at all ages, from four months upward. The uniform internal medication consisted in the administration of the bichloride of mercury. The smallest daily dose was a quarter of a grain. Half a grain daily, continued through five or six, sometimes eight, ten or even twelve days, has not been rare amongst children of from three to six years. The doses varied from one-sixtieth to one-fortieth of a grain, and sometimes more. They are given every hour. They require dilution in a tablespoonful of water or other compatible fluid, for instance milk, in order to be quite innocuous. They are not liable to produce gastric or intestinal irritation. When the latter occurred, it was generally found that by some mistake the solution was as strong as 1 : 2000 or 1 : 3000. In the few cases in which it did exist, or was believed to result from the

remedy, a few minims of camphorated tincture of opium administered with every dose, for a short period, proved sufficient to check it. The beneficial effect of the remedy depends greatly on the time of its administration. As a rule, such complete stenosis as necessitates surgical interference develops after days only. This necessity is often obviated by the remedy when given as detailed. When an operation is required after all, the treatment must be continued. I have never since 1863 seen so many cases of tracheotomy getting well as between 1882 and 1886, when the bichloride was constantly used as mentioned. Nor am I alone with these observations. I can name a dozen of New York physicians, some of whom have often performed tracheotomy, who can confirm the above statements from their own observations. Nor does the opinion of those differ who constantly perform intubation. I know that O'Dwyer, Dillon Brown and Huber have come to the same conclusions, the latter having been a successful tracheotomist before he earned his laurels with intubation.

My experience in regard to the efficacy of the bichloride of mercury is mainly gathered in cases of laryngeal diphtheria, and a limited number of fibrinous bronchitis. It is there where it has been particularly effective. Still I must not say that they were localized affections. These, with us, are but very scarce. Our cases of diphtheritic laryngitis are mostly decreasing, and complicated with either diphtheritic pharyngitis or rhinitis, or both. Not a few, mainly of the latter kind, exhibit constitutional symptoms, sepsis. But cases of that kind, also, I have seen getting well. One of the most interesting was that of a girl of seven years whom I saw a single time in consultation with Dr. J. Anderson. There was nasal and pharyngeal diphtheria, cervical adenitis and some laryngeal stenosis. I recommended an hourly dose of one-fortieth of a grain of bichloride, which she took for ten days, also nasal injections of the same, one grain to a pint. They were made hourly for many days, and altogether continued for more than a fortnight, for the patient lived so long, and is still alive. She swallowed almost all the nasal injections, and great was my surprise when, after some weeks, I received the report of the case, and learned that about twenty grains of the bichloride had found their way into the stomach of the little girl. She lived, had but little stomatitis, and hardly any intestinal irritation. If the case does not prove anything else, it proves this, that even desperate cases will get well; this case got well with the bichloride of mercury, and resembles all the other cases in this, that after the rational and careful administration of solutions of hydrargyrum bichloride, local mercurial symptoms about gums, mouth, pharynx and intestines are extraordinarily rare in infancy and childhood.

ON GOUTY SORE THROAT.[1]

By HARRISON ALLEN, M.D.,
of Philadelphia.

By the term "gouty sore throat" is meant the presence of distress, in or about the pharynx or larynx, dependent upon the existence of gout in the system. Such a clinical condition is mentioned by writers, but, for the most part, in connection with metastasis. For example, an affection of the pharynx is known to be of a gouty nature when its announcement is connected with the sudden disappearance of gout elsewhere.

The recognized forms of sore throat which relate to diathesis are the rheumatic, the tubercular (probably including the so-called scrofulous), and the syphilitic. Schech includes a scorbutic form. In the tubercular and syphilitic varieties a lesion or local deposit would be requisite to a diagnosis. In the rheumatic form this is not the case, nor is it so in the gouty. Schech[2] does not admit the gouty form. It is accepted by Prosser James.[3] The account given by Morell Mackenzie relates only to metastasis. Lennox Browne[4] agrees with Schech in the main, though acknowledging that cases are seen in which the administration of gouty specifics is a necessary adjunct to the local measures. This writer accepts a gouty variety of perichondritis.[5] That Scudamore[6] may be said to have recognized sore throat in connection with gout is likely, if we correctly interpret the following language:

"A cough with much mucous secretion in the tracheal membrane sometimes precedes the fit; yielding when the gout becomes fixed, *occasionally continuing with the other symptoms*. This description of cough is to be distinguished entirely from the recent catarrhal cough and symptoms which sometimes usher in a paroxysm, when exposure to wet and cold has been the exciting cause. The mucous membranes of the parts which have been affected with disease, or which are prone to disease, *are much disposed to acquire a state of unhealthy action*; in apparent sympathy, either with that condition of the constitution which borders on a fit of the gout, or in which the *disease is threatening its return, but does not develop itself*."

The literature of gouty sore throat is scanty. Musgrave[7] is accredited with a good account of the condition. The following detailed examples, which have been diagnosticated gouty apart from metastasis, are the only ones known to the writer. It will be seen that they are of doubtful value. In a case reported by J. de Lagoanère[8] under the title of "an-

gine goutteuse" an account of septicæmia is given. It occurs in a man thirty-seven years of age, without gouty antecedents, and by occupation a house painter.

The patient is admitted into the Hotel Dieu suffering from acute inflammation of the right ankle, tarsus, and the joints of the great toe. The fourth day after admission a phlegmonous inflammation of the pharynx is abruptly developed, without metastasis; an abscess is detected which is spontoneously ruptured upon the seventh day. Retention of urine, albuminuria, endocarditis, and empyema ensue, and the patient dies on the fourteenth day.

Garrod describes a form of gout which is often seen among workers in lead, but in connection with gout already established. The case narrated belongs, if to the group of gout cases at all, in such a subdivision. The pharyngeal complication which preceded the fatal termination, can scarcely be embraced under the head of "angine goutteuse."

Lasègue appears to have recognized the coexistence of sore throat with gout. But the description by Lagoanére[1] of a case of Lasègue[2] does not give the writer the impression that it is similar to any of the instances upon which this paper is based.

A merchant, aged thirty-eight, is treated for a sore throat. No exact gouty history is given. The mother of the patient had suffered at the menopause from painful and swollen joints of the fingers. It is thought that these swellings are *either* rheumatic or gouty. There is no description of gouty attacks in the patient. An account of chronic pharyngitis is detailed In the treatment neither colchicum nor other anti-lithic appears to have been administered.

I have thought a study of sore throat which, while independent of metastasis, was found in gouty subjects, and which yielded only to remedies for gout, might prove of interest.

No one group of symptoms is to be expected in a disease so protean as is gout. The subjects of gouty sore throat have been almost always in middle life. A disposition to gout has been traced through several members of the family in all but a single example.

The distress may be confined to the throat, or be referred to it from a catarrh of the nasal passages. It is not apt to develop during an acute attack, but to occur in those who are prone to neuralgic forms of irregular gout—especially of the viscera—or in persons of gouty habit who are careless in their diet. Thus dyspepsia and constipation are of frequent occurrence. The tongue is often persistently furred or pasty.

It goes without saying that a sore throat occurring in a subject who inherits or acquires gout is not of necessity of a gouty nature. The judgment of a careful observer is alone required to distinguish between the essential complaint and its counterfeits.

The only ailment with which gouty sore throat may be confounded is the irritable throat of lithæmia. Lithæmia occurs at any time of life. It is often dependent on the diet, and can be controlled by the withdrawal of wines and nitrogenous food, and by increasing the activity of the kidneys. In young persons, the subjects of lithæmia, the pharynx presents a definite appearance. The mucous membrane is of a uniform red color, the secretions are abundant, and the tonsils are tumid. The health is good, often, indeed, robust. In older persons the appearances are less constant. The tonsils are often small and concealed, and the parts bathed in secretion. Pain is usually not severe, and is referred to the pharynx and not to the muscles at the side. In true lithæmia, the gouty history is absent.

Perhaps the best guides to a gouty condition are furnished by the permanent teeth. While not essential to a diagnosis—for in a marked instance known to the writer, the teeth do not conform to the rule, it is very generally found that the teeth are large—the antero-posterior diameters being especially exaggerated, the enamel thick and of a yellowish color. The peculiarities of gouty teeth are confined to the incisors, canines and bicuspids. The crowns are often marked by transverse lines, and the bases of the lingual and palatal surfaces are apt to be gibbous. The cutting edges of the crowns of the incisors are without serrations. A disposition exists for recession of the gums from the necks of the teeth.[1]

In the local treatment of gouty sore throat, it is only necessary to remember that all agents must be soothing in character. Operative procedures are not well borne. If they are demanded, they must follow the use of general remedies.

The constitutional treatment of gout need not be entered upon here. As is well understood, no single plan is adapted to all cases. In the main, preparations of colchicum can be relied upon to assuage the disease, careful attention being directed to the digestive and urinary functions. Most of the cases are improved by omitting meat from the dietary. Sweet wines and spirits are to be avoided.

Case I. *Irritable pharynx, associated with neuralgic pains of gouty origin.*—Miss A. B., aged forty-five, reported through the courtesy of Dr. James Tyson, March, 1888, complaining of neuralgic pains in the muscles of the side of the neck, a burning sensation in the tongue, and constant pain in the ears. The hearing was normal, and the tympanic membranes were healthy. The pharnyx was excessively irritable, and very susceptible to the presence

[1] Ibid., p. 47.

[2] I have examined Lasègue's Clinical Memoirs, but do not find this case. Neither is it contained in E. C. Lasègue's Traitè des Angines.

[1] Fothergill (Vaso-renal Changes *versus* Bright's Disease, 1887, p. 85) describes the gout-tooth as "worn down and blunted at the edge; at first slightly, subsequently till they look more like pegs than edge-cutting instruments."

of hot fluids; the amount of heat required to warm the rhinal mirror would cause complaint, if by chance the edge of the instrument touched any part of the pharynx. The basi-lingual glands were large. The base of the tongue was occupied by a persistent white fur. The patient had suffered from attacks of aural and pharyngeal pains for several years; they were always worse during the inclement March season. The teeth were large, of a yellow color, but no more worn than might be expected at forty-five years. The patient was a sufferer from atonic dyspepsia. Gout had been in the family on the paternal side through a number of generations. The father had been for years a sufferer and a confirmed invalid from this cause. The pains yielded promptly to the exhibition of colchicum, after they had resisted all other treatment.

CASE II. *Catarrhal pharyngitis and retained tonsil-secretion in a subject of gouty inheritance.*—Mr. C. D , aged thirty-four, was referred to me in February, 1888, by Dr. D. Murray Cheston. She had suffered for five years from a sensation of "throat-closing," which was due to mucus collecting in the naso-pharynx and passing down over the lower portion of the pharynx. Additional sources of irritation existed in an abnormal state of the tonsils. The patient had had in all four attacks of catarrhal laryngitis, and was liable to distressing cough when walking against a high wind. The pharynx was very red and irritable, but not swollen. The tongue was moderately furred at the base, but clean for the most part. The tonsils were not enlarged, but of firm consistence. The right tonsil was concealed.

After a treatment of three weeks, the case not progressing satisfactorily, an inquiry was made into the family history, when a gouty history was traced through both maternal and paternal lines. The teeth were observed to be large and firm, and of the characteristic gouty type. The lateral borders of the central maxillary incisors were unusually thick. The lateral maxillary incisors were congenitally absent. Out of six members of her immediate family this peculiarity was noticed in four.[1] Wine of colchicum was now administered, but interfered with digestion. The bowels were kept soluble by sulphate of magnesia. Lithia water was ordered, the diet guarded. Improvement soon was announced. The treatment was interrupted by a general catarrhal attack with fever, during which the family physician, following up the treatment, administered the bromide of lithia.

Upon reporting for further local treatment the condition was found greatly improved. The cause of local pharyngeal tenderness was now carefully inquired into and a number of tonsil-pellets dislodged from both tonsils. The pharyngeal tenderness disappeared soon after these explorations.

Mrs. D. is now recovered from the throat ailment —the "closing" sensation has disappeared. She has been comfortable during our recent trying spring weather.

The following case illustrates the most common form of gouty sore throat—namely, a form in which the gouty habit is conjoined with a moderate amount of indulgence in the pleasures of the table.

CASE III. *Pharyngitis in a male subject of gouty habit.*—Mr. A. T., aged forty-five, a lawyer by profession, of gouty inheritance, suffered from continuous sore throat. The parts were red, moderately swollen, and excessively irritable. The tonsils were small but hard, the right body being retroverted. The voice was husky, and the patient annoyed by futile efforts to clear it. The patient was liable to attacks of herpetic tonsillitis. The habit was full, the trunk large, and the neck short. The teeth were not characteristic. The patient was aware of the nature of his distress. He was always worse after times of more than usual indulgence, when he would experience pain in the right toes. He was restless under the restrictions of treatment, and after remaining under care for a few weeks, ceased to report.

CASE IV. *Chronic nasal catarrh and acute pharyngitis in a male subject who suffered from acquired gout.*—Mr. G. H., aged fifty-five, reported in September, 1880, has suffered from attacks of gout in the feet for fifteen years, which have always yielded to "Lavilles' gout fluid." The patient had an attack in January. The duration of the nasal catarrh was about eighteen months. For one week before reporting he had an acute sore throat with an attack of coughing. The catarrh was much better than was usual and the sore throat appeared to have no connection with it. The sore throat was associated by the patient with the gout.

The throat structures were purplish-red in color and œdematous; a line of gray infiltration was distinguishable on the sides of the uvula. The sense of smell and taste were slightly impaired. The appearances within the nasal chambers were characteristic of chronic nasal catarrh. The treatment consisted in reducing the size of the intumescent membranes. They presented no features which need be recorded.

CASE V. *Pharyngitis in a male subject who was syphilitic and at the same time gouty.*—Mr. I. J., aged thirty-six, reported in January, 1879. He was a lawyer by profession, and had a history of inherited gout, and had suffered from three acute attacks involving the great toe of the right foot. He is also a sufferer from hay-fever. The gums were receded from the necks of the teeth. He had an abscess in the right maxillary sinus two years ago. In 1868 the patient had synovitis of the shoulder, the knee of the left side, and the right toe which was probably of a syphilitic nature. He had a lesion of constitutional syphilis in the form of a small serpiginous ulcer on the roof of the mouth beginning near the first bicuspid tooth of the right side, extending to the middle line, and thence deflected along the raphè to the middle of the hard palate. The ordinary appearances of chronic nasal catarrh and pharyngitis were present.

[1] The absence of the permanent lateral incisors of the upper jaw has been associated so frequently by the writer with constitutional impression that it may be included among the minor signs of a gouty, syphilitic or strumous state.

VESICAL CALCULUS WITH CHYLURIA.[1]

By FERDINAND H. GROSS, M.D.,
SURGEON TO THE GERMAN HOSPITAL, PHILADELPHIA, ETC.

I am led to report the following case of vesical calculus in a female because of the features of unusual interest which it presented.

Mrs. J. S., aged nineteen, of Italian birth, but now residing in this city, felt very ill after her first confinement in July, 1887. She complained greatly of pain in her back, and was rapidly losing strength. An irregular Italian practitioner was first consulted, who pronounced the case one of kidney disease.

About the 20th of September, 1887, she having become very weak and discouraged, Dr. A. A. O'Daniel, of this city, was requested to take charge of her case. He found her confined to her bed, in a feeble condition, and unable to take sufficient nourishment. She was occasionally affected with vomiting. There existed a painful spot over the left kidney, decided tenderness in the region of the ovary of the same side, and pain which ran down the inside of the corresponding thigh to the knee. An examination *per vaginam* revealed nothing abnormal about the uterus or its appendages. She stated that she "passed milk from her bladder instead of urine." The specimen which was obtained had the appearance of milk. When it was allowed to stand twenty-four hours, it presented the same peculiar appearance as before. No sediment was noticeable. By repeated examination a small amount of pus was found, but by no means sufficient in quantity to account for the emulsive character of the urine, which, after standing for several days, showed a scum on top. Upon agitating the urine with ether a quantity of fatty matter was separated, leaving the residue comparatively clear.

The case was now regarded as one of chyluria, and acting upon this diagnosis Dr. O'Daniel administered thirty grains of gallic acid daily, with very satisfactory result. The urine became almost clear, but if the drug was omitted for a day, its milkiness would return, and when, on account of an irritable condition of the stomach, the use of gallic acid was for a time discontinued, the urine became so thick that it could scarcely be voided, and the pain in the back increased in severity.

By the administration of diuretics and the application of counter-irritants to the back at this time, a degree of relief was afforded, but the urine remained milky. The patient's temperature at different periods ranged from 99°–102° F. Gallic acid was again resorted to, but in small quantity, and with an occasional dose of quinine. The urine thereafter presented somewhat different characters from those which had been noticed before. On standing four or five hours its emulsive character was less thoroughly preserved, and its constituent parts began to separate.

Dr. James Tyson saw the case in consultation, on October 26, 1887. The patient's temperature was then 102°, and the urine slightly milky. A specimen which had stood from the previous night contained some deposit and showed only slight turbidity. The possibility of the existence of filariæ having been discussed, a few drops of blood were taken from the woman's finger for microscopic examination, but no filariæ were found. Pus was detected in the urine.

When the gallic acid was again discontinued, the urine once more became so thick that it could be passed only with difficulty, and now showed an increased quantity of pus.

When, for the first time, the medical attendant by means of a double current catheter washed out the bladder with a solution of boric acid, he was surprised to discover a stone of large size in that viscus. Tonics were administered and the bladder was washed out daily with the above-named solution.

On November 28th, the patient being a little stronger and the urine having become almost clear, I removed the stone, assisted by Drs. O'Daniel and J. B. Deaver, the latter giving the ether. The urethra was dilated sufficiently to allow the introduction of the index-finger, which came in contact with a calculus too large to be removed unbroken through the natural canal. A pair of forceps was introduced through the dilated urethra, and a portion of the calculus crushed off. On reintroducing the finger, the bent end of a hairpin about an inch in length was felt among some broken débris of the stone. A little delay was occasioned in extracting this forked-shape wire without lacerating the bladder or urethra. A number of stony fragments were removed, and the bladder well washed out. But some difficulty was now experienced in bringing away an olive-shaped fragment measuring an inch and a quarter in length and three-quarters of an inch in its greatest diameter, and having running through it lengthwise one of the wire prongs of the hairpin, two and a quarter inches long. The free or projecting ends of the wire were buried in the coats of the bladder holding fast the remaining large fragment of the stone, of which the wire formed an elongated nucleus.

By an examination through the vagina, one of the points of the wire buried in the tissues could be readily felt. With only the index-finger in the bladder, this end of the hairpin was disengaged and brought toward the urethra, through which by means of forceps it was extracted with its stony accretions still fastened about it.

The patient recovered well from the effects of the ether and the shock of the operation. On the first evening her temperature rose to 102°, but sank on the following day to 99°, and did not again rise. In a very few days she was able to retain her water perfectly. She was kept in bed for ten days; in a few weeks she gained forty pounds in weight, and has since remained entirely well.

The stone, including all the fragments and lesser débris, weighed five hundred and forty grains. It was composed of mixed phosphates, urates, and fat.

No information could be gained from Mrs. S. as to how or when the hairpin got into her bladder. From her mother it was learned that the patient began complaining of pain in her back and of feeling

[1] Read before the Philadelphia Academy of Surgery.

ill about four years before her marriage, but that no particular discomfort was complained of during her pregnancy.

In regard to the diagnosis of chylous urine in this case, I would add that, after repeated conversations with the medical attendant on that point, I cannot but adhere to its correctness. In this I am strengthened by the report of a chemical analysis of the calculus, made by Dr. Lawrence Wolff, in which he states that he found fat; which was a substance he had failed to find in the examinations of numerous other vesical calculi, although it was fair to assume that some of the patients from whom they had been taken had had pus in their urine.

The only explanation I can offer for the existence of the chyluria is that the lymphatics of the bladder were wounded by the points of the hairpin, and that a lymphatic varix may have existed, causing a direct leakage from that system and producing a non-parasitic chyluria.

MEDICAL PROGRESS.

A Case of Complete Recovery after Removal of the Larynx.—The Paris correspondent of the *Lancet* writes in that journal of April 28, 1888, that at No. 22, Rue de la Banque, Paris, may be seen a man (a wine merchant) who has been living without a larynx for the last two years. In April, 1885, he consulted Dr. Fauvel, the celebrated laryngologist, on account of severe dyspnœa, to which he had been subject for some time. Dr. Fauvel diagnosed an osteosis with œdema and ulceration of the larynx, and proposed to perform tracheotomy on the man. This he refused to submit to, and consulted other physicians; but, as he was getting worse and the danger of suffocation became imminent, he decided upon the operation. Tracheotomy was practised on February 13, 1886; but, as this did not afford much relief, Dr. Péan on February 27th—that is, a fortnight afterward—performed ablation of the larynx. This was done at the hospital, and on March 19th he was able to eat, and left the hospital cured and apparently in good health. As newspaper reports of medical cases are not always very correct, I resolved to call at the residence given, and verify the statement published. I saw the man in his shop (a public-house), serving his customers as if nothing had happened to him. He is thirty-seven years of age, but looks about fifty. At my request he very willingly showed me his throat, where I perceived the canula which was introduced by Drs. Péan and Fauvel, and whenever he had to answer my questions he closed the orifice of the canula with his finger, and, although his voice was not very audible, yet he spoke distinctly. He has not changed his habits, but eats and drinks as much as he ever did. As far as I could learn, the man had no antecedents of syphilis or tuberculosis, but had been frequently treated for "colds on the chest."

Rattlesnake Bite Successfully Treated by Permanganate of Potassium.—Gaston, of Atlanta, reports the following case in the *Brooklyn Medical Journal* for May, 1888: As the patient placed his hand on a crate he felt a stinging sensation in one of his fingers, and saw that a huge snake had fastened its fangs in his flesh. In a few seconds the hand and arm began to swell, and he was brought to Dr. Gaston's office. On examination, he found that the fang of the snake had penetrated the anterior portion of the end of the third finger, and a ligature was tied tightly around the finger below the first joint immediately, which strangled the circulation. The patient came directly to the office, only a few blocks off, and so soon as a solution of permanganate of potash, grs. ij. in distilled water, f℥j, could be made by the nearest druggists, the quantity contained in an ordinary hypodermatic syringe was injected, by passing the needle through the orifice left by the fang. The ligature was then released, and the patient made great complaint of the pain in the part, from the medication, for a few minutes. There was a dusky, ashy hue extending around the point where the injection penetrated, which gradually passed away, and in the course of fifteen minutes there was no further notable effect of the bite or of the injection. His brother reported that some swelling of the finger and arm occurred during the following day, but it was not requisite to visit him again. It is stated that the patient took aqua ammonia in doses of fifteen drops every hour during the afternoon of the bite, but there were no indications of the effects of the poison requiring this remedy, and it was only used from prudential considerations.

Tannin for Burns of the First Degree.—Mikalsky uses tannin in burns of the first degree, as follows:

Tannin,	
Alcohol	āā ℥ i
Ether. sulphuric.	℥ 7½

For local application.—*Revue de Thérapeutique*, May 1, 1888.

Kephir, as Infant Food.—Taylor reports, in *The Archives of Pediatrics* for May, 1888, his use of kephir among children as follows:

1. If the infant is less than a month old, give it diluted one-third with water. This proportion may be gradually lessened until at from four to six weeks of age it is given undiluted.

2. It should be fed slowly from a simple, easily cleansed nursing-bottle.

3. When used, it should constitute the only food, except in children over a year of age, when crackers, toast, etc., may be given with it, and one meal a day can with advantage consist of oatmeal mush or other farinaceous food.

4. For young infants it is best adapted when given in its young or weak state. As the child grows older the medicine or even the old kephir may be used.

Its greatest usefulness is in cases of infantile atrophy and of chronic diarrhœa, and it will undoubtedly prove to be a valuable addition to our resources in the care of hand-fed infants.

A New Antiseptic Soap.—The *Lancet* of May 12, 1888, writes that until quite recently a satisfactory soap containing as an antiseptic one of the salts of mercury has been difficult to prepare on account of the alkaline soap

refusing to yield a good lather, oleate of mercury being formed—a compound which has little or no germicidal action. One of the most powerful antiseptics of the mercury salts is, as is well known, the bichloride. Moreover, it is cheap, and easily soluble, but it has the disadvantage of being extremely poisonous and easily reduced by albuminoid matter, with which it combines, thus being rendered inactive. In a paper recently read before the Society of Chemical Industry, in Glasgow, by John Thomson, the solubility of the red biniodide of mercury (which is claimed to be even a more powerful antiseptic than the bichloride) in iodide of potassium has been made use of. A soap can thus be easily prepared containing a certain proportion of the biniodide in a soluble form. It is stated to be permanent, having no tendency to separate, and to be more germicidal in its properties than any other antiseptic soap yet known. Experiments were made to demonstrate this. Sterilized silk threads were suspended in a solution of the biniodide soap for ten minutes, after being saturated with solutions containing well-known microörganisms, amongst which were the streptococcus scarlatinæ (Klein), bacillus subtilis, orange sarcina, white bacillus from Tweed water, organisms from putrid urine, the micrococcus of osteomyelitis, aspergillus nigrescens, spores from various fungi, yellow micrococcus from pus, putrefactive organisms, bacterium termo, and bacillus scarlatinæ (Edington). The threads were then carefully washed to remove the soap, and placed in sterilized gelatine in the ordinary way. The threads were controlled by first sterilizing, and then plunging into nutrient gelatine; if no growth occurred, they were accepted as being fit for use in the experiment. Washing the threads previously contaminated with organisms two or three times carefully with distilled water was shown by experiment not to remove the organisms, for on being placed in the gelatine, growth readily took place. The results, as shown in tables, are very remarkable. In all the experiments, with a few very uncertain exceptions, growth of the organisms was completely prevented, even after the lapse of four days. Similar experiments made with "carbolate of mercury" soap showed it to be less powerful as a disinfectant, and much slower in its germicidal action. In experiments carried out in the same manner with other antiseptic and ordinary soaps, it was shown that the growth of the organisms in many cases was not prevented. The importance of such a soap in medical and sanitary science is very obvious. The biniodide soap has been used in the treatment of eczema with well-marked success, especially where the irritation is due to the fermentations of accumulated secretions, the fermentation being set up by microorganisms. It has also met with similar success when used in parasitic skin diseases, such as favus and ringworm. As a parasiticide, too, the importance of its application to patients during the period of desquamation in scarlet fever is evident.

Hydrofluoric Acid in Pulmonary Phthisis.—Dr. de Giacoma, of Berne (*Correspondenz-Blatt für Schweizer Aerzte*, March 1, 1888, p. 142), has tested the treatment in eight advanced cases of his own. He simplified the Seiler-Garcin method in so far that a mixture of one hundred grammes of fluoric hydrogen with three hundred grammes of water was heated in an open leaden vessel by means of a spirit lamp. The patients sat around the vessel and inhaled the vapors for an hour daily. Dr. de Giacomi's experience was not so favorable as that of the French observers. In six of the eight patients the result was absolutely negative; in a seventh some temporary improvement of appetite and decrease of dyspnœa were observed; in the remaining case a striking relief of all symptoms ensued after the very first sitting. The author, however, reasonably enough, hesitates to attribute such an extraordinary and sudden change to the treatment employed; the improvement might have been purely accidental. At all events, he thinks that the method deserves a further and more extensive trial. The inhalation does not cause any discomfort to the patient. The only drawback which he mentions is that window-panes gradually become opaque under the influence of hydrofluoric vapors. As the acid has a violent caustic action on the skin, Dr. de Giacomi recommends the utmost caution in manipulations with the solution. Dr. Collon employed the method in two cases of advanced tuberculosis with high fever and extreme emaciation, and did not see any good beyond some amelioration in respect of sleep.—*British Medical Journal*, April 28, 1888.

An Anæsthetic for Minor Operations.—The *Revue de Thérapeutique* of May 1, 1888, gives the following convenient mixture:

Chloroform,
Spirits of wine,
Cologne water . . . . equal parts.

To be inhaled for transient anæsthesia.

Micro-organisms in Surgical Wards.—At the last Congress of Italian Surgeons, Durante reported experiments performed, at his suggestion, by his assistant, to determine the presence of germs in the air about the bed of a surgical patient, and in the ward. It was found that the greatest number of germs were present about forty inches above the borders of the bed; in all other directions the number of germs greatly decreased. Culture materials placed beneath the bed and about the bottoms of the neighboring walls, remained frequently sterile. The germs most frequently found were *staphylococcus aureus*, *streptococcus of erysipelas*, and Fränkel's *pneumococcus*. —*Deutsche medicinische Wochenschrift*, May 3, 1888.

A Simple Operation for Lacerated Cervix.—Herrick, in the *Medical Record* of May 26, 1888, reports a simple method of closing a lacerated cervix as follows:

The lacerated edges of the cervix are denuded as usual, care being taken that they are properly coapted; then, instead of introducing sutures, a wide elastic rubber band, shaped like the cervix, and large enough to cover the whole os and neck, with the exception of a hole in the end for the secretions to pass through, is slipped over the os, while the lacerated edges are held together by a pair of tenaculum forceps, over which the band is first passed; the band being wide and covering the whole neck, it keeps up equal pressure upon the bloodvessels, thus preventing enough blood getting into the parts at any one time to produce inflammation or swelling, and, as a natural sequence, union takes place much sooner than it otherwise would. The introduction

of sutures is often followed by inflammation, and when suppuration follows there is non-union, which is prevented by the use of the elastic band.

The advantages of this method are: 1. As about all the pain experienced during the operation is from the introduction of the sutures, if they are not introduced there is little pain, and hence an anæsthetic may be dispensed with. 2. If the patient is not etherized it is not necessary to have professional assistance, and one can operate on patients that would not listen to such a proposition if strange physicians were to be present. 3. The parts are kept in just as close contact, and union takes place just as soon. 4. There is less danger of inflammation. 5. There are no stitches to remove. 6. In slight cases patients can be operated upon without their being obliged to keep their beds for a single day, or their knowing they are undergoing an operation.

Cerebral and Spinal Abscess Successfully Drained.—Ruggi, at the Congress of Italian Surgeons, reported two interesting cases, as follows:

The first was that of a healthy workman, aged twenty, who received a severe blow upon the left parietal region, followed by paralysis of the right arm, and later, by convulsions. Craniotomy revealed a splinter from the internal table of the skull perforating the dura mater; the brain was contused, and blood and pus were evacuated. The case progressed to comparative recovery without fever.

The second case was one of præ-vertebral abscess in the region of the ninth and tenth dorsal vertebræ. Ruggi resected a sufficient number of ribs, removed the transverse process of a vertebra, and evacuated pus and a fragment of bone from the vertebral canal. Recovery followed.—*Deutsche medicinische Wochenschrift*, May 3, 1888.

A Prescription for Sea-sickness.—Rouquette prescribes:

Antipyrin.	gr. 75.
Cocain. hydrochlorat.	gr. 1½.
Caffein.	gr. 4.
Strych. sulphat.	gr. $\frac{1}{32}$.
Cognac	℥ 2½.
Aquæ destillat.	ad ℥ 25.

A teaspoonful before embarking, followed by two during the twenty-four hours: when at sea, three teaspoonfuls daily.—*Revue de Thérapeutique*, May 1, 1888.

Anatomical Differences in the Perinea of White and Colored Women.—Dr. Rafael Weiss, writing in the *Revista de Ciencias Medicas* of Havana on the different position occupied by the vulva in white and colored women, states that, according to his measurement, made on colored multiparæ, the average distance from the coccyx to the fourchette is 2.18 inches, and that between the fourchette and the symphysis 2.65 inches, the anus and fourchette being 0.7 of an inch apart. Comparing these with the measurements given by Föster for European multiparæ—viz., 2.8, 1.8, and 0.8 inches,—it is evident that the vulva occupies a distinctly lower position amongst negresses than it does amongst Europeans. Dr. Weiss's own measurements of Europeans do not differ very widely from Föster's. A very low position he found quite exceptional amongst white women, while a very high one was not uncommon, the coxi-vulvar distance being in some cases as much as 3.4 inches. With women of unmixed negro blood, on the other hand, he never saw a case where the position was high, though it was sometimes so low that the fourchette occupied the position usually held by the anus in white subjects. The consequence of these differences is that in colored women the period of perineal distention in parturition is much shorter and easier than amongst white women.—*Lancet*, May 5, 1888.

Smokers' Vertigo.—Dr. Decaisne recently investigated a number of cases of vertigo in smokers. Out of sixty-three patients, forty-nine were between fifty and sixty-six years of age. More than half of them suffered in addition from digestive troubles, with constipation alternating with diarrhœa, insomnia, palpitations, dyspnœa, and diuresis. In a third of the number there were marked intermittence of the pulse and granular pharyngitis, while others suffered from aphthæ, amblyopia, etc. Thirty-seven were persons who smoked habitually on an empty stomach, and these suffered from vertigo, principally in the morning. The vertigo generally coincided with suppression of perspiration and diminished excretion of urine. The treatment consisted mainly in regulating or suppressing the cause, but thirty-three out of thirty-seven patients ceased to suffer on merely refraining from smoking on an empty stomach.—*Medical Press*, April 25, 1888.

Repeated Typhoid Fever.—Eichhorst has collected the statistics of 666 cases of typhoid, treated at Zurich during three years time. He found that a second attack occurred in 4.2 per cent. (twenty-eight persons). Susceptibility to typhoid infection was not destroyed by a first or second attack; cases of three and four times repeated infection were observed. The mortality of repeated attacks was the same as those of first illness, and the severity of the symptoms was the same. Men are more liable to repeated attacks of typhoid than women.—*Correspondenz-Blatt für Schweizer Aerzte*, May 1, 1888.

Antipyrin Locally in Gonorrhœa.—Audhoui prescribes:

Aq. rosæ,	
Aq. lauro-ceras.	āā ℥ 3⅛.
Antipyrin.	gr. 75.
Zinc. sulphat.	gr. 7½.

For urethral injection.—*Revue de Thérapeutique*, May 1, 1888.

Permanganate of Potassium Locally in Diphtheria.—Mason, in the *Brooklyn Medical Journal* for May, 1888, writes that a solution of permanganate of potash, used in the form of a spray through the atomizer, has given him more satisfaction and better results than any other drug so used. A stock solution is prepared of potas. permanganate, ℥ij to distilled water ℥iij, or grs. v to ℥j; ℥j of the solution is added to about ℥jss or ℥ij of water, the average capacity of the atomizer bottle. It is then ready for use as a spray, in the manner already indicated.

The first notable effect is the almost immediate arrest of the fetor exhaled by the patient; and when once this is corrected and the disinfection properly kept up, it will not recur during the treatment.

The Disinfection of Rooms Occupied by Infectious Cases.—SWEETING, Superintendent of the Western Fever Hospital, Fulham, describes his method of disinfection as follows; The wards of this hospital, the walls of which consist partly of brick piers and partly of corrugated iron lined by felt and matchboard (in that order from without inward), have over and over again been used, after disinfection, successively for smallpox and for febrile diseases of various kinds—e.g., scarlet fever, measles, diphtheria, enteric, etc. In no case whatever has the preceding disease affected the new occupants of the ward. The plan consists in free fumigation by nitrous fumes (produced by the action of nitric acid on copper filings), followed by thorough cleaning by carbolic soap and water of all wood and iron work, and by distempering the brick portion of the wall of the ward.—*Lancet*, May 5, 1888.

The Treatment of Fissure of the Anus.—CRÉQUY has secured good results by instructing his patient to empty the bowels thoroughly by injections every morning, after which the surgeon lays in the fissure in the mucous membrane of the anus a pledget of lint soaked in a solution of chloral, one to five. This remains until it is expelled when the bowels move on the following morning, when another is inserted.—*Gazette de Gynécologie*, May 1, 1888.

Jambul in Diabetes.—OLIVER reports, in the *Lancet* of May 5, 1888, his use of jambul as follows:

Jambul was recommended a few months ago as a cure for diabetes mellitus. The powdered seed was credited with having the property of diminishing the secretion of urine and of arresting the formation of sugar. Four patients suffering from diabetes have been treated by me with powdered jambul. I began with five-grain doses thrice daily, and gradually increased the dose to fifteen grains. Two of the patients died, both from coma; the other two are still alive, but are no longer taking the drug. It cannot be said that any one of them received the slightest benefit. The daily amount of sugar passed out of the system was not diminished, thirst was not in any way abated, the daily discharge of urine remained as before, and the weight of the body was not increased. In one of the cases, strange to say, two days after taking the jambul the daily elimination of sugar fell from 4000 to 600 grains, but on the following and succeeding days the amount rose, and by degrees increased until it reached the sum eliminated before the drug was administered. Arterial tension was not in any way affected by the drug.

Tolerance of Bacteria by the Lining Membrane of the Uterus.—STRAUS and TOLEDO, at a recent meeting of the Academy of Sciences of Paris, reported experiments upon animals of various species, which had recently given birth to young by normal parturition. They introduced into the uteri of such animals large numbers of microbes ordinarily pathogenic to them, but with infection. Only the microbe of chicken cholera proved infective. The experimenters offered no explanation of this interesting phenomenon.—*Gazette Hebdomadaire*, April 20, 1888.

The Treatment of Enlarged Prostate by Electrolysis.—At a recent meeting of the Berlin Medical Society, CASPER reported cases of hypertrophied prostate treated by electrolysis, by the following method:

He first experimented upon animals to determine whether the destruction of the tissue of the prostate would cause disturbance in the animal's general health. Finding that electrolysis upon these tissues was followed by no ill effects, he operated upon four patients by placing a broad electrode from a battery of twelve cells, furnishing the constant current, over the pubes; a point for puncture was selected by examining the prostate by the finger in the rectum, and a needle was introduced into the prostate through the rectal wall. The needle was connected with the negative pole of the battery, and a current of from ten to twenty-five milliampères was passed. Without withdrawing the needle from the rectal wall, Casper inserted it into three points in the prostate; the operation lasted fifteen minutes, and, as the needle was carefully insulated, no damage was done to the rectal and surrounding tissues. Of the four patients so treated, two were much improved; one was not influenced by the treatment, one was injured by defective insulation of the rectal needle.—*Deutsche medicinische Wochenschrift*, April 26, 1888.

Phenacetine.—SUCKLING, in the *British Medical Journal* of April 28, 1888, reports his experience in the use of phenacetine as follows:

During the past three weeks I have been using this drug as an antipyretic, and I can confirm Dr. Bell's statement as to its efficacy. I find that it is quite equal to antipyrin, but it is not nearly so powerful as antifebrin.

Phenacetine in moderate doses is not followed by any disagreeable after-effects. Antifebrin, on the other hand, causes profuse perspiration accompanied with great depression and should be given with care, not more than five grains at a time to an adult. Rigors occur after both antipyrin and antifebrin, but I have not yet observed them after phenacetine.

From five to ten grains of phenacetine may be safely given to an adult and frequently repeated. It reduces the temperature considerably in two or three hours, but the reduction is a very transient one, lasting a few hours only.

I consider sponging with tepid or cold water to be far more effective and agreeable than any of the antipyretic drugs, and it not only reduces the temperature but it relieves thirst, induces sleep, and is agreeable to the patient.

Abdominal Pressure in Hysteria.—DR. A. M. DOKHMAN, in a note communicated to the *Russkaya Meditsina* on the arrest of hysterical paroxysms by pressure on the "ovary," points out that the treatment is by no means new, as blows on the abdomen used to be administered by means of iron instruments in the Senmedarski epidemic, and were employed very largely by Goltz as early as 1727. He suggests that, although pressure is made over the region of the ovary, it does not appear that the ovary has much to do with the effect produced, for similar pressure is efficacious where no ovary exists—that is to say, in male patients. He is disposed to compare the effect to that produced by compression of the carotid artery, which will sometimes arrest a paroxysm, and he suggests that the sudden stimulation of the splanchnic nerves may produce an alteration in the vasomotor relations, and in this way may cause the arrest of the paroxysm.—*Lancet*, April 28, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,
PER ANNUM, IN ADVANCE . . . . . $5.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JUNE 16, 1888.

THE ORIGIN OF TYPHOID FEVER IN HOSPITALS.

HOLDING, as we firmly do, that certain of the infectious diseases can, in the course of time, be "stamped out," we hail with satisfaction every carefully worked-out contribution to preventive medicine. The study of familiar diseases from the standpoint of etiology is, as yet, far from attracting the attention it merits among sanitarians and pathologists. To the profession at large it is too often a matter of curious theoretical speculation, rather than a subject of every-day, practical application.

Etiological investigations, to yield full results, must include not only the life-history of the *contagium*, but also, to the minutest detail, the mode of the *contagion*. The acquisition of this kind of knowledge, and its general acceptance by practitioners and the people, will render scarlet fever and variola as rare in well-ordered communities as the plague now is in Western Europe, and keep the cholera east of Suez.

Especially do these remarks apply to typhoid, the great fever of the present historical era, the endemic, acute, infectious disease of modern civilization. This is a disease the spread of which can be absolutely controlled by the systematic, routine application of the simplest rules of disinfection. Not only in theory but in practice is it within the power of the physician to prevent any individual case under his care from becoming a focus of contagion, and to destroy the infecting principle definitely and finally. The rigid application of preventive measures to every case, and the detection and eradication of foci of contagion outside the human body, would soon lead to the extinction of typhoid fever in the most gravely infected locality.

FITZ has recently made a critical investigation of eleven cases of typhoid fever, of which seven probably, and four possibly, originated in the Massachusetts General Hospital in the course of six years, from 1882 to 1887 inclusive (*Boston Medical and Surgical Journal*, May 24, 1888). While the evidence of infection within the hospital is in none of these cases absolutely conclusive, it warrants the fear that familiarity has bred contempt for a danger that is real, and that we may be less habitually careful in guarding the medical officers, ward assistants, nurses, servants, patients and laundry workers against typhoid infection than the facts demand. The Massachusetts General Hospital, however, affords in these cases an experience widely at variance with that of other institutions. Hutchinson, whose article in the *System of Medicine* is referred to by Fitz, saw only one case of typhoid originate in hospital in twenty-four years: Murchison has collected, in his *Treatise on the Continued Fevers*, an imposing array of facts and testimony as to the infrequency of ward contagion. Liebermeister, in an enormous experience, has seen no case develop in hospital, except such as were attributed to defect in drainage.

The "special directions in typhoid fever," suggested by Fitz and his colleagues, are worthy of general adoption. They are as follows:

"1. Mattresses and pillows (when liable to become soiled) are to be protected by close-fitting rubber covers.

"2. Bed and body linen are to be changed daily. Bed-spreads, blankets, rubber sheets and rubber covers are to be changed at once when soiled. Avoid shaking any of these articles.

"3. All changed linen, bath-towels, rubber sheets and covers are to be immediately wrapped in a sheet soaked in carbolic acid (1 : 40). Remove to the rinse-house as soon as possible, and soak six hours in carbolic acid (1 : 40). Then boil the linen for a half hour, and wash with soft soap. The rubber sheets and covers are to be rinsed in cold water, dried and aired for eight hours. The bed-spreads and blankets are to be aired eight hours daily.

"4. Feeding utensils, immediately after being used, are to be thoroughly cleansed in boiling water.

"5. Dejections are to be received into a bed-pan containing half a pint of carbolic acid (1 : 20). The nates are to be cleansed with paper and afterward with a compress-cloth wet with carbolic acid (1 : 40).

"6. The bed-pan and cloths are to be carried to the tower. Add two quarts of carbolic acid (1 : 20) in divided portions to the contents of the bed-pan; mix thoroughly by shaking, and throw the liquid into the hopper. The bed-pan and hopper are to be cleansed with carbolic acid

(1 : 20), and wiped dry. The cloth used for the above purpose is to be at once burned.

"7. The corpse is to be covered with a sheet wet with carbolic acid (1 : 40).

"8. After the discharge of the patient from the hospital, the mattresses are to be thoroughly beaten and aired every day for a week. The bedstead is to be washed with corrosive sublimate (1 : 1000).

"9. These directions are to be followed until the patient is free from fever."

These rules, if carefully observed, would save much pecuniary loss, suffering and life. Useful as they would be in hospitals, their greatest value would be shown in private practice. The way to escape danger is not to ignore it, but to recognize it, proclaim it and intelligently guard against it.

AN ADVANCE IN MEDICAL EDUCATION.

In his recent address, as President of the American Medical Association, Dr. Garnett proved from the statistics collected by government, what ought to be conceded without argument, that medical colleges exacting a graded course of intra-mural study extending over three years, produced better qualified doctors than those requiring but two years of intra-mural instruction. He thought that the Association might take a hand in reforming the two years colleges by a peremptory call upon them to meet in convention and adopt uniformly the higher methods under penalty of exclusion of future two years graduates from membership in the American Medical Association. The plan, however excellent, is impracticable, since a large part of the active membership at each meeting of the Association is made up of teachers in two years schools, who will oppose all mandatory legislation. If the colleges ever convene for this purpose, it must be as the result of pressure from without, from the State Examining Boards, from the medical press, from the general public, including the non-teaching part of the profession.

It is an open secret that during last winter active efforts were made to get the leading medical colleges of Philadelphia and New York to adopt an obligatory three years course. Strange to say, opposition was developed where it was least expected. The school having the amplest facilities for thorough and extended teaching did not feel that this entailed any immediate obligation to lengthen and make more practical an antiquated course of instruction.

It is a pleasure to learn that Jefferson Medical College of Philadelphia has announced its intention, two years hence, to make an extension of its obligatory, intra-mural instruction to three annual winter sessions. East of the Ohio River but three colleges have taken this step, Harvard, the University of Pennsylvania, and now Jefferson Medical College. To this complexion all the colleges must come at last. The Maryland State Board of Health has announced a medical practice act, which, like that of Illinois, requires a three years course; and the Medical Examiners of California, after April 1, 1891, will not recognize diplomas from schools that do not require attendance on three full regular courses of lectures delivered in three separate years. No half-way house is allowed on the road, no such paltry substitutes as one year of home study from a syllabus will be recognized in these States as anything but a pretence of systematic instruction.

Two years college faculties are made of mortal stuff, and however indifferent they may seem to professional clamor, they cannot much longer keep their god-like serenity. If the unendowed professors of Jefferson Medical College, with their expensive hospital, laboratories and salaried corps of instructors, now, in compliance with the demands of higher education, take this step, it must be with some assurance of professional support. They will doubtless have diminished revenues for a term or two, but with the sympathetic support which the profession and the public have already shown for the cause of improved medical education, their loss will be only temporary, and at the same time the Jefferson school will strengthen its ancient prestige while making troops of new friends.

It is gratifying to find Philadelphia maintaining its old reputation as a centre of medical education, and that its two prominent schools have committed themselves to the cause of improved medical instruction. We hope that they, with Harvard, will not long stand alone in this advance, but that we may soon have the pleasure of also recording that the other leading schools have taken a like step.

CEREBRAL SURGERY.

On April 30th, Dr. W. W. Keen operated successfully on his third brain case. The patient was a man, aged twenty, who had suffered from epilepsy for seven years. The cause was obscure, but observation of a number of attacks showed that they all began in the left hand, and it was hoped that excision of the hand centre would arrest the attacks.

This centre lay in the post-Rolandic convolution, toward its inferior extremity.

An inch and a half trephine opening was made over the selected spot, and subsequently enlarged to two and a quarter by two and a half inches. Three parallel convolutions were disclosed, and it was difficult to decide which was the post-Rolandic convolution. By the use of a faradic battery, however, the hand centre was readily determined to lie in the anterior of the three gyri. This portion was excised. The membranes were œdematous over all three gyri, though to the eye the brain tissue itself seemed normal. After securing the dura, the trephine button and a number of the smaller fragments were replaced, and suitable drainage employed. The stitches were all removed in five days, the temperature never having risen above 100° F., and on the eighth day the patient was so well that he went out and was shaved. The integrity of the skull is entirely reëstablished.

The left hand has been paralyzed ever since, but no other paralysis has followed, thus establishing clearly the localized function of this part of the cortex. The epileptic attacks were at first increased in number, but have so far progressively diminished in frequency and severity. Should the ultimate result be favorable, it will go a long way to encourage such surgical treatment of this distressing malady.

At the meeting of the Pennsylvania State Medical Society held in Philadelphia, last week, Dr. J. B. Murdoch, of Pittsburg, was elected President for the ensuing year. The next meeting will be held at Pittsburg.

The New Hampshire Medical Society will hold its ninety-eighth annual meeting on Tuesday, June 19, 1888, at 11 o'clock A.M., under the presidency of Dr. S. W. Roberts, of Wakefield.

We take pleasure in calling attention to a letter from the Port Physician of Philadelphia in reference to the introduction of smallpox into Philadelphia last winter, which appears in another column. He claims that there was no evidence at the time to justify the detention of any passenger on the ship which is supposed to have brought over the first case.

The State of New York will be the first to make trial of electricity as a means of execution instead of hanging, Governor Hill having, after some delay, concluded to approve a bill for that purpose, passed by the State Legislature. The bill makes some other changes which are reformatory: the execution must take place at a State prison, and not at a county jail, as formerly; the priestly offices must be private; no farewell speech or publicity of funeral is allowed; the only attendants shall be the specified officers of the law; all parade and ostentation of sympathy are prevented. The law will go into effect January 1, 1889. One feature of the new bill which may be regarded as of doubtful expediency is that the selection of the form of instrument or means through which the fatal current is to be applied to the condemned person is left with the warden in charge of the prison in which the penalty is enforced.

On May 27th, at the Women's Clinic of the Berlin University, a bust of Prof. Carl Schröder was unveiled with appropriate ceremonies.

In the *British Medical Journal* of April 14th, Mr. Henry Fenwick gives the history of a case of urinary calculus consequent upon an ovariotomy two years before. The nucleus of the calculus was a silk ligature used in securing the pedicle. One or more ligatures ulcerated their way through into the bladder, causing cystitis and stone. By means of the electric cystoscope, one of these foreign bodies was seen before removal from the bladder.

Professor Leopold Max Politzer, the well-known specialist in children's diseases, died in Vienna on May 23d, aged seventy-four years. A contemporary of Skoda and Oppolzer, it devolved upon Politzer to place his chosen work upon a scientific basis; and, at a time when the Vienna Medical School was in its glory, to nurture his department and give it a worthy position. He was the founder of the *Jahrbuch für Kinderheilkunde* and of the Children's Hospital, now conducted by his former pupil and friend, Kassowitz. Politzer was made a Professor in the University in 1875. By his learning, his humanity, and his modesty, he earned the confidence of the public, as well as the esteem of his colleagues.

REVIEWS.

Transactions of the Brooklyn Pathological Society. Session of 1885–86. A. H. P. Leuf, M.D., Editor. New York: D. Appleton & Co., 1887.

This handsome and ably edited volume gives evidence of active work on the part of the Brooklyn Path-

ological Society. It contains descriptions of the various specimens in morbid anatomy, many of them of great interest, with abstracts of the discussions thereon. In addition there are a number of formal papers on various subjects of interest in general and special pathology. Judging from the active discussion and criticism these papers called forth, carried out in a truly scientific spirit, they must have been the most valuable and instructive part of the winter's work. As an example of the variety and practical interest of these articles we may mention: "The Nervous Symptoms of So-called Lithæmia," by Dr. Landon Carter Gray; "Some Serious Sources of Error in Studying the Course of Disease," by Dr. R. G. Eccles; and "The Pathology of the Lymphatic Glands in Children," by Dr. Henry N. Read.

CORRESPONDENCE.

QUARANTINE AT PHILADELPHIA.

To the Editor of THE MEDICAL NEWS,

SIR: I beg your indulgence for a few words of explanation in regard to your editorial comment and disquisition upon "Inefficient Quarantine," contained in THE MEDICAL NEWS of June 9th.

He who excuses, also accuses himself; therefore, I shall make a simple statement of the unvarnished facts and legal aspects of the case. Both officers and passengers of vessels have rights which are entitled to respect, in so far as those rights do not conflict with the *public* safety and welfare. The law very distinctly defines that the Port Physician has the right to detain any vessel whose passengers, officers or cargo may offer any evidence of suspicion as to being carriers of contagious disease. Now as to the case in question, and concerning which you have evidently been misinformed, I would say, that the said vessel, reported to have entered this port about February the first, containing a case of smallpox, did not at the time of entry present any evidence of contagious disease, either among the crew or passengers. During my close inspection of the said vessel, its crew and passengers, there was not manifest any symptom, either objective or subjective, to warrant a diagnosis of contagious disease. It may be well, also, to state, that the period of incubation of smallpox varies from five to fifteen days. Furthermore, the vessel presented a clean bill of health; "no sickness on board" attested to, under oath, by the captain and surgeon.

I trust that the above statement will suffice in placing the matter in its proper light, and receive the fair and impartial consideration which it merits.

Very truly,

W. H. RANDLE, M.D.,
Port Physician.

PHILADELPHIA, June 13, 1888.

THE TOXIC SYMPTOMS OF STROPHANTHUS.

To the Editor of THE MEDICAL NEWS,

SIR: On May 22, 1888, I was called to see a female child of five summers, who had thirty minutes previously been given by mistake of the mother *twenty drops* of the tincture of strophanthus hispians.

The face was flushed, lips scarlet; eyes brilliant; elevated temperature; skin dry, tongue normal. Pupils quivering, dilating and contracting alternately every few seconds; pulse 140, arteries distended; left ventricle contracting with unusual vigor; aortic valves closing with a loud and distinct "tup;" a slight mitral regurgitant murmur; intellect clear. The child was precociously loquacious during the five hours in which the toxic symptoms were apparent.

The treatment was half drachm doses of fluid extract of ipecac with copious drinks of warm water, repeated every ten minutes until the child had vomited five times, then followed with a half drop of tincture of aconite and one drop of the ipecac every half hour until the skin moistened and the pulse became normal. No urine was passed for ten hours after taking the drug.

HORACE Y. EVANS.

PHILADELPHIA, June 11, 1888.

NEWS ITEMS.

The American Laryngological Association announces the following programme for its Tenth Annual Congress, to be held in Washington, D. C., on September 18th, 19th and 20th, 1888:

Ten Years of Laryngology. By Rufus P. Lincoln, M.D., of New York.

Congenital Bony Occlusion of the Posterior Nares. By Charles H. Knight, M.D., of New York.

The Effects of varying Rates of Stimulation on the Action of the Recurrent Laryngeal Nerve. By Franklin H. Hooper, M.D., of Boston.

Subglottic Laryngeal Enchondroma. By E. Fletcher Ingals, M.D., of Chicago.

A Photographic Study of the Laryngeal Image during the Formation of the Registers and Production of Variations in the Pitch of the Singing Voice. By Thomas R. French, M.D., of Brooklyn.

Lupus of the Nose, Pharynx and Larynx. By Samuel Johnston, M.D., of Baltimore.

Imaginary Lingual Ulceration. By George M. Lefferts, M.D., of New York.

A Possible Substitute for Tracheotomy and Intubation in certain Cases. By Edgar Holden, M.D., of Newark.

Antiseptic Nasal Surgery. By Clarence C. Rice, M.D., of New York.

A Case of Sarcoma of the Tonsil. By Alexander W. Mac Coy, M.D., of Philadelphia.

A Case of Subglottic Chronic Stenosis of the Larynx Cured by Dilatation. By Frank Donaldson, M.D., of Baltimore,

Internal Œsophagotomy. By John O. Roe, M.D., of Rochester.

The Treatment of Atrophic Rhinitis by the Galvanic Current. By J. H. Hartman, M.D., of Baltimore.

The Anatomy of the Nasal Chambers. By Harrison Allen, M.D., of Philadelphia.

Notes on a Case of Nasal Caries, complicated with Meningitis; successfully treated by means of a Surgical Drill. By William C. Jarvis, M.D., of New York.

On Fixation of one or both Vocal Bands in the Phonatory Position. (So-called Abductor Paralysis.) By F. Donaldson, Jr., M.D., of Baltimore.

Residence at certain High Altitudes as a means of Cure for Laryngeal Phthisis. By Clinton Wagner, M.D., of New York.

Further Investigations as to the existence of a Cortical Motor Centre for the Human Larnyx. By D. Bryson Delavan, M.D., of New York.

Besides the above titles, papers have been promised by Drs. Morris J. Ash, J. Solis-Cohen, John N. Mackenzie and Beverly Robinson; and by Dr. A. Gougouenheim, of Paris.

Dartmouth Medical College.—Dr. Paul F. Mundé, at the request of the Faculty of Dartmouth Medical College, has consented to deliver the course of lectures on Gynecology at that institution this year, beginning July 13th, to fill the vacancy caused by the death of Dr. Dunster. Dr. William H. Parish, of Philadelphia, will give the course of lectures on Obstetrics.

A New Chest and Throat Dispensary has been inaugurated at 411 Spruce Street, Philadelphia, under the auspices of the Protestant Episcopal City Mission. Drs. F. P. Henry, Thomas J. Mays and William M. Angney are the medical staff of the chest department, and Drs. A. W. Watson and C. Jay Seltzer, that of the throat department.

An Exposition of Aids to Scientific Research.—The *Lancet* of May 12, 1888, writes that a most interesting adjunct to the meeting of German naturalists and physicians, which is to be held at Cologne, from Sept. 18th to the 23d next, will be its exposition of the mechanical aids to research, scientific in general, and medical in particular. In twelve comprehensive groups, every kind of instrument or appliance in surgery, medicine, and practical hygiene will be represented—among the exhibitors being some of the most noted mechanicians in Europe.

An Engraved Portrait of Dr. C. R. Agnew.—At the last meeting of the Ophthalmological and Otological Section of the New York Academy of Medicine, the following motion was made and carried:

"That a committee be appointed, of which the chairman of the Section, Dr. David Webster, be a member, whose duty it shall be to obtain a good photograph of the late Dr. Cornelius R. Agnew, for the purpose of having engravings suitable for framing made from this. The right of issue and sale of such engravings shall be given to some first-class publisher, if practicable; if not, the committee shall offer them to the profession at cost."

In accordance with the above, a committee has been appointed. Members of the profession who desire such an engraving, accompanied by an autograph signature, should send their names and addresses to the Secretary of the Committee, Dr. Charles H. May, 640 Madison Avenue, New York City, at once. When all such names shall have been recorded, those who have requested a copy of the engraving will be notified of the cost of the same, either by the publisher, or by the committee having the matter in charge.

Professor Donders attained on May 27th his seventy-first year, an age at which the Dutch law compels him to resign his professorship in the University of Utrecht. At the festivities with which the occasion was celebrated, a large number of distinguished men, not only from all parts of Holland and the Dutch colonies, but from this and other countries, assembled. An address was presented to Professor Donders, recognizing his forty years' services to science and humanity. The Professor announced that he desired the memorial fund to be appropriated to assisting young physiologists and ophthalmologists at the University. The King conferred the distinction of Commander of the Golden Lion on Professor Donders, and the Government was represented at the ceremony by the Home Minister. King Humbert sent him the Order of the Crown of Italy, and Sir Joseph Lister congratulated the Professor on behalf of the Royal Society of England. A medal was also struck commemorative of the day's ceremony. Professor Donders declared that, although he was leaving the University, he had not finished his task. A banquet was given to him in the evening.—*British Medical Journal*, June 2, 1888.

Impure Ice.—The danger of an impure ice supply has been the subject of a very thorough investigation by the Massachusetts State Board of Health, which attributes many cases of typhoid fever occurring in cities in autumn to bad water and the results of bad drainage, or none at all, at the summer resorts. The board, therefore, urges upon people who are considering the question where to spend the summer, the importance of selecting places which have proper drainage and pure water supply. In places where ponds are made for the purpose of collecting water for a supply of ice, it is almost certain to be contaminated with sewage, as freezing does not kill, but only conceals, bacteria. A most mysterious case of wholesale poisoning at a summer hotel was finally traced to the impure ice which had been secured from neighboring, shallow ponds. Upon analysis, the melted ice was found to contain, in suspension, a large quantity of decomposed, vegetable matter. The organic matter mostly settled at the bottom of the vessel, but the lighter matter remained diffused through the water. The pond, the source of supply, was examined and found stagnant, and at one end a putrescent mass emitted an intolerably offensive odor. It was reasonably supposed that the ice was the cause of the sickness, and upon its disuse the epidemic abated. Prof. Raphael Pumpelly, who made investigations for the National Board of Health, has no doubt that ice can carry any disease that the water from which it is frozen can convey and that there is even more danger from the ice than there is from the water itself, since sewage is more easily decomposed in summer than in winter. While in cities the greater part of the ice received is pure, in towns where the supply is taken from shallow ponds, both the water and the ice may be a source of danger.—*American Analyst*, June, 1888.

A Prize Awarded.—The Institute of Venice has just awarded the Balbi-Valier prize in Medico-Chirurgical Science, value 6000 francs ($1200), to Professor Sangalli, of Pavia, for his work, "La Scienza e l'Arte dell' Anatomia Patologica." Dr. Sangalli is the Nestor of Italian anatomists and pathologists, and his essay, full of independent research and original thought, has also a special historical value.

The Death of Dr. Snowden.—DR. JOHN WIEGAND SNOWDEN died at Hammonton, N. J., on May 28, 1888.

Dr. Snowden was born in Philadelphia, April 22, 1823. He was the son of Thomas Snowden, who was, for over thirty years, associated in business with John Wiegand,

as a manufacturer and importer of surgical instruments in Philadelphia.

He was educated at the "Engle" classical school in Philadelphia, assisted Dr. George McClellan as demonstrator of anatomy, and graduated from the Medical Department of the University of Pennsylvania in 1844. He commenced the practice of medicine in his native city, but soon removed to Middletown, Delaware, and thence to Chew's Landing, Camden county, New Jersey. He was of feeble constitution and subject to pulmonary diseases. Learning from the natives that a residence in the barrens of New Jersey, called the "Pines," was a sovereign remedy for these affections, he removed, in 1846, into what was then the centre of that wilderness, near where is now the Angora station on the Camden and Atlantic Railroad. In June, 1849, he joined the Camden County Medical Society, and was at his death the oldest member on its roll. He had filled all the important offices in the Society, having been twice its president, and for nine years chairman of its "Standing Committee," resigning, in 1887, in consequence of ill health. He was a member of the New Jersey State Medical Society, and its president in 1882, a member of the American Medical Association and of the Obstetrical Society of Philadelphia. A few years prior to his death, he removed from Angora to Hammonton, six miles below the former place, and just within the limits of Atlantic County, where he died May 28, 1888.

At a special meeting of the Camden County Medical Society held at Camden, N. J., May 30, 1888, the following was ordered to be placed upon the minutes.

"In the death of Dr. John W. Snowden, who was a member of this Society for thirty-nine years, who rarely was absent from its meetings, who filled its highest posts of honor, maintained its dignity, and used his rich fund of experience and ripe judgment in the interest of harmony, this Society has sustained a great loss."

"We commend to the members of the Society this bright example of the true physician, one who, for forty years, by night and by day, in sunshine and in storm, devoted talents, worthy of a more brilliant theatre, to the people of a sparsely settled district, and ministered with great medical skill to alleviate their sickness and sufferings; and often with true Christian piety, furnished them with spiritual consolation."

"We extend to his bereaved family our sincere sympathy in their sorrow and loss, knowing that, although his place cannot be filled, their and our remembrance of him will be of one who, in all his relations in life, both public and private, was the embodiment of purity, honor and dignity."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING JUNE 9, 1888.

MAGRUDER, A. F. *Surgeon.*—Detached from the "Yantic" and granted sick leave.

BATES, N. L., *Medical Inspector.*—Ordered to the "Richmond."

KIDDER, B. F., *Medical Inspector.*—Detached from the "Richmond," and waiting orders.

MACKIE, B. F., *Surgeon.*—Detached from the Naval Examining Board preparatory to sea service.

HEYL, T. C., *Surgeon.*—Ordered to the Receiving Ship "St. Louis."

STREETS, T. H., *Surgeon.*—Detached from the "St. Louis," and ordered to the Medical Examining Board as Recorder.

DUBOISE, W. R., *Passed Assistant Surgeon.*—Detached from the Naval Hospital at Norfolk, and ordered to the "Jamestown."

WELLS, HOWARD, *Passed Assistant Surgeon* —Detached from the "Jamestown," and ordered to the Hospital at Chelsea.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING JUNE 9, 1888.

BAILHACHE, P. H., *Surgeon.*—Detailed as Chairman of the Board of Examiners, to meet in Washington, June 25, 1888. June 8, 1888.

FESSENDEN, G. S. D., *Surgeon.*—Detailed as a member of the Board of Examiners, to meet in Washington, June 25, 1888. June 8, 1888.

PURVIANCE, GEORGE, *Surgeon.*—Detailed as Recorder of the Board of Examiners, to meet in Washington, June 25, 1888. June 8, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 29 TO JUNE 11, 1888.

WHITE, ROBERT H., *Major and Surgeon.*—Will report to the regimental commander, First Infantry, to accompany Headquarters, Field, Staff, Band and Battalion of the First Infantry to Santa Barbara, Cal., on or about June 15, 1888, to remain until about September 1, 1888.—*S. O 25, Division of the Pacific*, May 28, 1888.

APPEL, D. M., *Captain and Assistant Surgeon.* — Upon the arrival of Captain J. V. Lauderdale, Assistant Surgeon, at Fort Davis, will proceed to Camp Pena Colorado, Texas, for temporary duty at that camp; and upon the return of First Lieutenant H. S. T. Harris, Assistant Surgeon, to Camp Pena Colorado, Assistant Surgeon Appel will return to Fort Davis.—*S. O. 57, Department of Texas*, May 28, 1888.

KEAN, J. R., *First Lieutenant and Assistant Surgeon.*—Will accompany Troop C, Ninth Cavalry, from Fort Robinson, Nebraska, to Fort Du Chesne, Utah, and return with Troop B, Ninth Cavalry, to Fort Robinson.—*S. O. 39, Department of the Platte*, May 19, 1888.

MORRIS, E. R., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for one month, with permission to apply for an extension of one month.—*S. O. 61, Department of Arizona*, May 28, 1888.

FINLEY, JAMES A., *Captain and Assistant Surgeon.*—Granted leave of absence for six months, on surgeon's certificate of disability, with permission to leave the Division of the Missouri.—*S. O. 129, A. G. O.*, June 5, 1888.

BENHAM, ROBERT B., *Captain and Assistant Surgeon.*—Is relieved from duty at Fort Du Chesne, Utah, to take effect upon completion of the duty assigned him in par. 2, S. O. 33, c. s., Department of the Platte, and will then proceed to Fort Laramie, Wyoming, reporting to the commanding officer for duty at that post.—*S. O. 44, Department of the Platte*, June 4, 1888.

PILCHER, JAMES E., *First Lieutenant and Assistant Surgeon.* —Detailed as a member of a Board of medical officers appointed by S. O 108, A. G. O., May 10, 1888, to meet at the U. S. Military Academy, West Point, N. Y., to examine candidates for admission to the Academy, etc., vice Major Robert M. O'Reilly, Surgeon, relieved.—*S. O. 128, A. G. O.*, June 4, 1888.

CHERBONNIER, A. V., *Captain and Medical Storekeeper.*—Granted leave of absence for four months, on surgeon's certificate of disability —*S. O. 133, A. G. O.*, June 9, 1888.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

VOL. LII. SATURDAY, JUNE 23, 1888. NO. 25.

ORIGINAL LECTURES.

ON THE MUSCULAR REACTIONS KNOWN AS TENDON-JERKS AND MUSCLE-JERKS.

A Lecture Delivered at the Infirmary for Nervous Diseases, May 17, 1888.

BY S. WEIR MITCHELL, M.D.,
PHYSICIAN TO THE INFIRMARY.

IT has long been my wish to give in this hospital a series of lectures on certain symptoms of nervous diseases. This would have included what I may call their natural history—the modifications they exhibit in various diseases and in different people. Circumstances will interfere with the full development of my project, and I shall this May be able to give but one lecture. For this I have chosen muscular reactions in health and in disease, and, limiting our study to mechanical stimuli, I shall have little to say as to electricity.

There are symptoms which exist in health and are changed or abolished by disease. There are reactions known only to disease. Most of the muscular reactions are present in the healthy, and are merely altered by sickness. I have selected them for treatment in this lecture because a full enough statement of recently acquired knowledge as to them is not to be found in the text-books, and because with the material in our wards it is easy to illustrate my subject.

These symptoms, which are also facts of health, include what results we get from striking a tendon, and those which follow a blow on the muscular tissue.[1]

If the tendon of a muscle be abruptly pulled upon, the like effect is conveyed through it to the muscle and this responds by a contraction, which in turn pulls on the tendon and moves the connected part. In certain morbid states any muscle can be made to react to a blow on its tendon, but in health, with less sensitiveness of muscular reply, only favorably situated tendons can be so used with certainty of response. The tendon must span some region of soft tissue, so that being struck while tense, it may be driven down in a loop, and thus occasion a quick jerk of the muscle. The lower tendon of the patella and that of the gastrocnemius are best situated; the biceps at the elbow, not quite so favorably; and the temporals reply to a blow on the lower jaw.[2]

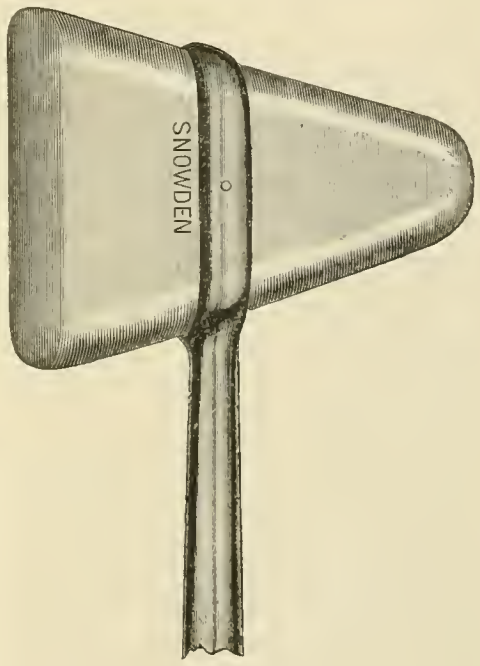
Tendon-jerks may be had elsewhere even in health, but care is needed, and peculiar forms of hammer. Indeed, for accurate study of any tendon-jerk the hammer with a head of not too hard caoutchouc is desirable. Dr. J. M. Taylor has devised the one I show you, the long side for use on tendons, and the round end to get muscle responses by a direct blow on the muscle (Fig. 1).

1 For the best account of them see Buzzard's admirable essays, and Ross, p. 162, vol. i.

2 First discovered in this hospital by Dr. Morris J. Lewis.

It will be easiest and best to begin with the study of the knee-jerk or knee-phenomenon, as that was the first of its class to be clinically utilized, the one best known, and most fully studied.

Fig. 1.



Taylor's hammer.

Let us see, in a normal man, how readily to evoke knee-jerk, or what we briefly call K. J.; how to measure it; what modifies it; how to explain it and its variations; and, lastly, what clinical value it has. When we have covered this ground as to knee-jerk, the other like phenomena will demand little additional explanation.

To test roughly the mere presence of knee-jerk, it suffices to set the patient on a table's edge, so that the legs may swing, or to let him cross his legs so as to allow the upper limb to hang passive. Then strike, with the side of the palm, on the tendon of the knee-cap above its tibial attachment, a smart, quick blow. The tendon thus abruptly jerked communicates its motion to the muscle, and this responds in mass by a contraction which moves the leg and foot. A prettier way is to put the left forefinger on the tendon, and then to strike with the other hand, or, better, with the hammer, upon the finger so placed. The faintest response is felt by the finger while the eye may observe also the lift of the foot.

This plan is very useful for examining a man on his back in bed. You properly flex the knee, and with the man's foot at rest on the bed, put a finger on the tendon and strike on it, judging by the sense of touch the

amount of the knee-jerk. Very often I seize the extensor mass with the left hand and strike the tendon with the ulnar edge of the right hand. You thus feel the muscle as it swells responsive to the jerk made through its tendon. In rapid examinations, in women, it is usually easy to decide as to the mere presence of knee-jerk, by striking on the finger without lifting the skirts. The best plan of all is to feel for the tendon, place thereon firmly a small rod about three-quarters of an inch in diameter and covered with rubber tubing, and strike on this. You waste no blows and cause less pain by use of this method, and can at once get the maximum effect. With this arrangement, also, it is easier to get correctly the moment for reinforcements, of which I shall presently speak.

These methods answer very well to tell us simply whether or not knee-jerk exists; but if as to this there be any doubt, we have to resort to other and more careful arrangements. In my clinic, the patient sits at ease, and well back, in a high chair, with the leg and body both at right angles to the thigh. If the response be feeble, it is still better to let the body fall back slightly, and to lift the leg a little above a right angle, so that it rests quite passive. You thus stretch the whole muscle from above and from below before you strike.

It is sometimes hard to make a patient entirely passive, and this passivity, some of the books say, is essential; but a man cannot entirely stop or conceal the knee-jerk response, be he ever so nervous or unable to relax his muscles. *Violent* innervation of the crural nerve will stop it, but milder effort will not.

The books tell you to seat the patient on a table without back support for this examination, but, as I shall soon point out, there is reason in doubtful cases for securing a more passive position, since motion elsewhere unnaturally increases the knee-jerk. For very delicate studies, like those in Lombard's admirable essay, he puts the patient on one side, the leg in a guttered splint, the foot suspended in a stirrup by a long string. Thus placed, the leg moved easily in response to the knee-jerk. In our own researches, a variety of positions were employed. In common practice the crossed leg answers, but if there be doubt as to whether the knee-jerk is either above or below the normal standard, certain precautions must be taken to insure accuracy. The need for such care will be seen as we go on to study what I like to call the natural history of this symptom. Let us observe it. As the hammer falls on the tendon of my patient, at ease on the lounge, or leaning back in a chair, the muscle contracts and the foot and leg are lifted and then fall back. We see that the excursion of the foot is less or more. As we strike again, and again, this excursion varies.

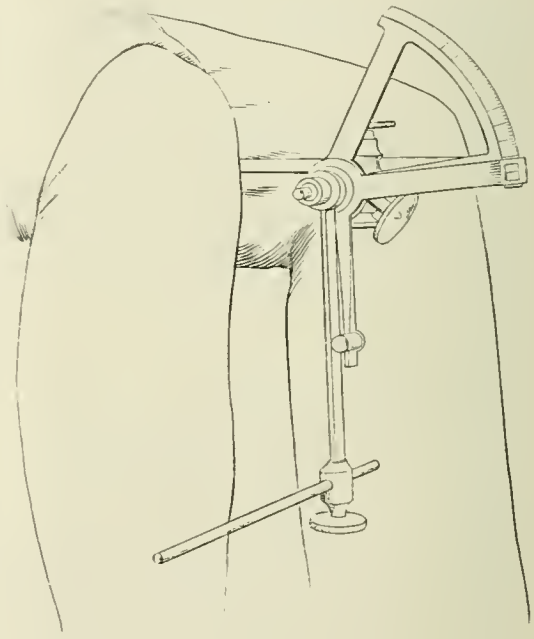
In some normal men, and often in spastic disorders, the jerk calls the opponents into action, and as Lombard shows, when the foot swings laterally suspended, and thus free, it does not always return to its place, as if the muscle did not fully relax. The primary jerk varies, but there is always a maximum beyond which the foot does not go, no matter how hard we strike.

Let us further study the influence of position; I lessen the angle of the leg to the thigh, and, as you see, the repeated blows on the tendon get slighter and slighter responses. A very able observer (Gowers) thinks this is due to the fact that tension is physiologically essential to the evolution of knee-jerk. As to this, I think him mistaken.

It is only mechanically essential (and under certain conditions it is not required at all). The tension enables us to act sharply on the largest mass of muscle. Tension is convenient for this reason. I showed long ago that a certain amount of tension, even in spastic cases, causes knee-jerk to cease. To show this, I place a spastic patient on his belly, and with the knee at a right angle, continue to strike the tendon as I further flex the limb. At a certain point the knee-jerk ceases. This is not (as you might suspect) merely because the tendon is at a disadvantage, mechanically, on account of extreme flexion, as may be easily shown, and very prettily.

The subject is seated, and the knee held at nearly that limit of flexion which stops knee-jerk; as you see, we get fair replies. Then the man is allowed to fall back supine, and the tension thus added at the truncal end of the muscle, stops all knee-jerk. You may now see why we are careful as to position, both of body and of leg.

Fig. 2.



Lombard's meter.

To get the best results out of knee-jerk, a little practice is needed. If we desire greater accuracy in our record than merely to be able to say knee-jerk present in excess or not, we have here, for clinical use, my friend Dr. Warren Lombard's simple meter. The instrument, as I now show it to you, will probably be used by neurologists only. A strong clamp attaches the instrument to a chair raised so as to keep the patient's legs off the floor. A bar which projects between the patient's legs, and which can be pulled out or shortened, carries a dial plate divided into centimetres. A light swinging rod, with a cross bar, is set so as to drop on to the middle of the tibia. The patient sits back at ease; the blow on the tendon is struck; the rising leg lifts the rod, and this carries before it an index which it leaves so as to mark the limit reached.

Two or three blows give us the maximum, and then we go on to get, also, the maximum reinforcement.

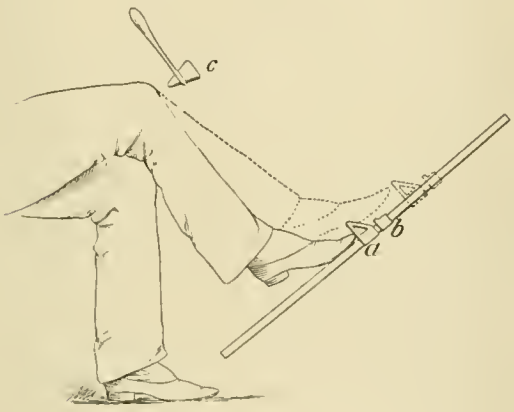
Should this instrument come into use, it would be well to agree on a common method of dividing the dial, and on a common length of lever.

Dr. Lombard's ingenious instrument, which is too costly for common use, set me to thinking how more easily to get a numerical statement of knee-jerk for reference.

With the patient always in the same position, with care to avoid reinforcements, place a yardstick or metre against the wall, in front of the foot, so that some one else can note the height to which the tip of the foot rises; get the maximum from several blows on the tendon, and note it for future use.

Here is a better measure (Fig. 3): A metre or yardstick carries a light, very movable arrangement of wire, about four inches in height, by five inches in breadth (*a*). This is set or fixed so that the toe rising with the tendon-jerk, will push it up the scale. As it moves it pushes up, and leaves behind it as a marker a double loop of wire (*b*). This I had made yesterday. It answers

FIG. 3.



The author's meter.

admirably, and in a little more complicated form will do still better. Needless to insist that the results may not be generally comparable, but, in a measure, they may be, and, for comparison, from time to time, in individual cases, are most desirable.

Our object is, of course, to get a normal expression of the knee jerk. As we avoid, therefore, too great or too slight flexion, so also do we avoid all other influential agencies. Thus, if it did not take too long, you might easily be made to see that pressure on the sciatic nerve, —constriction of the leg (even so slight as that made by a rolled-up pantaloon) serves to lessen knee-jerk. Even fatigue may do this. In my own case, and in others, the knee-jerk is least at night and best in the morning. Moreover, damp, relaxing days lessen it notably, and always after my winter work it is not so good as in the autumn after my holiday. It is different also in most men in the two legs. On the other hand, several things increase the knee-jerk, and may cause it to seem great, when, without such aids, it is not. These influencing additions were called by Dr. Morris Lewis and myself "reinforcements."

What these are—how to avoid their deceptive presence—how also to use them, will be the next subject to which I now ask your attention. About this matter more is known than was at our disposal three years ago. Much of what *is* known was contributed by members of the staff of this hospital, and the four papers which have cast a flood of light on the phenomena of knee-jerk are, I am glad to say, entirely the work of American physiologists.

The germination of thought in crops is often interesting. For years there had been no large addition to our knowledge of knee-jerk, when Jendrássik of Prague made the most interesting observation that certain *violent* motor acts increased the knee-jerk, if they took place in time nearly coincident with it. That he should have here left this fruitful fact without further study seems amazing. Still more that it should have remained for some years almost unnoticed.

Turn with me now to the normal subject before us, and let us illustrate the strange harvest, which for Dr. Lewis and for me, grew out of Jendrássik's pregnant observation. I shall show that every motion, if at all decided (even if it involve a small single muscle), increases knee-jerk. To wink, speak, cough, move a finger is enough, as you see. Probably all coincident motions thus reinforce knee-jerk in degrees which vary with their intensity. A vast range of facts in these directions was evolved by us out of Jendrássik's single statement. Just now they interest us on but one side. Presently we may discuss their cause. Enough at present to show that they teach us two things. First—that when a knee-jerk is seemingly absent an added motor reinforcement may show it to be not entirely lost. Second —that in estimating normal, or other knee-jerks, if we desire accuracy, the patient must be at rest with closed eyes, and neither speak, nor laugh, nor swallow, nor make any avoidable movement.

But while we were thus enormously adding to the singular fact made known by Jendrássik, we discovered a new set of reinforcing agencies. Just as it seemed that all voluntary motion apparently increased knee-jerk, so also, we found that a vast range of sensations had the same power. This discovery has, as yet, been of no direct clinical value. It has, however, been shown by us of late that in certain cases, motor reinforcements fail to act, and sensory reinforcements remain efficient. In others the reverse obtains, and it is to be hoped that as we get clear ideas as to the spinal tracks of reinforcements such knowledge as this may become valuable.

To exhibit an illustration of sensory reinforcements, I strike the tendon lightly, so as to cause a gentle foot movement. Just before the next blow I touch the skin anywhere, on the arm, neck or leg, with ice or a hot blade, or pull a hair or pinch the skin. The results as seen are startling. There seems to be a minimum limit of sensory reinforcement. A touch does not answer, or seems not to do so, and yet, probably all sensory impressions, like all motions, act in this direction. Not all, however, have power visibly to represent their effects. The most tremendous influence is to be had by passing galvanism through the anterior part of the brain, and if we add to this consentaneously also a sensory and a motor reinforcement we get such knee-jerks as elsewhere are seen only in spastic disease. Galvanism, thus used, has probably a complex effect, made up of sensation, motion, emotion, and some other more immediate affections of the brain.

In practice I find you can get the united influence of sensory and motor reinforcements by asking a man to pinch his arm at a signal; if, then, also he should make a grimace, you will have powerful reinforcements of two kinds.

When you come to suspect that a diseased zone of cord may probably reinforce parts below it, such sensory increments become most interesting to think of.

But let us turn, for the time, to the next crop evolved by the work of Lewis and myself. My friend Dr. Warren J. Lombard took up the subject, and with accurate laboratory methods, confirmed all of our results, and added many things of interest. He showed, as we had done, how fatigue of body lessens knee-jerk, how sleep affects it, and how the weather influences it. We come to see, as we read these two papers, that this responsive act represents well the state of the body. For reasons to be later stated, it is as yet clinically valueless in this direction, because of its too delicate cognizance of actions, sensations, and emotions. Indeed, the most brilliant discovery of Lombard was that "emotion enormously affected the knee-jerk." If you listen to music, or read poetry and a passage touches you, the knee-jerk obtained just then is vastly reinforced. A cry of a child, a sudden knock at the door suffices to do the like. And all this is to be remembered, because it gives some clew to the mechanism of reinforcements, and because of the influences of emotion in cases examined, especially for the first time. In fact, emotion seems to be, of all reinforcements, the most remarkable, save galvanism of the head. When, for example, you have before you an hysterical girl, what with fear, excitement, apprehension, and perhaps shame, there is an emotional state which seems strangely competent to exaggerate the knee-jerk, and to do so for some considerable time, making what I might call a quasi-permanent state of reinforcement.

In Lombard's experiments it was brief, transient emotions which were thus active, and he was not called upon to see, as we are, the whole spinal system thus excited for half an hour or more by the grouped excitatory power of many emotions. Every neurologist sees this condition. You strike the knee in an hysterical girl and the knee-jerk is surprising, and with it often enough the other leg flies up, and one arm—usually the left. A blow on the tibia will not do this as a blow on the tendon does. It is a combined result of a blow on the tendon and of emotion.

We see the same thing in the first examination of neurasthenic, timid and apprehensive men. At another visit, the exaggeration is missing. It has gone with the subsidence of emotion, or has much lessened.

I have enumerated most of the known agencies which lessen or increase knee-jerk. There may be many others, and Lombard's study and our own show that in all likelihood the interior operations of the body, and even of the mind, may furnish reinforcing agencies which we have no means of analyzing or explaining.

I have dealt thus far only with the natural history of the evolved symptoms of knee-jerk. What, now, is the explanation of this occurrence?

All muscles have a certain capacity to respond by motion to the two means of excitation known to us. These are, first, mechanical, as a blow, or a sudden pull on the muscles through the tendon; and, second, the various forms of electricity.

Let us deal with the first. I strike a blow on the tendon of the patella below the knee. The crural mass of muscle answers by motion. Again, I strike just above the patella—we are still on tendon—and the muscle moves in mass. I go higher, and the extent of the movement lessens as I leave the tendon. Now, I turn my hammer, and strike with the point on the muscle. There is still motion, but it is limited in amount, and as to the area affected. On the thin chest muscles, with bone beneath them, you see best what occurs. The blow falls; a certain length of fibre shortens, and in some cases, and always in certain situations, just under the hammer a hump of muscle rises slowly, and as slowly falls away. If all at once you could strike every fibre of the muscle, you would have a result in effect like that which the favoring relation of muscle to tendon enables you to get when you strike the latter. So far the two sets of motor responses are much alike; also, there is a further resemblance. Both are reinforcible by distant motion and by sensation. Strike lightly with the rounded hammer point on the supinator longus, and at the next blow tell the patient to shut the other hand strongly, and you get a visible reinforcement.

How, then, do they differ? Both involve primarily the presence of that intrinsic irritability which all muscle possesses. If disease or injury severs the motor or sensory nerve of a muscle, or damages its related spinal centre, the tendon-jerk ceases, but the muscle-jerk from a direct blow remains. The inference is that the spinal cord contributes something, which, by adding to the responsive capacity of the muscle, enables it to move in reply to the pull made on its tendon. The direct muscle blow still causes motion, and whether this response be, in a measure, *lessened* by such nerve or spinal paralysis as *destroys* tendon-jerk, is yet to be learned.[1] The same elements may be needed for the *full* reply to both forms of stimulus, but the direct blow is what I may call a more positive stimulus than the tendon-pull, and so evokes a reply from the intrinsic unassisted muscle quality of excitability. This property of muscle may even be increased by disease which destroys the knee-jerk. The nerve or spinal loss which acts thus destroys for both tendon-jerk and muscle-jerk the capacity to be reinforced by distant motion or sensation, so that here, too, is an added resemblance between muscle-jerk and knee-jerk.

And now as to the mechanism, which, in health, causes a muscle stretched abruptly through its tendon to contract. The mere intrinsic muscular irritability will not suffice. That gives the muscle power to contract under a blow, or from electricity, but something more is wanted to give rise to the response to a pull. What is the addition which supplies this excess of excitability? Whatever it be is present in excess during reinforcements, and whatever explains the mere knee-jerk must also, in a measure, explain reinforcements.

We are thus brought to the much disputed question as to whether knee-jerk be a direct muscle act or a reflex. At first, it seemed simple to suppose it a reflex from the

[1] Thus, if we conceive that both a direct blow and tendon-pull act alike, and both profit by the spinal aid, this latter being taken away destroys the tendon-jerk, but leaves us able to see a muscle-jerk, because, even if this loses something by loss of spinal connection, the mere intrinsic muscle properties enable violent local stimulation to get responses. To prove that something is thus lost, for it is but theory, we have yet to study the facts with more care.

tendon, but when all tendon nerves are cut it still occurs. Then it was presumed to be a reflex, due to the sensory effect of the multiple pulls on the nerves of the muscular aponeurosis, through the tendon. This was supposed to cause excitation of the spinal cord, an efferent motor response ending in a muscle act. This would be an ordinary reflex act. But, as against this, was the fact that the time of a tendon-jerk is not less than a fourth that of a common skin reflex. This objection seemed final to most physiologists as against the reflex theory. And yet, some spinal aid was clearly requisite. An able English neurologist (Gowers), deceived, as I think, by the mechanical needs of the knee-jerk, came to believe that tension was the precedent requisite, and that preparatory passive tension, obtained by flexion, excites by a reflex influence a state of extreme irritability to local stimulation which enables knee-jerk to occur. In other words, there is a precursory tuning of the muscle.

My previous remarks show that tension is less needed than Gowers supposed; and of late, his ingenious explanation has received less acceptance.

Another view presumes that the muscle is kept constantly in a state of sensitiveness by contributions of excitation from the spine. Out of the influence of these, *plus* the normal excitability, arises the so-called tone of the muscle. It would be lost by nerve injury, sensory or motor, and by certain central diseases, and with its loss the increment of sensitiveness due to spinal contribution would fail, and with this of course, too, the knee-jerk.

All reinforcements would be explained as coincidently supplying power to these ever-flowing tone waves. Under this explanation, knee-jerk becomes a local muscle-jerk, and its brief time not so surprising or embarrassing. When I last wrote of this matter, we were inclined to accept the tone theory as explanatory of all the facts; but, in the light of Lombard's and Bowditch's work, and my own further reflections, I have come to doubt more and more, and to feel it as possible that knee-jerk is really a peculiar reflex, with a short time. To settle the matter we require fresh laboratory studies of muscle-muscle reflexes in man.[1]

As regards the tone theory, it seems hard to conceive that instantly on nerve section the muscle should be so toneless as to give no knee-jerk, and there are other opposing facts. Section of the motor nerves through which the tone waves flow (if they exist) paralyzes knee-jerk; but section of sensory nerves does the same, and it is hard to explain this, unless we conceive of the individual muscle metabolisms as furnishing to the spine the essential excitations which return from it to the muscle in the tone waves.

If tone, in the sense here explained, be not a competent theory, then we must consent to call knee-jerk a reflex, and consider all reinforcements as not going beyond the spinal ganglia, and as therein reinforcing reflex excitations, in place of spreading out as tone waves to the muscle, and therein reinforcing.

Tone has been taken to mean tension, or some more mysterious preparation, for response to excito-motor agencies. If it be tension, this ought to be capable of being shown. I spent a great deal of time in efforts to see, if with the leg at an angle and without a blow on the tendon, reinforcements would not show themselves. In this I failed entirely. I do not say it is not to be shown. But if tone waves reach the muscles, and are the positive things they seem to be, they ought to be capable of registration. Certainly they cannot mean tension; and, if not measurable in muscle, it would look as though they did not reach it.

Time may settle this question. Meanwhile, as against reflex theories is the time. As to this, however, it is unwise to be sure that skin-muscle reflex time is the only one. Muscle-muscle reflex time has yet to be more fully studied, and may be more brief than has been supposed. We were quite unable to reinforce skin-muscle reflexes, such as that of the cremaster. The study was excessively difficult, and I do not yet feel absolutely assured that we were correct. If it should prove that we were, this might be regarded as measurably against the view that the muscle-muscle acts (K.-J.) are true reflexes. At all events there seems to be this difference between the two sets of replies to excitations.

There are other points which look favorable for the reflex theory, or as against tone explanations. Thus, when we cut the motor roots which enable knee-jerk to occur, we cannot restore knee-jerk thus lost by substituting a delicate electric current in the peripheral nerve end to imitate the lost spinal contribution. Again, a blow on the tendon causes not only local, but sometimes also distant reflex muscle acts in the other leg or in an arm. These cannot be skin reflexes,[1] and are seen best in the presence of emotional reinforcements.

Again, it often happens to one to strike a tendon with equal force over and over, and only after a time to get a violent response, far beyond the man's normal. I have seen this in tired men. It appears to be a summation of excitations and an explosive reply. I find it hard to conceive of this as a localized muscle phenomenon. It is like a reflex occurrence. A blow on a muscle elongates a limited breadth of fibre. It contracts, and this is like a knee-tendon jerk, but is a limited and coarse reply. If knee-jerk depended only on perfect extra-spinal muscular excitability, when this quality rises, as it does in some diseases, the knee-jerk ought also to increase, but in these very states it may be lost, and yet, the answer to a blow remain above the normal.

We were never able to reinforce muscle acts electrically caused. As Professor John Curtis suggested to me, this may be because electricity is a less potent reflex excito-motor than mechanical force. If the reinforcements reach muscle as tone waves, one excitor should be as good as another; but if they do not, then the only agents which will reinforce will be such as competently reach along reflex nerves to the spine, and it would look as if a blow did this, and moderate faradic currents did not.

There is, indeed, already some reason to suppose that mild electric currents are less competent reflex excito-motors than mechanical force. Thus, while a mere touch on the side of the thigh will excite the cremaster reflex, a faradic current strong enough to evoke muscular motion may not cause the testicle to stir.[2] The argu-

[1] I should then propose to use these terms, muscle-muscle reflex and skin-muscle reflex.

[1] A blow elsewhere does not cause them.

[2] To test this place both conductors dry on the excito-cremasteric region. The first cool touch may cause cremaster reflex. Then, being careful not to move the conductors, make and break

ment as concerns electricity and mechanical stimulus is emphasized in spastic cases. In these, the faradic electric reactions are usually not increased, while a tap or squeeze or tendon-jerk is competent to excite extensive movement. The blow gives rise to excessive action, the electricity only to common responses.

I have stated the gathering arguments for and against, but after all has been said, we are still in doubt as to the true nature of tendon-jerks. Yet, as the matter now stands, it is more and more clear that the time element is not the convincing argument against considering the knee-jerk a reflex, which many writers have held it to be.

Since Jendrássik's discovery and its extension by Lewis and myself, with our additional discovery of the reinforcement power of sensations, and Lombard's emotion reinforcements, the question of the nature of these has also to be considered.

There seem to be but two possible ways in which motion, sensation, or emotion can reinforce. One is indirect and one direct. It may be that all motor or sensory activity tends to release from inhibitory control other ganglionic masses than those in immediate use, and sets them in a measure free to respond to other agencies, such as external stimulus. To use a homely comparison, "the brakes are taken off." Thus a motor volitional act may so affect a spinal centre as either to set it at liberty to send out more energetic tone-waves, or more potently to feel, or to feel and reply to reflex excitants. The other view is that every motor act or sensory impression sets free surplus energy, which is felt as reinforcement throughout the body. And this is the doctrine of overflow.

I have already pointed out that every positive and abrupt motion or sensation, however remote and wherever it may be, is able to reinforce any tendon- or muscle-jerk. What is true of the stronger influences must be measurably true of the weaker. The reinforcing excitations may not show in the increase of the jerk, and yet may exist. Accept this quite possible conception that every sensation, every volition, every emotion (perhaps every mentation) sends its excess of force over countless tracks into many parts of the nervous system, and possibly into every muscle. The effort to realize this incessant effluence of energy is difficult. Some attempt at analysis may be of use, and I would also like to point out what are the problems, for the solution of which we must look to the laboratory and clinic. When we will a motion with some positiveness, the knee-jerk is reinforced, and so is the muscle-jerk. This happens whether the muscle called to act exists, or has been lost by amputation, or is above the knee in walking, or below it. If it were only to occur when the muscle is (let us say) in the feet, or below the knee, we might think of the nerve influence as passing through the crural centre, but a wink does it even better. How then does the efferent force reach the knee-centre? Is it a mere overflow, or is it an inhibitory act releasing the crural centre from cerebral control, and what columns of the spine must in any case rest uninjured to enable it to occur? Also what is the time of this reinforcement?

Then, as to sensations. I pull at a hair on the arm, and get prompt reinforcement of the knee-jerk. In this case does the afferent impression reach the sensorium first, and then affect the knee-jerk? Is the time of motor and sensory additions alike, or how nearly? Does the pinch of a foot influence the knee-jerk as the afferent impression goes up the spine, or does it first reach the sensorium, and act thence downward on the centres finally concerned in the knee-jerk?[1]

Emotions increase the knee-jerk. Do these act so as to set the spinal centres free, or is their influence also one of overflow?

Thus at every step the question of overflow or inhibition faces us, and in disease it is still the same. Certainly in health either explanation seems competent. But in disease and injury this is hardly so. When we cut the cord a state of shock, so called, occurs, that is—the reflexes and the knee-jerk are lost for a varying time. This may be merely exhaustion from a tremendous hyper-physiological excitation. Recovering, the knee-jerk and reflexes get more and more sensitive, and, at last, reach the normal and rise far above it. Why do they go on increasing, unless the pathological changes at the point divided act as irritative reinforcing foci? Again, in some spastic palsies, the knee-jerk being enormous, it is easily reinforced by winks or hand acts. It is hard here to conceive of the cerebral influence as largely cut off. Indeed it is not. Volition exists and is really good, but not competent because of the rigidity it causes. Generally, in all irritative spinal maladies the knee-jerk rises before destruction of the centre checks it. Also, after section of the cord, inhibition does not explain the gradual increase of excitability, while it is explained by the coming on and increase of inflammation at the lower surface of the section and the sequent changes.

Suppose, now, we can show that one volition reinforces another—*i. e.*, that the tired right hand gains vigor from sudden coinstantaneous use of the left hand. Either this is overflow, or else the willing of motion in the untired left hand must be supposed to relieve the tired centres from inhibition, and thus enable them better to obey the will they are failing to obey. If we accept overflow to explain such volitional reinforcement, there is no reason why we should not do so in regard to knee-jerk reinforcement.

Men who hold theoretic explanations too tightly, are apt nowadays to get sharp lessons. Yet, on the whole, it is often wise to possess some binding explanation of groups of facts. It is helpful in many ways. Possessing no certainty, I most incline, for the present, to look upon all reinforcements as overflows, and to consider all abnormal increase of knee-jerk as the product of irritative lesions. Physiologically, the conception of innumerable effluences of energy, motor, sensory, emotional in endless activity fills us with wonder and tempts one, however we explain them, to speculations remote from the purpose of this lecture.

Before dealing with the little there is to add as to ten-

circuit (faradic). A current powerful enough to excite the muscles will be found up to a certain point comparatively incompetent to occasion reflex stimulation of the cremaster.

[1] In the case of fractured spine (spoken of later in this lecture), there was every reason to believe the paths from leg to brain, and from brain to leg, were cut off. I examined this case with Prof. Osler, and both were satisfied of the completeness of the isolation. At last, after many blows on the right knee tendon, it began to respond better, and then we found it could be reinforced by a grimace, so that here was a path open from brain to leg. Also, it was not reinforced by a sensation (cold from ice). This seems to be a novel use of reinforcement.

don-jerks elsewhere, I desire to allude to the last facts which have been born of Jendrássik's discovery. My friend Prof. Bowditch, of Harvard, has been studying with care the time of reinforcements. His result is most interesting. I quote, by permission, Dr. Bowditch's brief summary of his paper, which is not yet in print.

"A sudden, brief muscular contraction reinforces the knee-jerk when the latter occurs within a brief interval of time (less than 0.25 second) after the former. With a longer interval the reinforcement gives place to an inhibition. With a still greater length of interval this inhibition disappears, so that when the blow on the tendon follows the muscular contraction with an interval of 1.06 second, the knee-jerk has its normal value. The interesting feature of the result is, to my mind, the evidence of a sort of oscillatory activity, or rather change of irritability in the centres concerned in the knee-jerk. I attach no particular importance to the figures I have given. They will doubtless have to be changed when more observations are accumulated. It would be interesting if this period of oscillation of the nerve centres should be found to differ in different persons, after the manner of the personal equation of astronomers."

This discovery that a sudden brief reinforcement first increases knee-jerk and then lessens it for a brief season is curious. The latter may be read as a brief expression of fatigue in the centre, or as interference of nerve waves; coincidence with increase, interference with decrease of knee-jerk.

Let us now turn again to the muscle-jerk. When a blow falls on a muscle, is the response purely the answer of intrinsic muscular irritability? This is a question which so far seems not to have been asked. The muscle shortens when struck, even though without spinal connections; but as I have already said, it may be that so long as these are whole, muscle-jerk may be like knee-jerk, and profit by spinal contributions to its coarser phenomenon. If it be a double phenomenon, its curve should show this fact and exhibit a double ascent, since the time of the muscle-jerk and its spinal addition cannot be one.[1] If the whole matter is but a response from a toned muscle, then we should have but a single curve.

The direct muscle-jerk must be familiar to all the observant among you, as seen easily when the percussion hammer strikes on the thin chest walls and instantly the pectoralis fibres, for about the width struck, contract from end to end. They have been violently pulled upon by the indenting hammer; a coarse, powerful excitation. You observe their responsive contraction. Next, at the point struck, you see a small hump quite slowly form and as slowly disappear. The first phenomenon you can see in all muscles more or less well; the second is not so easily obtainable. As concerns the first, it varies as do tendon-jerks. It is reinforcible and obeys the same laws as these do. In the muscle backed by bone, as on the chest or over the scapula, it is well exhibited; but also in other muscles it is well shown. The arm muscles are especially sensitive, and it is possible to pick out muscles as we do with electricity.

In the leg it is more difficult to get as good responses, except in thin people; and here, as elsewhere, we get exaggerated effects, near to the "nerve-points" of Ziemssen. To get the best results slight extension is needed. The pull on a length of muscle can only be had when the tissues are so mechanically stretched as to enable a blow to pull sharply on a length of fibres. Extreme tension lessens the response. In the feeble, and in the tubercular, the direct muscle-jerk is best. Partly, this is due to the great effect of blows on uncushioned muscles. Partly it is, I suspect, physiological, but whether from increase of intrinsic excitability, or from spinal contributions is not known. In some diseases, as in ataxia, it increases.[1]

The hump which slowly rises at a right angle to the longer rise of a length of fibres is the direct effect of the impact. Over muscles backed by bone we get it best, in either health or disease. It is in its larger expression and where found in other muscles than those mentioned, more or less, a sign or an accompaniment of feebleness. If we kill an animal, this response to a blow increases for a time, and in some diseases, with nervously isolated parts, is increased. Stokes mentioned it about 1848, and I experimented and wrote upon it in 1858; and often since it comes up as a re-discovery.

In section of the spine, or fracture with like result, the muscle changes are curious. I show you an illustration from one of Dr. Osler's cases: here is a fracture of the spine, at the ninth dorsal vertebra. It took place early in April, 1888. There is as you see, no sensation for pain. Pin pricks do not bleed, for this is not, as described, to be found only in hysterical anæsthesia. There is no voluntary motion.

I strike the leg-muscle anywhere, it moves better than usual in its length, but, also, the local hump is huge. I never before saw it so remarkable. Even a pinch causes it. The observation is to me a novel one. And observe that there is a spot of local gangrene on the heel. Some undamaged ganglia exist below the seat of injury, or we would not have even the faint knee-jerk seen after several blows on the right tendon. What is the reason for the peculiar irritability to a blow? Electrical tests show, I am told, no remarkable degenerative reaction. Possibly there may be an increase of muscular irritability from chemical irritative changes in the muscle, but the whole subject awaits more careful study.

In practice we have to deal only with ankle-jerk, knee-jerk, and biceps-jerk, and chiefly with the latter as a means of learning when certain spinal maladies are invading the arms. As concerns biceps-jerk, I hear men complain that they cannot get it. Let the patient rest the bared limb on the arm of the chair in which he sits. The operator feels for the insertion of the biceps tendon; puts on it a finger and strikes upon that, thus. He at once feels in the finger the muscular response. In thin persons a blow directly upon the tendon causes the arm to jerk visibly. Sometimes I put on the tendon a bit of caoutchouc, and strike on this firm cushion.

Pray attend to the fact that the biceps tendon, like the knee-cap tendon, must be stretched to enable us to influence the attached muscle. Elbow-jerk is certainly less easy to get than knee-jerk, but it is worth looking for, and is often a valuable aid to prognosis.

While much care is apt to be given to the presence of clonus, a symptom only as a rule present in excess in

[1] This is, of course, if the knee-jerk and measurably the muscle-jerk be reflexes.

[1] Buzzard first pointed this out in an admirable article on knee-jerk, from which some of my arguments are taken.

disease, the normal expression of it, ankle-jerk is, I fancy, less sedulously studied. The usual mode of evolving ankle-jerk is to strike a smart blow on the stretched tendo Achillis. The patient being seated, or supine, take up the foot in the left hand and flex it so as to make slightly tense the tendon on which you strike, and preferably with the hammer. If there be no response, flex the leg slightly and repeat the blow. The reaction of the muscle is felt by the hand which holds the foot. To show it better, I loop a thin rubber band over the tip of the sole, and with it make a slight extension. As now I strike, you see the foot move because of the contraction of the abruptly stretched gastrocnemius. I take another case, and show you another method which I do not see elsewhere used. It seems to be new. With the foot as before, I strike on the sole of the foot. This, also, acts so as to make a quick pull through the tendon on the muscle. It is less awkward than the blow on the tendon, and shows best with the boot or shoe on the foot. In the books you will see mentioned what Gower calls the "front tap," which now I show you. The foot being flexed, we strike a blow on the anterior muscle, or with less effect on the tibia. You see that the foot moves, showing that the calf muscles have acted. Gower mentions this as seen when the phenomena are in excess, but, as a fact, this reaction is common enough in the healthy, if the blow be given near the ankle. I believe that the front tap phenomenon has been sometimes considered as positive evidence of organic disease of the cord. As I now show it to you, it is strongly marked in spastic disorders, and more mildly expressed in some well people, or in neurasthenics.

And now as to clonus. It is easy to illustrate, but, in some cases, needs a little care to develop. To get it, I place the subject (a well man) so as to have the knee a little bent, then I suddenly flex the foot. You see I get no answering motion. This is because the flexion so made is not abrupt enough to secure even a single reply, for, remember, a sharp blow on the tendon or sole does usually secure this in health. In a spastic case, like this boy, who has Pott's disease, the apparatus involved is excitable enough to go on responding so long as I keep up flexion of the foot.

See what happens. I push up the foot and the stretched muscle moves the foot. My continuous pressure once more stretches the muscle. Again it moves, and so on, till the power to reply is exhausted. We may substitute a weight, or an elastic attachment, for the hand and see the motion continue for an hour or more. Here is a set of curves written by causing the foot to record its motion on a moving sheet of smoked paper. A second marker notes the time. You see the clonus is seven to the second. It varies from five to nine, and the time of the two feet taken together varies a little. It causes no fatigue, although moving for an hour at the rate of 420 to the minute.

In milder cases it ceases after a few movements, but we never see clonus continuous and energetic save in true spastic cases. In milder examples, as in hysteria and neurasthenia, we must consider it as to amount and vigor, and as to its presence with other symptoms. I now speak of what you get by using the hand alone, and keeping up pressure. You may sometimes, though rarely, get it in a mild form in health—that is, in place of a single response to the blow on foot or tendon, two to six, such motions occur, each slighter than the last. There is, of course, in all this a vast amount of physiological interest upon which I have dealt but slightly.

I come now to say what amount of practical use we can get out of the varied phenomena I have described. Keep clearly in mind that if you find a tendon-jerk lessened or extinct you must try if it can be revived or increased by motor or sensory reinforcements. Absence is most suspicious, but do not let this alone make you decide that you are in the presence of coarse spinal lesions. I know two ideally healthy people, who have no knee-jerk, ankle-, or biceps-jerks; no reinforcements. Both have direct muscle-jerk, non-reinforcible. Explain this, I cannot. I cannot even guess at an approach to an explanation, but it is enough to make one careful. Taken alone, this negative sign has little value. It usually means, when present with other suspicious signs, that the nerve loop from muscle to spine, and back to muscle—*i. e.*, the muscle-muscle loop—is damaged in the spinal centre, in the nerve loop afferent or efferent. It may mean, also, that the muscle has itself lost power to respond. To know what has suffered, we must appeal to other symptoms. It tells us that something is wrong, but not what is wrong. Thus it lessens, and at last is lost in posterior sclerosis, and in sclerosis of the gray anterior columns, and also in hypertrophic muscular palsy, thus affording illustrations of loss of knee-jerk from disease of either the sensory or motor columns, or the muscular mass. I do not see that, as yet, we have got out of the knee-jerk changes all that we may yet hope to win. Except in locomotor ataxis, and in the early recognition of spastic states of the cord, it has little direct practical usefulness. But it has a negative value, and a great one, owing to its remarkable sensitiveness. Let us deal first with its negative utility.

It is a common case to see, nowadays, a man of thirty, free from constitutional taint, or with a doubtful history, ruddy, and well nourished. Otherwise he is easily tired, and this may apply to body and mind, spine and brain, or to either. He has fugitive numbness of the extremities and ache in the cervical or lumbar spine. Beyond this he has no spinal symptoms, and his knee-jerk, ankle-jerk, and elbow-jerk are perfect. You may be sure that he has merely neurasthenia. But if he be very emotional, and this exaggerates his tendon-jerks, and even causes slight clonus, you may have to wait long, and be careful in order to get undisturbed results. It is an every-day experience that in suspicious cases integrity of tendon-jerks helps us to clear views. It is quite certain that some cases of posterior sclerosis begin with excessive knee-jerks, which by and by fail, and at last disappear. For a time they can be recalled by reinforcements, but, sooner or later, are lost altogether.

An interesting case of ataxia of the arms with nearly normal legs was recently in our wards. I use it here to illustrate the history of tendon muscle-jerks in ataxia, and also to call attention to the way in which we state with brevity such phenomena.

Modern note-taking is so elaborate that whatever rationally shortens its method is a pure gain. Let me point out how you can record these phenomena briefly in a sort of equation, and refer you to the paper by Dr. Lewis and myself for fuller statements.

I give below a sufficiently full explanation of the abbreviations:

Arms: R. E. J. o. Rt. o. L. E. J. o. Rt. o.
R. M. J. + +. Rt. o. L. M. J. +. Rt. o.

Legs: R. K. J. 25°. Rt. 40°. L. K. J. 27°. Rt. 36°.
R. M. J. quadriceps, n. Rt. n. L. M. J. n. Rt. n.

Station: $\frac{2}{A}$, $\frac{1\frac{1}{2}}{D}$. Eyes shut.

Explanation.—Arms: Right elbow-jerk, none. Reinforcement, none, etc. Right muscle-jerk, excessive. No reinforcement, etc. Legs: Right knee-jerk, 25 degrees Lombard's meter. Reinforcement sends lever to 40 degrees, and these records mean maximum of several trials. As concerns muscle-jerk, n means normal, + excessive, and — less than normal. Station $\frac{2}{A}$, $\frac{1\frac{1}{2}}{D}$, means the anterior sway is 2 inches, and the dextral 1½.

Of course, in the not rare examples of posterior sclerosis with lateral column involvement and spastic gait, there is exaggerated knee-jerk, but also, I am sure, as I have said, that excess of knee-jerk may exist in the preataxic stage of unadulterated disease of the posterior columns.

As Lewis and I have urged, it is in the arms of men who have ataxic legs and no knee-jerk that we can follow the whole series from the normal to lost elbow-jerk. And so also muscle-jerk +, with + reinforcements through to loss of all but intrinsic muscle-jerk. I saw, to-day, an ataxic man. He has knee-jerk o. Reinforcements o. Arms, elbow-jerk and reinforcements + +, and muscle-jerk and reinforcements + +. He has no ataxia of arms, but the faintest traces of occasional numbness in the finger-tips. With shut eyes he falls.

I believe that attention has not been called to the fact that, now and then, in diseases a blow on the patellar tendon causes response in but a part of the biceps mass. I saw this lately in a case of partial destruction of a segment of dorsal cord. For several days, only the vastus internus seemed to act, and that feebly. My colleague, Dr. Sinkler, has made a similar observation recently in a case of syphilis of the dorsal cord. Only the external vastus responded.

I cannot enough warn you against regarding even entire loss of knee-jerk as always a grave matter. At the same time, it is a sign not to be neglected. The sensitiveness of knee jerk, its delicacy, makes it valuable. But illustrations are better than mere general statements. I saw last week a case of mild non-febrile muscular rheumatism. The patient was in bed and under daily use of sixty grains of salicylate of soda. For a week or more he had much lessened right knee-jerk, and none on the left, and no reinforcement. It came back a few days later. The cause of the loss I do not know.

Again, a case of frank meningitis in a lad of sixteen was rapidly relieved. The knee-jerks were good—rather excessive. About the fourteenth day a dull, but very painful ache in the lower dorsal region came on, chiefly on the left side. There was, also, at this time, a sudden albuminuria without signs of congestion. I was not secure as to the cause of the ache, until I observed entire loss of left knee-jerk. I then felt pretty certain that the pain was due to a new focus of meningitis. There was little else to help me, for all through there had been slight pricking sensations in the feet, and this did not largely increase with the coming of the dorsal ache. I next observed, with interest, that while the left knee-jerk was gone there was excess of left foot-jerk from a blow on the sole, and even slight clonus.

There are many disorders, some maladies, and certain normal conditions in which we meet with increase of knee-jerk and ankle-jerk, or even presence of faint clonus. Of some of these I have already spoken. Only the hasty, or the unwary, could be taken in by the excess of knee-jerk, or the slight clonus of neurasthenia or hysteria. Care will, however, be needed, because it is in these very cases that emotional reinforcements are most violent, and because, also, we now and then meet with incipient spastic palsies, in which there are associated hysteric or neurasthenic states.

There are, of course, many forms of disease which give rise to spastic paraplegia, and in some of them, the earliest distinct warning is to be found in the increased knee- and ankle-jerk. This is especially the case in some of the insidious forms of syphilis, which seem, by preference, to affect the lateral colums of the spinal cord. In the absence of other symptoms which help to reveal improvement, diminishing knee-jerk in spastic disease becomes a valuable index of the change for the better in the disease which at first caused its increase. In the future. Dr. Lombard's meter or my simpler one will be of great value as giving us reasonably precise records of knee-jerk.

I have limited myself, in this lecture, to tendon-jerks and muscle-jerks in chronic neural maladies. A not uninteresting, and a little explored subject, is the study of these in acute diseases. I have said least of ankle-clonus, because, this winter, clonus in general has been the subject of careful experimental study by Dr. Morris Lewis and myself. Our paper will shortly appear.

ORIGINAL ARTICLES.

A CASE OF SÄNGER-CÆSAREAN SECTION.[1]

BY JUSTUS OHAGE, M.D.,
OF ST. PAUL, MINNESOTA.

ON May 29th I performed Cæsarean section, after Sänger's method, upon a rachitic dwarf, who died June 3d, from septic endometritis resp. diphthritic endometritis.

Although the result in regard to the life of the woman was most unfortunate, the result in regard to the operation was as satisfactory as could be wished for, and fully demonstrated the value of Sänger's method, a method which has completely revolutionized operative midwifery in Europe.

It would at first seem absurd to call an operation satisfactory when the patient dies, but by a little attention to a few facts which I shall relate, it will be seen that the fatal termination was in no way due to the operation *per se*, but to a process which I fear

[1] Read at the annual meeting of the Minnesota State Medical Society, at Duluth, Minn., June 17, 1887.

has repeatedly been witnessed even in women who had a perfectly natural and easy delivery.

In our State, with its vast numbers of foreign emigrants, who in their native countries, to a great extent, belonged to the poorer laboring classes, among whom rickets is no uncommon disease of childhood, the indications for artificial delivery, on account of deformed pelvis, much oftener present themselves than in communities where the well-shaped American woman predominates. The influence of the teachings of our British brethren had caused us to try first every possible obstetrical expedient, as craniotomy, embryotomy, etc., and to look on Cæsarean section only as a forlorn hope. The natural consequence was that most of our cases of Cæsarean section were forlorn hopes before they were operated upon, and that the statistical records put us at the bottom rank with our British confrères.

To Dr. Robert P. Harris, of Philadelphia, is due the credit of endeavoring to introduce Sänger's method into this country. Comparing our results with those of the Dresden and Leipzig maternities, he comes to the conclusion that it is quite time that we should follow the example of the German rather than of the British operator.

The records of the German maternities show that Cæsarean section, after Sänger's method, is not as fatal even as craniotomy, and when performed in good season, and with careful uterine closure, a favorable result to both mother and child may justly be expected. In the closure of the uterine wound lies the success of the Sänger operation, and even after his original mode of muscular resection and peritoneal undermining has been abandoned as unnecessary, it is still proper to call the operation by his name, for it was he who first pointed out the necessity of deep muscular and superficial sero-serous (Jobert-Lembert) sutures, by which alone the peritoneal surfaces could be brought into such close contact, the tension of each individual stitch moderated, and the gaping of the uterine wound prevented, through which uterine discharge could escape into the peritoneal cavity. The value of this method is shown by the fact that Germany in seven years, out of 33 cases, saved 29 women and 30 children,[1] a mortality of less than 13 per cent., while Lawson Tait, but a short time ago, claimed a mortality by Cæsarean section of over 99 per cent.[2] In considering this low mortality of the German maternities, we must and will hope for the time when the Sänger operation will supersede the piecemeal extraction of viable children, that it may no more be necessary to destroy one life to save (perhaps) another.

"Parce matri et proli, si parcere possis."[3]—*Berruti.*

[2] MED. NEWS, July 17, 1886.

[3] "Save the mother *and the child*, if save thou canst."

I had this point specially in view, and to turn the tide which runs yet among us in favor of craniotomy *vs.* Cæsarean section. For this reason, and to demonstrate the different steps of the operation, I had invited a limited number of surgeons from different parts of our State to be present, whose professional standing leads me to think that if an indication for abdominal delivery in their respective territories should occur, they would certainly be on hand and utilize the points demonstrated on this occasion. The interest felt by these gentlemen can be best demonstrated by my asserting that every single one of those invited was on hand, though some of them had to travel hundreds of miles. Their zeal and sympathy are a guarantee that they will be coöperators in a work which is so eminently filled with good, and which must be done—the sooner the better.

CASE.—My patient was a rachitic dwarf, twenty-nine years of age, and of German nationality. Last menstruation August 22d. Quickening January 10th. She called at my office some time in March, telling me she was *enciente* and requested my attendance at her confinement, for the old women in her neighborhood had told her she would have a hard time. She expected her delivery about the 1st of June. An examination revealed a kyphotic spine with lumbar compensating lordosis, depressing the sacrum to such a degree that it lay almost horizontal; the promontory nearly above the symphysis pubis, distance barely one and three-quarters inches. Transverse diameters elongated and irregularly contracted. This condition of the pelvis called for delivery by Cæsarean section, especially as the arching of the sacrum would have made craniotomy, had it been contemplated, fully as dangerous to the mother, to say nothing of sacrificing the child.

I saw her about a month later, in consultation with my friend, Dr. Park Richie. We both made a careful examination, and came to the same conclusions in regard to diagnosis and treatment. In order to have her in the best possible condition I secured for her a private room in the St. Joseph's Hospital, through the charity of a few ladies, and had her removed there about a week before her expected confinement. I had concluded to induce labor for fear that it might set in just at a time least desirable for us, when some of us had perhaps just been in contact with infectious diseases, and when antiseptic precautions might not be carried out as fully as they ought to be.

Therefore, on the evening of May 28th, I saw her again in consultation with Drs. Richie, Nelson, and McLaren. We all agreed on a conjugate diameter of one and three-quarters inches, and the course to pursue, and concluded by inducing labor by the introduction of an elastic catheter which ruptured the bag of waters and caused their escape. It is needless to say that all antiseptic precautions were taken. She also had taken daily baths, and disinfecting vaginal injections. The catheter was removed and we left her for the night, to await the setting in of labor.

When I called the next morning, shortly after 7 o'clock, I found that she had had sufficient pains during the night. The os uteri was dilated to the size of a silver quarter, and uterine contractions were well pronounced. Her bowels were moved by enema, and she was put in readiness for the operation. Fœtal movements were strong, heart-sounds plainly audible to the right of the median line, and the occiput to the right forward.

At 9 A.M., May 29, 1887, I operated assisted by Drs. Richie, Nelson, McLaren, Quinn, Spencer, and Philips, and nurse Frazer, and in presence of a number of invited surgeons. Ether narcosis. Bladder emptied, mons veneris shaved, vagina and abdomen again disinfected. Incision in median line, beginning two inches above the umbilicus and ending one and a half inches above the symphysis pubis. Peritoneum opened in the usual manner, The womb being righted and the abdominal walls firmly pressed against it, I opened it by a few quick sweeps with a scalpel, carefully avoiding the lower uterine segment. The abdominal wound was about nine inches, the uterine about seven inches in length. The child presented with its left shoulder. I extracted it, breech first, without much difficulty, handed it to an assistant, who tied and divided the cord, and who took charge of it. It was a female child, cried at once lustily, weighed seven pounds, and is doing nicely.

The placenta lay to the right, backward. A rubber tube was now passed around the uterus at its upper vaginal junction, the uterus lifted out of the abdominal cavity and a large, warm pad of Listergauze put over the abdominal wound to prevent the prolapse of the omentum and bowels, and the entrance of extraneous matter into the abdominal cavity. So far very little blood had been lost, and after the tube was applied there was no more hemorrhage. The placenta and membranes were easily detached and removed, the womb thoroughly mopped out with a 1 to 4000 corrosive sublimate solution, and a quantity, enough to cover thickly the whole endometrium, of equal parts of iodoform and boric acid sprinkled in.

The walls of the womb were now firmly pressed together, and I proceeded to close the wound after Sänger's method, without resecting any muscular tissue or undermining the peritoneum. I used a long, straight, round needle and carbolized silk. The needle was inserted one-third of an inch from the edge of the wound through the peritoneum, through the muscular substance, and out again before reaching the mucosa, then on the opposite side into the muscular tissue above the mucosa, and out through the peritoneal, again one-third of an inch from the edge of the wound. None of the stitches was tied at once, only after all were *in situ*, and a flat sponge removed which had been placed in the cavity of the womb to catch up any blood, were they knotted and cut short. There were eleven deep muscular sutures in all. Next came the sero-serous row of sutures (Lembert-Jobert's) similar to those which we use after resection of the bowels. They were of fine carbolized silk. To apply these I used a half-curved needle in a holder. The needle was inserted between the deep stitches and over them, just as necessity demanded, and entered about three-eighths of an inch from the edge of the incision line and out again at incision line, then in again at and out three-eighths of an inch from incision line, taking in only the peritoneum. Each thread was knotted as soon as applied, and when all seventeen were *in situ* there was an uninterrupted apposition of serous surfaces covering the muscular stitches and completely closing the uterine gap. The same mixture of iodoform and boric acid was sprinkled over the line of incision, the tube removed and the peritoneal cavity cleaned out, though nothing had escaped into it. A few hypodermatic injections of ergotin and massage brought on good uterine contractions. The womb, which at first, after the removal of the constricting tube, looked rather pale soon assumed a livid color, and when all signs of bleeding had stopped it was returned to its place, and the abdomen closed in the usual manner by eight deep and fourteen superficial silk sutures.

Time from first incision to delivery of child, six minutes.

Time from first incision to application of dressing, thirty-five minutes.

Time given in text-books, one hour and fifteen minutes.

The dressing consisted in iodoform sprinkled over the line of incision, and a large pad of absorbent cotton held in place by a broad binder, the ragged ends of which were tied over the cotton pad. There was no shock, the temperature of the operating-room being above 90° F.

The patient was put in a warm bed, she reacted well, complained of no pain, and would not believe she had been delivered until the child was shown to her.

At noon, temp. 98.4°; pulse 96; cracked ice *ad lib.*; catheter every six hours. At 7 P.M., temp. 98.6°; pulse 108; cracked ice, iced milk, feels comfortable, one-sixth of a grain of morphia subcutaneously.

May 30. 7 A.M., temp. 99.5°; pulse 118; cracked ice, iced milk; lochia normal; ice, wine, and milk. 7 P.M., temp. 99°; pulse 108; cracked ice, iced milk, coffee; lochia normal; comfortable.

31st. 7 A.M., 99°; pulse 108; cracked ice, beef tea; wind passes and urine yet drawn; lochia good; comfortable. 7 P.M., temp. 98.5°; pulse 108; everything favorable; passes water and wind notably.

June 1. 7 A.M., 98.6°; pulse 108; everything favorable; bowels moved by injection; lochia good; milk begins to appear. Beef-tea, milk, coffee, ice, and wine. 7 P.M., temp. 98.6°; pulse 108; comfortable and feels like sitting up.

2d. 7 A.M., temp. 99.4°; pulse 110; restless, lochia scanty, no chill, tympanitic distention of bowels, abdomen tender, vomited once or twice. Enemata and five grains of calomel ordered every four hours; cracked ice and one-quarter of a grain of morphia subcutaneously. At noon Professor Ritchie saw her again with me. Temp. 98.6°; pulse 118; respiration, which up to now had been normal, 28. Ordered one ounce of digitalis infusion with each enema. No movement nor flatus from bowels

yet. Ice-bag to abdomen. At 7 P.M., her condition was much worse. Temp. 104°; pulse 130; vomiting continues. I gave her another one-quarter of a grain morphia injection, and as her condition kept rapidly getting desperate, I removed the dressing, opened the abdominal wound at its lower third, and introduced a drainage tube, through which I washed out the abdominal cavity with a warm 1 to 4000 corrosive sublimate solution. The water returned just as clear as it was injected.

It was evident we were dealing with a septic process by far too rapid and powerful to control. Her pulse ran up to 150, 160, 180, as far as we could count it. Subcutaneous injections of camphor and ether, and of digitalis had no effect whatever. She became delirious and more and more collapsed. At 10 P.M., being fully aware that she had but a few hours to live, I had ice-bags and ice-cap removed, and as she began to show signs of suffering one-quarter of a grain of morphia was given hypodermatically. She died a little after midnight, June 3d.

Autopsy.—June 3d, 9 A.M., Drs. Nelson, Schulin, and Phillips. Examination confined to abdominal organs. Body of a well-nourished, though deformed, woman. Total length three feet ten and one-half inches. Kyphosis of dorsal, lordosis of lumbar region of spine. Legs large, but excessively short. Large panniculus adiposus. Wound in median line of abdomen agglutinated by first intention, except at lower angle, where a rubber drainage tube projected. On opening the abdomen the bowels were found to be distended by gas, but of a natural color; the peritoneum of natural color and consistency throughout, except a small spot in the neighborhood of the left Fallopian tube, which was slightly discolored. No blood, pus, or fluid of any kind in the peritoneal cavity. The uterus well subinvoluted, the size of a child's head. The uterine wound perfectly closed and united, every stitch in its place, resisting a considerable strain which was made upon the sutures after the womb had been opened at its posterior portion to test their strength. Thickness of uterine walls three-quarters of an inch. Muscular substance of good color. The endometrium well covered with iodoform, but discolored to the extent of a few square inches, especially in the neighborhood of the left Fallopian tube, where a grayish exudation was present. No bad odor anywhere, but that of iodoform. Ovaries, tubes, etc., healthy. Pelvis generally contracted, conjugate nearly two inches.

Diagnosis.—Endometritis septica (diphtheritica).

Here we have a case, which clinically and pathologically exactly corresponds to one of our old-fashioned childbed fever cases. Especially to that variety where the poison in an overwhelming quantity, so to speak, is conveyed through the lymphatics into the system and where all measures, as curetting the endometrium, intrauterine injections, active catharsis, etc., fail to save women who had just fulfilled their highest and noblest mission.

If we consider how faithfully antisepsis in all its details was carried out in this case it is difficult to answer the question, how and whence infection took place. And yet we cannot harbor the idea that woman is like a scorpion which carries within its body the poison with which to destroy itself!

The comparatively short space of time which it took to do the operation is noticeable. There was neither hitch nor hurry. For this I am greatly indebted to my corps of often tried and able assistants to whom I take this opportunity to acknowledge my gratitude.

59 Irvine Park, St. Paul.

AN UNPLEASANT EXPERIENCE WITH THE NEW LOCAL ANÆSTHETIC—HYDROCHLORATE OF ERYTHROPHLEINE.

By SAMUEL THEOBALD, M.D.,
one of the surgeons to the Baltimore Eye, Ear, and Throat Charity Hospital.

After reading, with interest, Dr. Alt's article upon hydrochlorate of erythrophleine in the February number of the *American Journal of Ophthalmology*, I procured through Messrs. J. H. Perkins & Co., of Baltimore, a small quantity of the salt made by Merck, wishing to test, for myself, the action of this last-discovered local anæsthetic. On March 23d I used it for the first time, making but a single application of a 1 : 1000 solution to the eye of a man from whose cornea I wished to remove a foreign body. The anæsthesia which resulted was slow in manifesting itself, was preceded by considerable ciliary irritation, and was not as profound as that which is usually produced by cocaine. The foreign body was removed, however, twenty minutes after the application, without appreciable discomfort to the patient, who was then kept under observation for about an hour longer in order that the subsequent behavior of the eye might be observed.

During this time the pupil of the eye into which the erythrophleine had been instilled became decidedly smaller than the opposite pupil, and accompanying this myosis there was an unmistakable reduction in the intraocular tension. The myosis was by no means as pronounced as that which is induced by even a weak solution of eserine, but the reduction in tension was very marked, and it occurred to me at once that this property of the new agent might make it of value in the treatment of glaucoma. Hirschberg, it was true, had called attention to the fact that rainbow-colors were seen by several patients into whose eyes he had instilled a 1 : 500 solution of erythrophleine; but, knowing that the seeing of rainbow-colors about a candle-flame does not necessarily indicate high intra-ocular tension, but rather misty media, I felt myself justified two days afterward in trying the effect of the erythrophleine in a case of subacute glaucoma, in which eserine had been used with little effect, and in which I was about to perform an iridectomy.

The patient, a man, forty-nine years of age, and of full habit, was seen at my office. A single application of two drops of a 1 : 1000 solution of erythrophleine hydrochlorate was made to the affected (L.) eye. The condition of the eye before the instillation was as follows, a two-grain solution of eserine having been applied to it the previous night—pupil somewhat contracted; + T. 1; cornea very slightly misty (as seen by oblique illumination), but details of fundus well made out, notwithstanding some post-polar lens opacity; V. (with Ah. $\frac{1}{24}$ corrected) = $\frac{20}{XLV}$ (?). Within a very few minutes after the instillation of the erythrophleine the eye became more irritable, slight pain was felt in it, and the conjunctival and subconjunctival injection, which previously were insignificant, became much more marked.

At the end of fifty minutes, the symptoms of irritation having increased rather than abated in the interval, the condition of the eye had undergone an astonishing and rather startling change. Instead of the almost imperceptible corneal mistiness previously observed, there was now a very marked cloudiness of the cornea, and apparently of the aqueous humor as well, so that the iris was seen very indistinctly, and the retinal vessels could be distinguished with difficulty. It was thought best not to alarm the patient by testing the sight of the eye, but it could scarcely have been more than one-fourth of what it had been a few minutes before. The tension was probably a little increased, but certainly not markedly so. A subacute glaucoma had, apparently, been converted into an acute attack, and the necessity of an immediate iridectomy suggested itself. I preferred, however, not to operate in the condition the eye was then in, if it could be avoided; so I applied a four-grain solution of eserine sulphate, and, keeping the patient under observation, was gratified to find in about an hour some change for the better in the condition of the eye, the pupil contracting, and the cornea becoming somewhat less misty. Four hours later (*i. e.*, at 4 P. M., the erythrophleine having been applied at 10 A. M.), there was but little further change in the condition of the eye, and I decided to perform an iridectomy on the following day, a two-grain solution of eserine being directed to be used in the meantime.

The next day the patient reported that he had passed a very uncomfortable night, suffering more pain in the eye than he had ever experienced before; but, since morning, the pain had disappeared, and at the time the iridectomy was performed (2.30 P. M.) the eye had returned to about the condition (as to clearness of cornea, etc.) in which it was before the application of the erythrophleine. The eye did well after the iridectomy, and the subsequent progress of the case presented nothing of an unusual character or worthy of note.

I have not been disposed to experiment very freely with erythrophleine since meeting with the experience which I have related. In several cases of granular lids with pannus, however, which had been treated with nitrate of silver, preceded by instillation of cocaine (4 per cent.), I substituted for the latter one instillation of erythrophleine (1 : 1000), and in every instance the patient subsequently reported that the eyes felt worse, and that the pain experienced was more severe and more persistent than when the cocaine was used.

PERNICIOUS ANÆMIA WITH JAUNDICE.

BY JOHN GUITÉRAS, M.D.,

PASSED ASSISTANT-SURGEON UNITED STATES MARINE HOSPITAL SERVICE; PROFESSOR OF THEORY AND PRACTICE AND OF CLINICAL MEDICINE IN THE MEDICAL COLLEGE OF THE STATE OF SOUTH CAROLINA.

THE following case of pernicious anæmia, though imperfectly recorded, is deemed of interest; first, because it occurred in a colored man, and in the Southern States; second, because the case throws some light on the question of the relations between jaundice and pernicious anæmia.

George S., twenty-eight years old, was admitted into the Charleston City Hospital on January 25, 1888. He was a mulatto, with a large frame, and excellent muscular development.

On the 12th of last November he had been admitted to the surgical ward for the treatment of a large serpiginous ulcer, involving the right groin and portion of the scrotum. He refused treatment, and was discharged on the 24th. All that was noticed, at the time, about the man, beside the ulcer, was his stalwart form.

He was readmitted on January 25th, complaining of weakness, dyspnœa and cough. He stated that he had been feeling weak since last fall. He had been, however, working as a mason up to two weeks before admission. The diagnosis on his card for admission was pulmonary consumption. I found him very anæmic, but not emaciated. A physical examination of the chest proved that there was no tuberculosis, but a general emphysema of the lungs. The serpiginous ulcer was still present, though of smaller size. I ordered, therefore, the patient to be transferred to the surgical ward on the 27th. By this time he had had several paroxysms of dyspnœa, and I was asked to examine the patient again. I found a marked reduplication of the first sound. This symptom, taken in connection with the fever, the history of suppuration and the peculiar paroxysms, led me to diagnosticate infectious endocarditis. Under this erroneous diagnosis I received the patient once more in the medical wards on January 31st.

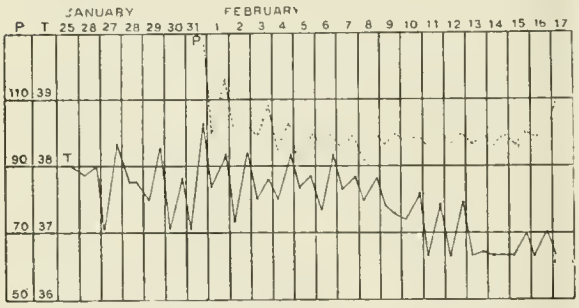
The following symptoms were observed: The mucous membranes were blanched, but the striking appearance of pernicious anæmia was masked by the color of the patient. The conjunctivæ were distinctly yellow. The skin of the front of the legs was scaly and purplish, as if marked by traces of chronic eczema. The eyelids were always more or less puffy, and the ankles swelled slightly when the patient sat up any length of time. This he was inclined to do in spite of orders to the contrary. His mood, in fact, was often buoyant, and some-

times flighty. He was easily tired, however, and would take to his bed.

He took very little food of any kind, and vomited very often. The vomiting was never spontaneous. The matters vomited consisted of food, and a frothy chyme of a light yellow color. There was no diarrhœa.

The patient had much cough at the time of admission, but this symptom subsided gradually. He complained of a constant uneasiness about the precordia, which was aggravated, at times, by paroxysms of precordial pain with suffocation. These occurred more frequently at night. The pulmonary resonance was exaggerated throughout the chest, and the emphysematous lung encroached upon the areas of cardiac, hepatic and splenic dulness. It was possible, however, to discern some enlargement of the left side of the heart. The heart sounds over the body of the organ presented a well-marked galloping rhythm. The intervening sound became so friction-like toward the last, that I concluded there must be some pericardial roughness.

The urine was examined soon after admission by the Resident Physician, Dr. A. H. Hill. It was found to contain biliary coloring matter, but no albumin and no sugar. The liver was found to be pushed down by the emphysematous lung. There was some enlargement of the liver and spleen.



Temperature chart. Pernicious anæmia.

On the 14th of January the patient began to appear dull and drowsy. The icterus became more marked, and the œdema of the face more pronounced. The swelling now produced considerable distortion of the features, the right side of the face being more swollen than the left on account of the decubitus. There was very little general œdema.

On June 17th the patient was comatose, and had been so since the previous evening. The inspirations were remarkably deep and regular. The heart beat 110 to the minute, but no pulse could be felt at the wrist.

A drop of blood was obtained this morning with difficulty, by sticking and forcibly squeezing the finger. The fluid had a reddish amber color. On microscopic examination the oligocythæmia was found to be extreme. Though the quantity of blood under the cover glass was sufficient completely to fill the space, yet the red corpuscles were found isolated and sparingly scattered. There was no marked poikilocytosis. In several fields no leucocytes could be found. Instead of making a more careful examination of the blood I satisfied myself with the explanation that some serum from the subcutaneous connective tissue had been pressed out with the blood.

The patient died on the evening of the 17th, without convulsions. The treatment consisted principally in the administration of gtt. x of tincture of the chloride of iron every three hours.

Autopsy twelve hours after death. There was some purplish discoloration of the skin on the anterior surface of the legs. The œdema was scarcely noticeable except about the face. The *panniculus adiposus* was normally distributed, and the color of the muscles was pale. These tissues were bloodless.

The lungs were found abnormally distended, covering much of the pericardium, though this sac was large. The pleural cavities contained a small amount of serous effusion stained yellow. The lungs, after removal, preserved their form and bulk, as if they were inflated. Near the anterior border of the left lung there was a small bleb of vesicular emphysema. The rest of the lungs was in a condition of universal lobar emphysema. There was no tuberculosis. A yellowish, frothy fluid could be expressed from the anæmic lungs. The pericardium contained about six ounces of serum decidedly stained with yellow. The visceral layer of the membrane presented a patch of chronic thickening upon the body of the right ventricle. There was no excess of fatty deposit. The heart was somewhat enlarged, especially the left ventricle, which was firmly contracted. The muscular tissue was pale but not friable. The ventricles contained each a small lump of yellowish clot, tangled with the cords, but no fluid blood. The mitral valves were somewhat enlarged and thickened at the edges. There was some thickening and opacity of the endocardium toward the apices of the papillary muscles. The walls of the large bloodvessels were stained yellow.

The peritoneum was blanched. The intestines, below the duodenum, were remarkably contracted, as they appear below the seat of an intestinal obstruction; the stomach and duodenum were comparatively dilated. There was no effusion into the peritoneal cavity. The peritoneum contained no excess of fat. The liver was somewhat enlarged; perhaps not indeed increased in volume, but flattened out, especially along the anterior border. The capsule was smooth and transparent. The color of the organ was dark bile-green. The section surface was smooth, and the parenchyma was uniformly infiltrated with bile. The acini were not distinct. The gall-bladder was half filled with bile, which was of a lighter color, and more fluid, perhaps, than usual. The biliary passages were not obstructed. The mucous chyme contained in the small intestine was evidently mixed with bile, being of the same color as the secretion in the gall-bladder. The mucous membrane was stained in the same manner. The stomach contained a small amount of pale yellowish fluid. The rugæ were not as prominent as usual, but the walls did not appear to be atrophied. The mucous membrane had a fatty appearance, and it was studded with ecchymotic spots to the number of one to the square inch. These had a

roundish outline, and measured from the size of a pin-head to that of a small pea. They were situated superficially, and some of them had been loosened, apparently by post-mortem digestion. The intestines were carefully searched for parasites, but none was found. The pancreas was somewhat enlarged and fatty.

The spleen was one-half larger than the usual size. The color was dark-purplish, and the consistence was firm. A considerable number of fine white connective-tissue trabeculæ were visible. The Malpighian bodies were not apparent. The kidneys were slightly enlarged, very pale and firmer than in health. The capsule was not adherent.

The medulla of the humerus, the radius and the ulna presented the same color as the spleen.

REMARKS.—My impression is that very few cases of pernicious anæmia have been reported from the South. Looking over the *Index Medicus* I find no case reported in any of the Southern medical journals, unless the two following be exceptions: W. Lee, a case of anæmia with excessive irritability of the stomach treated successfully by the hypodermatic use of ammonio-citrate of iron (*Maryland Medical Journal*, iv., 1878); and Miller, C. H., a case in search of a diagnosis (*Southern Clinic*, iv., 1881).

I confess that the error of diagnosis in this case has shaken my opinion concerning the rarity of the disease in the southern section of the country, for it has brought forcibly to me the possibility of being misled by the pigmented skin of the negro. The anæmias of this section, and of the tropics, certainly require extended investigation. The recent writers on tropical diseases of America do not mention, as far as I know, the special form of anæmia now under consideration, though they insist upon the pernicious tendencies of the paludal anæmia. One is inclined to suspect that cases of Biermer's disease may have been included in this category; but, it must be stated that the accounts given by students of tropical pathology do not coincide with what we still have to hold as a distinct disease under the description of Addison and Biermer. One case of pernicious anæmia, I find, has been reported from Havana, by Dr. Rijó, in the *Cronica Medico Quirurgica*.

Judging from my own experience, and again from the records of the *Index Medicus*, it appears that Hodgkin's disease is comparatively common in the South, and leukæmia very rare.

In regard to the relations of jaundice and pernicious anæmia, I must refer the reader to an interesting paper of F. E. Georgi, entitled "Gallensteine und perniciöse Anæmie" which appears in the *Berliner klinische Wochenschrift* of October 31st and November 7, 1887. The author reports a case of pernicious anæmia, in which, he contends, the first symptoms to present themselves were those of hepatic disturbance. The post-mortem examination revealed the presence of gall-stones. After referring to eight cases of pernicious anæmia with jaundice, he concludes that, in such cases, the retained biliary secretion is the essential cause of the anæmia, by inducing solution of the hæmoglobin. This opinion is criticised in the last of the two numbers just quoted, of the *Wochenschrift*, by C. A. Ewald, who contends that the jaundice is secondary to the anæmia. He maintains that the jaundice in question is not obstructive, but the result of rapid disintegration of red blood-cells. The consequence of this is excessive production of biliary products, inability of the liver and the digestive functions to dispose of this excess, and the reabsorption of the latter from the liver into the circulation. My own case gives very decided support to the latter view. The jaundice in this case was certainly not obstructive. The same may be said of the second of the two cases reported by F. P. Kinnicutt to the Association of American Physicians (*American Journal of the Medical Sciences*, October, 1887).

CHARLESTON, May, 1888.

FRACTURE OF THE STERNUM, WITH DISLOCATION OF THE FRAGMENTS: TREATMENT AND RESULT.

BY B. J. D. IRWIN, M.D.,
ASSISTANT MEDICAL PURVEYOR, LIEUTENANT-COLONEL AND BREVET COLONEL U. S. ARMY.

Two cases of fracture of the sternum having been recently reported in the *Boston Medical and Surgical Journal*, vol. cxviii. pp. 368, 369, the writer is induced to place on record, from notes taken at the date of the occurrence, another instance of this rare form of injury.

While on duty at the United States Military Academy, in the summer of 1876, I was called in consultation by Dr. J. B. Monroe, of Highland Falls, near West Point, New York, to see John Turner, a healthy, robust American, aged twenty-six years, who, while seated on top of an omnibus, was dragged by his unruly team through a low doorway of a carriage-house, his body being caught between the lintel and the driver's seat, and crushed violently backward and downward against the roof of the vehicle. As he was hurried forward toward the entrance he endeavored to escape the danger from above by stooping and leaning forward, but his body was caught by the lintel and violently crushed backward, his dorsal spine being pressed against the projecting comb of the seat, formed on the roof of the omnibus. At the same time the compression of the thorax fractured the sternum at the junction of the manubrium with the gladiolus, the lower end of the former being driven inward, while the upper extremity of the latter bone was pushed outward and upward upon the manubrium.

Attempts to return the fragments to their normal position having proved unsuccessful, a broad bandage

had been applied for the purpose of lessening the intense pain caused by thoracic respiration.

Examination of the injured parts disclosed marked projection of the spinal column between the second and sixth dorsal vertebræ, but, although the appearance of the parts indicated fractured bone, careful manipulation failed to disclose crepitus.

Efforts were at once made to replace the fragments of the broken sternum, but, although they could be reduced to position by pressing the overlapping, projecting end of the gladiolus downward, it would slip out and upward on withdrawal of the direct pressure.

To overcome that tendency, a large, hard pad, covered with soft material, was placed between the scapulæ. While the patient inspired deeply and the head and shoulders were extended well back, the displaced fragments were returned and retained in their normal position by a suitable splint applied over the pad and across the spine; the expanded condition of the thorax being maintained by aid of a figure-eight bandage, which bound the shoulders back to the projecting ends of the transverse splint.

To allay pain, which was very severe during the two or three days following the reception of the injury, morphine and potassium bromide were administered from time to time, as occasion required.

The apparatus was worn without change for three weeks. Its use secured perfect reunion of the broken bone and complete restoration of the sternum to its natural condition.

San Francisco, Cal., May, 1888.

MEDICAL PROGRESS.

Myxœdema.—Dr. Ord, as Chairman of the Myxœdema Committee of the Clinical Society of London, at the last meeting of the Society, presented its report, of which the following are the conclusions:

1. That myxœdema is a well-defined disease.

2. That the disease affects women much more frequently than men, and that the subjects are, for the most part, of middle age.

3. That clinical and pathological observations respectively indicate, in a decisive way, that the one condition common to all cases is destructive change of the thyroid gland.

4. That the most common form of destructive change of the thyroid gland consists in the substitution of a delicate fibrous tissue for the proper glandular structure.

5. That interstitial development of fibrous tissue is also observed very frequently in the skin, and with much less frequency in the viscera, the appearances presented by this tissue being suggestive of an irritative or inflammatory process.

6. That pathological observation, while showing cause for the changes in the skin during life, for the falling off of the hair, and the loss of the teeth, and for the increased bulk of the body, as due to the excess of subcutaneous fat, affords no explanation of the affections of speech, movement, sensation, consciousness and intellect, which form a large part of the symptoms of the disease.

7. That chemical examination of the comparatively few available cases fails to show the general existence of an excess of mucin in the tissues adequately corresponding to the amount recorded in the first observations, but that this discrepancy may be, in part, attributed to the fact that tumefaction of the integuments, although generally characteristic of myxœdema, varies considerably throughout the course of the disease, and often disappears shortly before death.

8. That in experiments made upon animals, particularly on monkeys, symptoms resembling in a very close and remarkable way those of myxœdema, have followed complete removal of the thyroid gland, performed under antiseptic precautions, and with, as far as could be ascertained, no injury to the adjacent nerves or to the trachea.

9. That in such experimental cases a large excess of mucin has been found to be present in the skin, fibrous tissues, blood and salivary glands; in particular, the parotid gland, normally containing no mucin, has presented that substance in quantities corresponding to what would be ordinarily found in the submaxillary gland.

10. That the full analysis of the results of the removal of the thyroid gland in man demonstrates in an important proportion of the cases the fact of the subsequent development of symptoms exactly corresponding to those of myxœdema.

11. That in no inconsiderable number of cases the operation has not been followed by such symptoms, the apparent immunity being, in many cases, probably due to the presence and subsequent development of accessory thyroid glands, or accidentally incomplete removal, or to insufficiently long observation of the patients after operation.

12. That, whereas injury to the trachea, atrophy of the trachea, injury of the recurrent laryngeal nerves, injury of the cervical sympathetic and endemic influences have been, by various observers, supposed to be the real causes of experimental or of operative myxœdema (cachexia strumipriva), there is, in the first place, no evidence to show that, of the numerous and various surgical operations performed on the neck and throat, involving various organs and tissues, none, save those in which the thyroid gland has been removed, has been followed by the symptoms under consideration; that in many of the operations on men, and in most, if not all, of the experimental operations made by Professor Horsley on monkeys and other animals, the procedure avoided all injury of surrounding parts, and was perfectly aseptic; that myxœdema has followed removal of the thyroid gland in persons neither living in, nor having lived in, localities the seat of endemic cretinism; that, therefore, the positive evidence on this point outweighs vastly the negative, and that it appears strongly proved that myxœdema is frequently produced by the removal, as well as by the pathological destruction, of the thyroid gland.

13. That whereas, according to clause 2, in myxœdema women are much more numerously affected than men, in the operative form of myxœdema no important difference of the same kind is observed.

14. That a general review of symptoms and pathology leads to the belief that the disease described under the name of myxœdema, as observed in adults, is practically the same disease as that named sporadic cretinism when affecting children; that myxœdema is probably identical with cachexia strumipriva; and that a very close affinity exists between myxœdema and endemic cretinism.

15. That, while these several conditions appear, in the

main, to depend on, or to be associated with, destruction or loss of the function of the thyroid gland, the ultimate cause of such destruction or loss is at present not evident. —*Lancet*, June 2, 1888.

Digitalis as a Diuretic and Laxative.—HUCHARD, in the *Revue Gén. de Clin. et de Thér.* of April 12, 1888, gives the following formula for a laxative powder containing digitalis:

Potass. sulphat.,	
Potass. tartrat.,	
Potass. nitrat.	āā gr. 90.
Fol. digital. (pulv.)	gr. 15.

In twenty powders.
One powder three times daily.

The Use of Gray Oil in Syphilis.—At a late meeting of the Society of Physicians at Vienna, PROF. LANG recommended the use of "gray oil" in syphilis. Recognizing the powerful curative properties of metallic mercury as it exists in blue ointment, the subcutaneous injection suggested itself. The preparation which he has used for four years consists of

Mercury,	
Lanolin	āā 3 parts.
Olive oil	4 parts.

As to the quantity of "gray oil"—as Lang entitles his preparation—to be injected, experience teaches that very small amounts have a powerful influence upon the syphilitic process. Moderately severe forms of syphilis require hardly more than five minims of gray oil a week. As a rule, one and a half to two minims of "gray oil" are injected into two places (buttocks or back) every five to eight days. In two or three weeks, most of the symptoms will have ameliorated or entirely disappeared, and the quantity can then be reduced. As the influence of the injections persists, treatment may be intermitted for ten to fourteen days. Then, the injections are resumed, a quantity equal to that first used being injected at longer intervals, or smaller quantities at like intervals, until twenty-four to thirty-two minims have been injected. Lang advises watching for affections of the mouth and other signs of acute mercurialism.

Knowing the technique, securing a faultless preparation of the remedy and observing antiseptic principles, good results are to be obtained almost without exception. The remedy is well borne; in the four years in which Lang has used "gray oil," only in four or five cases has he been compelled to withdraw the treatment, either because the patient could not bear injections or because an idiosyncrasy to mercury existed.

The inferences from his experience are:

1. That in "gray oil," the mercury is equably distributed, and the dosage can be accurately determined.

2. Convenience of the application.

3. Slight reaction. In none of the many cases thus treated by Lang did suppuration occur at the site of injection.

4. The manifest advantage of the method, however, is that in "gray oil" the mercury is contained in a form similar to that in which it exists in blue ointment.

The treatment with "gray oil" is indicated in all cases in which general treatment with mercury is indicated. There is no method more efficient, or whose results would be more permanent. The best test for a remedy for syphilis is in the success attained in syphilis of the central nervous system, and it is in doubtful cases of syphilis of the brain and spinal cord that Lang obtained very satisfactory results.

An important point is that "gray oil" can be used in cases in which blue ointment, or mercurial plaster cannot be applied. Thus, the author injected into a gummatous cavity in the tibia with a small external opening "gray oil," and the cavity closed. "Gray oil" is also adapted to the local treatment of syphilitic processes in the larynx, in the nose, of the tympanum and of the eye.

In reply to inquiries, Lang stated that immediately after the injection no pain is observed; on the following day, a small infiltrate is apparent, with sensitiveness, which lasts two to five days; after six to eight days, the site of injection is no longer discernible. Comparative experiments with injections of calomel showed that "gray oil" occasioned milder subjective and objective manifestations than calomel. Lang has not investigated how long the mercury remains in the organism, but it has not been demonstrated that remedies which are speedily eliminated are the less active. He has not used "gray oil" in hereditary syphilis. The remedy is not to be advised for children, because they bear subcutaneous injections poorly; but in the case of adults it ought to be useful.—*Wiener medizin. Presse*, May 20, 1888.

Intestinal Occlusion in Pernicious Fever.—DR. A. W. REYES, of Sagua la Grande, Cuba, in an instructive paper on rare forms of pernicious fevers, directs attention to the occasional sudden occurrence of intestinal occlusion due to violent tonic spasm of the intestinal muscular fibres, which is sometimes associated with spasm of voluntary muscles also. In these cases there is great difficulty in arriving at a correct diagnosis, for the temperature is usually only slightly above the normal, the extremely prostrate, sometimes cyanotic, condition of the patient coming on very suddenly, and there being nothing to point to the malarial origin of the affection. Nevertheless, the rapid and powerful effect of quinine, especially if administered hypodermatically, together with the exhibition of some alcoholic stimulant by the mouth, is, he considers, a pretty sure indication of the true nature of these cases.—*Lancet*, May 12, 1888.

Chloroform Water as a Vehicle.—UNNA, in *Monatshefte für Praktische Dermatologie*, No. 9, 1888, writes that he has found chloroform water an excellent vehicle for the hypodermatic administration of Fowler's solution and ergotin, as it prevents the decomposition of the solution. It is also useful in giving morphia where a local anæsthetic and counter-irritant effect is desired, as in neuralgias. It is equally valuable in the internal administration of drugs which decompose rapidly. Atropine and bichloride of mercury may also be given in chloroform water.

Alanin-mercury Hypodermatically in Syphilis.—PROFESSOR DE LUCCA, of Catania, has found that a combination of mercury with amido-propionic acid, or alanin, as it is called, is preferable to all other mercurial preparations for hypodermatic use in syphilitic cases. Alanin-mercury

is thus prepared: One part of alanin is dissolved in twenty parts of water by heating gradually until it boils. While the solution is boiling binoxide of mercury is added little by little until no more will dissolve. The whole is then filtered and evaporated. The alanin-mercury crystallizes out in minute needles of a dull white color. With this substance Professor de Lucca has treated forty cases of recent syphilis. A very small dose is sufficient, the average daily quantity, given hypodermatically, being $\frac{1}{15}$th of a grain dissolved in 15 minims of water. In very few cases were abscesses produced. Alanin-mercury seems to be peculiarly suitable for internal use in infantile syphilis. In these cases from $\frac{1}{30}$th to $\frac{1}{15}$th of a grain was given daily, and in no instance was there any sign that it could not be borne. Professor de Lucca states that the cures produced by alanin-mercury appeared to be of a permanent character.—*Lancet*, April 28, 1888.

Naphthalin in place of Arsenic as an Insecticide.—HAGER calls attention to the dangers attending the use of arsenic and its preparations as an anti-parasite and vermin-killer. He strongly recommends to use naphthalin whenever arsenic would be indicated for the above purposes. He gives among others the following formula:

Naphthalin	40 parts.
Chloroform	80 "
Benzine	100 "

Mix.

Heat carefully to about 20° C., and agitate till the naphthalin is dissolved. American petroleum may be substituted for the benzine. These solutions may be applied as they are to the skin of animals infested with vermin, or they may be applied in a diluted state. The naphthalin may be incorporated with vaseline if an ointment is desired for use, or if an oily liquid is wanted the above solutions may be mixed with liquid vaseline in the proportion of 200 of the former to 1200 of the latter. Hager also speaks highly of the infusion of quassia as an anti-parasitic application.—*Pharmaceutical Record*, May 15, 1888.

Guiacol in Phthisis.—HORNER, in the *Prager med. Wochenschrift*, No. 17, 1888, reports that he has used guiacol in phthisis for four years. The dose has been 7½ grains, in pill form, beginning with three pills and increasing to ten. General improvement followed in the greater number of cases. The tubercle bacilli became less in number.

Changes in the Oxyhemoglobin of the Blood Produced by Typhoid Fever.—HÈNOCQUE and BANDONIN have made daily spectroscopic examinations of the blood in typhoid fever, finding that the lowest point in the course of oxidation was reached about the eighth day. The occurrence of diarrhœa and of pulmonary complications reduced the consumption of oxygen by the blood and other tissues. In general, oxidation in the body was in inverse proportion to the elevation of temperature and severity of symptoms.—*Revue Gén. de Clin. et de Thèr.*, May 3, 1888.

Camphorated Carbolic Acid.—SCHNEIDER, a Swiss physician, recommends camphorated carbolic acid as an "elegant, reliable, and very convenient antiseptic preparation." As is well known, when one part of crystallized carbolic acid and three parts of powdered camphor are shaken up together in a test-tube, a colorless limpid fluid is produced. This mixture does not possess either the characteristic odor or the rubefacient and caustic properties of carbolic acid, while the antiseptic power of the latter remains intact. When placed on the tongue the compound causes but a very slight burning sensation. It has no effect on polished steel.—*British Medical Journal*, May 12, 1888.

An Application for Hysteria of the Larynx.—The *Journal de Médecine de Paris* of May 13, 1888, gives the following formula:

Cocain. hydrochlor. . . .	gr. $\frac{5}{10}$ to 1½.
Aquæ destill.	ʒ 11¼.
Potass. chlorat.	gr. ¾.
Aq. amygdal. amar. . . .	♏ 1.

For local application in laryngeal hysteria.

Atropine in Pilocarpine Poisoning.—DR. WICHERKIEWICZ records in a Polish medical journal a case of poisoning by pilocarpine. Eight minims of a two per cent. solution of pilocarpine had been administered hypodermatically in the temporal region for an ophthalmic affection. This was followed by very severe symptoms of poisoning and collapse. A subcutaneous injection of morphia and the inhalation of nitrite of amyl proving useless, two drops of a one per cent. atropine solution were administered hypodermatically. This had more effect, and the patient recovered.—*Lancet*, April 28, 1888.

The Germs Contained in Vaccine Virus.—PFEIFFER is quoted by the *Centralblatt für Bakteriologie*, No. 19, 1888, in his report of examinations of vaccine lymph to determine the germs contained in it. He found that an absolutely pure lymph is only rarely obtained; the germs most frequently found are spores, rarely in lymph from children, constantly in vaccine lymph. Sarcinæ are also found in both human and vaccine lymph, they are of no practical importance. Bacteria and bacilli are found exceptionally in human lymph, more frequently in vaccine matter. Micrococci are found, the most constant being *staphylococcus cereus albus* and an orange-colored micrococcus identical with the *pyogenes aureus*. Pathogenic micrococci occur frequently, most often the *staphylococcus pyogenes aureus*, *albus* and *citreus*; *streptococci*, those of erysipelas and the *pyogenes* are not found in animal lymph. The bacillus of syphilis does not flourish in bovine lymph and hence syphilitic contagion cannot be obtained from this source. The bacilli of tuberculosis may, however, be inoculated in vaccine lymph.

Imitation Kefir.—A very good and agreeable imitation of the Tartar beverage known as "kefir," which is, like koumiss, used extensively in phthisis and other wasting diseases, may be made by the following simple method described by Dr. Levy in a German chemical journal: Freshly prepared sour milk is briskly shaken up and then placed in a soda-water bottle, together with two per cent. of syrup. The mixture is well corked and kept in a warm place for three or four days. At the end of that time a most agreeable effervescing beverage is obtained

by uncorking the botttle. It contains some two per cent. of alcohol. If required for use more speedily, a few drops of lemon juice should be added to the syrup.—*Lancet*, April 28, 1888.

A Convenient Formula for the Treatment of Tapeworm.—Oil of male fern may be conveniently administered in the following combination:

Ethereal oil of male fern . . .	♏ 45.
Tinct. vanillæ	♏ 45.
Syrup rubi.	ʒ 6¼.
Gum. acac. pulv.	gr. 30.
Aquæ destill.	ʒ 6¼.

To be taken at one dose, in an equal quantity of milk. Castor oil should be taken two hours afterward.—*L'Union Médicale*, May 10, 1888.

The Histology of Peripheral Neuritis.—A new contribution to the histology of peripheral neuritis has been made by Prof. Eichorst, of Zurich (*Virchow's Archiv*, cxii. Hft. 2). The case he describes is that of an habitual drunkard, who died from alcoholic paralysis after six weeks' illness. The symptoms began with incoördination and then paralysis of the legs, followed by paralysis of the extensors of the wrist, with rapid wasting of the paralyzed muscles, tenderness of the muscles, some cutaneous anæsthesia, abolition of reflexes, and ultimately vesical and rectal paralysis. At the post-mortem examination, no gross lesions could be seen in the nerve centres. The brain was not examined microscopically, but the cord showed some asymmetry in the anterior cornua, and some recent hemorrhages in the gray matter in the dorsal region, with thickening of the bloodvessels—changes which did not suffice to explain the general paralysis. The spinal nerve roots were found to be normal. The tibial and radial nerves, on the other hand, were found to be profoundly diseased, osmic acid preparations showing very extensive degeneration and atrophy, with absence of the axis-cylinders in a large proportion of the nerve fibres. Tracing the nerves to their peripheral terminations in the muscles, Professor Eichorst found the lesions to be more advanced and complete there than in the nerve trunks. Indeed, within a muscle there was not a single normal nerve fibre. Nor were the lesions of these intra-muscular nerves limited to degeneration, as in the nerve trunks; but each degenerated fibre was surrounded by numerous laminæ of connective tissue produced from the endoneurium and perineurium. It would seem as if the existence of the degenerate nerve substance had excited inflammatory change around it. Another remarkable fact was that the muscular fibres did not exhibit the trophic changes usually met with in neuritis, although in the vicinity of the diseased nerve-endings the muscular fibres were atrophied apparently secondary to the perineural lesion. Professor Eichorst therefore proposes to term the condition "neuritis fascians," as denoting what he considers to be the essential feature of the change, viz., the inflammation of the nerve sheath, and the extension therefrom to the interstitial tissue of the muscles. He points out that similar changes in muscles have been described by Fränkel in phthisis, and by Eisenlohr in infantile paralysis; the former raising the question whether the ensheathing bands of connective tissue arose from the bloodvessels or the neurilemma. Eichorst does not infer that neuritis fascians is special to alcoholic paralysis, but that it is an important feature of it. Certainly the clinical phenomena of "peripheral neuritis" harmonize with the occurrence of lesions within the muscles themselves, and we may direct the attention of pathologists to the more precise determination of such lesions, which in all probability precede the degeneration of fibres observed in the nerve trunks. The latter change has been amply studied, but the former, and indeed the essential change, has not as yet been much dealt with.—*Lancet*, May 19, 1888.

Antipyrin as a Hæmostatic.—In view of the statements of Henocque and Huchard as to the hæmostatic properties of antipyrin, Dr. Alexëi G. Glinsky, of Kharkov, tried (*Transactions of the Kharkov Medical Society*, Part 1., 1887, p. 23) the drug (in the shape of cotton-wool plugs soaked in a five or ten per cent. solution, or powdered with the antipyrin) in a series of cases of bleeding, such as epistaxis, hemorrhage from surgical or accidental wounds, etc. On the whole, his results were unsatisfactory. In some cases of lacerated wounds of the fingers (inflicted by nail, etc.) hemorrhage was arrested, but it was not certain that this effect was not rather due to pressure than to the antipyrin. Dr. Glinsky tried it on a wound on his own finger, but was obliged to have recourse to perchloride of iron. In three cases of severe epistaxis the bleeding came on again in five or ten minutes after withdrawing the antipyrin plugs, and ultimately could be stopped only by plugging the posterior nares. Antipyrin had no effect in checking hemorrhage after excision of acute condylomata, labial papillomata, etc. On the other hand, Dr. Glinsky was much pleased with antipyrin as a dry dressing in indolent ulcers of the leg, fully confirming Dr. Boss's observations (*Berliner klin. Wochenschrift*, No. 33, 1886) on this point. The healing action of the drug in these cases is so rapid that he strongly recommends the use of antipyrin in powder when other means fail. He also obtained good results with antipyrin in acute articular rheumatism, in which it is said to act as effectively as salicylate of soda and more rapidly. It also proved useful in migraine and neuralgia of the fifth nerve. Unpleasant secondary effects (rash, sickness, collapse) occurred in his experience very rarely.—*British Medical Journal*, May 19, 1888.

A Simple Apparatus for Sterilizing Instruments.—De Backer describes, in the *Journal de Médecine* of May 6, 1888, a simple apparatus, consisting of a rectangular water-bath hermetically sealed containing a pound of paraffine, ordinarily melting at 119° F., and which can be heated to 572° F. without volatilizing. In the water-bath is placed a flask containing the articles to be sterilized. Heat is furnished by an alcohol lamp.

Skin Grafting with Cock's Comb.—Senor F. Altramirano mentions in a Mexican journal, *El Observador Médico*, a case in which he made some experiments in skin grafting on an obstinate ulcer left by a large carbuncle. More ordinary means having failed to cause it to heal, he applied three skin grafts taken from the patient himself. Of these only one took, and the man expressed so much repugnance to the proceedings that another source had to be found for subsequent grafts. A

cock was selected, and fragments cut from his gills; these were split, divided into ten pieces, and the raw surfaces applied to a freshened portion of the ulcer. A carbolized dressing was then bandaged on, the whole being constantly moistened. On the third day, on the dressing being removed, all the ten fragments were found organically adherent. A number of new grafts were then applied, cut from the comb, the gills, and the skin of the back of a chicken. None of these was successful. The cock's gills were again resorted to, and four more fragments successfully grafted. A fresh set of grafts were prepared from this source; but all the cellular tissue was cut or scraped away, in some cases little but the epidermis being left, in others the edges being bevelled, so that the epidermis was in direct contact with the new surface of the ulcer. This set of grafts proved very unsuccessful, so that Dr. Altramirano was led to the conclusion that no advantage is gained by applying the epidermic layer immediately in contact with the surface of the ulcer.—*Lancet*, May 19, 1888.

The Treatment of Gall-stones.—Rosenberg, at a recent meeting of the Berlin Medical Society, stated that upon an American suggestion he had treated with large quantities of olive oil a patient, who, for five years had suffered with attacks of nephritic colic, and had in vain used the most various remedies. The patient took on several evenings, without marked discomfort, from 3 to 5¾ ounces of olive oil, followed by some Cognac, and after the first dose passed 3 calculi, after the second, 243. In all, 26⅓ ounces of olive oil were taken, in five doses, and 629 calculi counted in the stools; subsequently to which the gall-bladder, which had previously extended markedly beyond the margin of the liver, could be no longer palpated. According to the views of American physicians, the usefulness of the olive oil depends upon its entrance into the gall-bladder and softening the calculi.—*Wien. medizin. Presse*, May 20, 1888.

The Influence of Antiseptics on the Kidneys.—At the last meeting of the Berliner Medicinische Gesellschaft, Dr. Emil Senger read a paper on the influence of antiseptic remedies on the organs of the body, with special reference to operations on the kidney. It is well known that after nephrectomy, or even nephrotomy, many patients die with symptoms of uræmia or anuria, even when it had been ascertained beforehand by careful examination that the other kidney was quite healthy and capable of secreting the necessary amount of urea. Dr. James Israël, chief surgeon of the Berlin Jewish Hospital, has propounded a very complicated theory as to certain nervous sympathies between the two kidneys, whereby an operation on one may give rise to degeneration of the other. Senger has now proved by experiments on rabbits and dogs that our antiseptic remedies are the cause of these complications. He injected into the animals, when in perfect health, one-tenth or twelfth part of the quantity of corrosive sublimate, carbolic acid, etc., which is sufficient to kill them. He then extirpated one kidney, and examined it microscopically, with the result that in all cases he found glomerulo-nephritis. There was exudation between the glomerulus and the capsule, and the epithelium of the tubuli contorti was almost entirely destroyed. He found also fatty degeneration of the liver, the spleen, the heart muscle, etc. The various antiseptic agents were found to be injurious in different degrees, corrosive sublimate being the most dangerous, then the others in the following order: iodoform, carbolic acid, salicylic acid, boric acid. Senger therefore recommends surgeons to avoid antiseptics in operations on the thorax and abdomen, and urges them either to employ sterilized water after the manner of Mr. Lawson Tait, or a solution of salt. By bacteriological and pathological researches he proved, first, that this kills the streptococcus pyogenes aureus in twenty-eight minutes, and that the effect is independent of the degree of concentration, for a five per cent. solution is just as effectual as a twenty per cent. Secondly, he claims to have shown that chlorate of sodium does not in any way injure the organs, and that no dose is strong enough to kill any animal.—*British Medical Journal*, May 19, 1888.

A Case of Ectocardia Relieved by Operation.—Lannelongue recently reported to the Academy of Sciences of Paris, the case of a female infant, six days old, brought to his care at the hospital Trousseau, with congenital absence of the anterior wall of the thorax, resulting in an ulcerated aperture as large as a ten cent piece. The day following admission to the hospital, a yellowish membrane which had partially closed the aperture, was removed by ulceration; the anterior surface of the ventricles was visible, and the pericardium was seen to be absent. Progressive ulceration of the borders of the opening, with retraction of the tissues, was gradually forcing the ventricle and apex of the heart forward and without the thorax. A plastic operation was made by loosening flaps on each side of the aperture, and uniting them by sutures, leaving their bases attached for blood supply. No blood was lost by the operation, and cicatrization resulted in less than three weeks. Two months and a half after operation the child was in comfortable health, and it was probable that as the heart increased in size, it would take its normal position within the thoracic walls.—*Gazette Hebdomadaire*, May 11, 1888.

Creasote Hypodermatically in Phthisis.—In a recent work on the treatment of phthisis by Hèrard, Cornil and Hanat, the following formula is given:

Peptone, dried	ʒ 2½.
Pure creasote, from beech wood	♏ 45.
Glycerin neutral	ʒ 17½.
Alcohol	℥ 2½.
Distilled water	ʒ 5.
Hydrochlorate of morphia	gr. 1½.

Dose.—Fifteen minims, repeated several times (as many as four or five times) daily, deeply injected.

Tar Water in Hemorrhage.—Dr. Corneille de Saint Marc finds that distilled tar water has a hæmostatic effect very similar to that of hamamelis. When prepared with the tar of pine wood it has valuable tonic astringent properties. It may be administered in quantities of from 10 to 15 drachms, during the twenty-four hours, in congestive pulmonary hemorrhage, and in hemorrhage of the uterus and kidney. It arrests the hemorrhage of the first two stages of phthisis with remarkable promptitude.—*Lancet*, May 12, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

PHILADELPHIA.

SATURDAY, JUNE 23, 1888.

THE CASE OF THE LATE EMPEROR OF GERMANY.

SINCE our remarks, in our issue of December 10, 1887, the telegraphic press reports of the medical aspects of this historical case have been so unsatisfactory, in a scientific point of view, that we have purposely refrained from further comment. The lack of information as to the laryngoscopic features of the disease since the performance of the tracheotomy has prevented any accurate interpretation of the meagre and conflicting press dispatches as to the progress of the malady. Now that the case has terminated, and the post-mortem examination has shown the disease to have been carcinoma, some very interesting problems are near their solution.

In our last remarks referred to, the observation was made that "if the disease in the larynx of the Crown Prince of Prussia be carcinoma, the clinical course has been different from what is usual in that disease." It would be injustice to the distinguished gentlemen who have had professional charge of this case to enter into any criticism of their opinions, or of their reports, until the entire clinical history shall have been written by them. In view of a statement that the physicians in attendance upon the Emperor, and notably Sir Morell Mackenzie, denied that the disease was cancer, because of certain clauses in the Prussian Constitution debarring princes afflicted with incurable maladies from accession to the throne, we have only to refer to Sir Morell Mackenzie's candor in his official report made at the request of his patient, and published in *The British Medical Journal* of November 19, 1887; in concluding which he says that "although the nature of the growth which has lately appeared has not been determined by microscopic examination, it presents every appearance of cancer." Surely nothing could be more explicit. If he really became more guarded in his later expressions, it was certainly for good reasons that he felt himself precluded from expressing his views more frankly; and, in justification of such a course for State reasons, he had doubtless the highest advice and authority.

Two important questions of scientific interest present themselves. The one is: Was the disease malignant from the outset? The other is: Supposing that the disease was malignant at the period at which Mackenzie's advice was sought, thirteen months before death, would it have been better practice to excise the larynx?

The fragments of growth removed intralaryngeally from time to time by Sir Morell Mackenzie revealed no malignant features under the microscopic scrutiny of Virchow—the acknowledged master of pathology. In commenting upon his official reports as to the benign character of these fragments, and while distinctly mentioning that that character was no accurate criterion as to the nature of diseased structures still *in situ*, Prof. Virchow made the statement (*Berliner klin. Woch.*, December 21, 1887) that in an examination, expressly instituted for the purpose, of such specimens of cancer of the larynx as he had been able to gather from several collections, he had failed to find a single instance of independent warty formation in association with cancer. This stamps the case under consideration as unique in that respect.

It is not at all probable that any topical interference with the disease, whether electric cauterization practised by Gerhardt, or the subsequent evulsions of morbid growths by Mackenzie, had any influence whatever in transforming a presumptively benign neoplasm into a malign one. Occasional instances of such transformation are on record, but the correctness of such views is a matter of great doubt. Hence the strong probability that the disease was malignant from the outset.

Whether laryngectomy would have removed the disease so thoroughly as to prevent recurrence of carcinoma, and thus have prolonged life for a considerable period, is highly doubtful in the light of the post-mortem investigation. The press report

of this examination is of no scientific value, but it is sufficient to show that the disease was very extensive. Official reports must be awaited to learn the character of the changes which had taken place, and the extent to which the perilaryngeal and peritracheal structures had become involved; but the press report is sufficient to indicate that laryngectomy would have failed to prolong life for as long a period as has followed the palliative and symptomatic treatment which was adopted. Unfortunately, tracheotomy prolonged life but for a very few months; while ordinarily it prolongs life from several months to many. This result is a further indication that laryngectomy would have failed in this instance to be of material benefit.

One comment that suggests itself is whether the amount of official work and worry which seems to have been crowded upon the late Emperor may not have had a good deal to do in so sapping his recuperative powers as to prevent him from reaping that prolongation of life which might have reasonably been expected in a man of his physical vigor at the time of the performance of the tracheotomy. He seems to have been engrossed in his official duties to the very last moment of tolerance, almost to the very day of death.

On the whole, we must come to the conclusion that the case of the Emperor has been handled with consummate ability, and that every untoward feature has been promptly met by Sir Morell Mackenzie in the most judicious manner, and that professional skill did all that human power could do to prolong to the utmost limit the lamented Emperor Frederick's waning life. The pluck and endurance of the patient, and his unflinching confidence in his chief medical attendant, have been such as to command the admiration of the whole world.

ABDOMINAL TUMORS IN THE NEGRO RACE.

It is well known to those who have had to deal with the negro race as it exists in our Southern States, that there is a difference in the susceptibility of negroes to the development of tumors from that of the whites; and this is especially true in regard to neoplasms of the female generative apparatus. Myomatous tumors of the uterus are exceedingly common in colored women; so much so, that it is rather uncommon to find a womb in a middle-aged negro cadaver, in which myomata have not developed. On the contrary, cystic tumors of the uterus or ovaries are very uncommon in the negro; but this infrequency must not blind us to the fact that such growths do occur, and probably more frequently than is supposed. The infrequency of cystic growths in this race has hitherto been considered a sufficiently diagnostic feature to exclude these tumors in a doubtful case, but we can no longer rely upon the statement of authorities that such growths are "almost unknown."

The above remarks are suggested by the fact that within the past few days we have seen an undoubted case of large multilocular ovarian cystoma in a negro woman, the character of the tumor having been verified by its removal by laparotomy.

In the *Maryland Medical Journal* of June 2, 1888, Dr. William Pawson Chunn, of Baltimore, has a suggestive article upon "Abdominal Tumors in the Negro Race," in which he shows conclusively by his own experience and that of Dr. Hunter McGuire and others, that cystomatous disease of the uterus and ovaries is far from being unknown. Renewed attention is called to the fact that cystomata do occur, and that we need not hesitate to make the diagnosis of ovarian tumor, if the symptoms correspond with those of that disease.

Dr. David W. Cheever has been elected President of the Massachusetts Medical Society for the ensuing year.

At the annual meeting of the New Jersey State Medical Society, held last week, Dr. H. Genet Taylor, of Camden, was elected President for the ensuing year. The next meeting will be held at Spring Lake, in June, 1889.

According to the *Maryland Medical Journal* of June 16, 1888, thirty-four graduates of the College of Physicians and Surgeons of Baltimore have appeared before the Virginia Medical Examining Board since January 1, 1885, and of these ten failed to pass the examination.

The University of Bologna, on the occasion of the eight hundredth anniversary of its foundation, conferred its honorary degree upon several representatives of literature, science and art, and included in the list was Dr. S. Weir Mitchell, of Philadelphia, who represented the National Academy of Science on the occasion.

The valuable addition to the structures at Princeton College of a new biological laboratory is an

accomplished fact. The building has been completed and is now being fitted out and made ready for occupancy at the coming fall session. The formal presentation of the property to the board of trustees will take place during the Commencement week. The donors of this important contribution to the scientific instruction of the college are the alumni of the class of 1877, and by their name the building will be known hereafter. Of the members of that class, three, at least, Professors Libbey, Scott and Osborn, have been identified with the upgrowth of the sciences on conservative Jersey soil.

PROFESSOR WILLIAM H. WELCH, M.D., of Johns Hopkins University, will deliver before the Yale Medical Society, New Haven, an "Address in Medicine," on June 26th.

The Canada Medical and Surgical Journal announces that on the first of July it will assume the name of *The Montreal Medical Journal*, will increase the size of its monthly issue by sixteen pages, and reduce its subscription price to two dollars. The *Canada Journal* has always been among the most welcome of our exchanges, and in its new departure we trust that it will receive the large measure of success which its enterprise deserves.

DR. A. C. HENDERSON, of Brooklyn, recently lost a son by a strange and sudden form of death. The lad, aged about twelve years, was assisting in the removal of a large iron retort containing strong commercial ammonia, such as is used in the artificial production of ice. The wagon, upon which the retort was transported, had been jolted much and incautiously and the receptacle was burst, the contained liquid being thrown over the face and body of the lad. He was burned most severely and suffered terribly, death ensuing in about twelve hours. It is altogether probable that if a greater degree of caution had been exercised in the transportation of the dangerous liquid this promising young life would not have been lost.

AN intercolonial commission on the rabbit pest of Australia has recently been appointed, composed largely of medical men: Dr. H. N. MacLaurin, President of the Board of Health of New South Wales, for that colony, with Dr. C. Wilkinson; Professor Allen for Victoria; Drs. Stilling and Paterson for South Australia; Dr. J. Bancroft for Queensland. A representative of New Zealand will be admitted to the commission. Dr. Camac Wilkinson, a member, is the author of a proposition to try Pasteur's plan for the destruction of the pest by inoculation, upon an isolated, uninhabited island which shall be stocked with rabbits and every form of useful animal found in the colonies, and test the method in a precise and thorough manner before adopting it on a wider scale.

A MONUMENT to the memory of Cohnheim was unveiled at Leipzig, with appropriate ceremonies, on the 3d of June.

AT the Second Congress of the German Society for Gynecology, held at Halle on the 24th of May, it was determined, in view of the meeting of the International Medical Congress in 1890 at Berlin, that the Third Gynecological Congress meet next year at Freiburg.

PROF. R. V. JAKSCH has been elected Chief Physician to the Anna Children's Hospital at Gratz.

THE Managers of the Pennsylvania Hospital last Saturday afternoon, formally opened a new villa for the treatment of the insane, which has just been erected, under the supervision of Dr. Chapin, on the grounds of the institution in West Philadelphia. The cottage is of an attractive style of architecture, and its interior arrangements and furnishing are both home-like and handsome. It will accommodate about sixteen patients. The erection of this building will enable those in charge of the institution to form an intelligent judgment as to the value of the cottage-plan in the treatment of the insane, and the result will probably be seen in the character of the buildings which, when the time comes, will be erected on the extensive, new grounds recently purchased in Delaware County.

ON October 26th, the International Society of the Red Cross will celebrate the twenty-fifth anniversary of its organization.

THE Canadian Medical Association will hold its twenty-first annual meeting in the city of Ottawa, on 13th and 14th of September, under the presidency of Dr. J. E. Graham, of Toronto.

AN International Congress for Dermatology and Syphilography will be held in August, 1889, at Paris. Its sessions will continue one week, and will be presided over by Ricord and Hardy.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, May 23, 1888.

THE PRESIDENT, J. SOLIS-COHEN, M.D., IN THE CHAIR.

DR. A. JACOBI read a paper on

THE THERAPEUTICS OF DIPHTHERIA.

(See THE MEDICAL NEWS, June 16th, page 654.)

DR. JOSEPH O'DWYER then read a paper on

THE USE OF INTUBATION TUBES.

After an experience with tubes of various sizes in over two hundred cases of croup, besides other forms of stenosis, in children, he is fully convinced that, as at present constructed, the intubation tubes afford ample room for carrying on the respiratory function in the most perfect manner. When the disease is confined to the larynx and upper portion of the trachea, it is not an uncommon experience, after the paroxysm of coughing that immediately succeeds intubation has subsided, to find the little patient breathing so quietly and imperceptibly that it is sometimes difficult to convince the mother, who has returned to the room after an absence of fifteen or twenty minutes, that her child is still living. Such complete freedom of respiration would be impossible were the opening too small. When the struggle for breath has continued long enough to produce extreme exhaustion, together with more or less atelectasis and congestion of the lungs, this perfect relief does not occur. The same is true after the partial asphyxia induced by prolonged or repeated attempts to insert the tube. Such cases sometimes never rally, although air enter the lungs in the freest possible manner. If any dyspnœa whatever remain for any considerable time after intubation, or if the respiration be much above the normal in frequency, it indicates the presence of some complication or extension of the disease below the tube. The fact that several times on removing a tube from the larynx he has found its calibre considerably reduced by firmly adherent secretions, when there had been no dyspnœa to indicate it, is good evidence that there is more room than is actually required for the free entrance and exit of air.

He then referred to the manner in which the machinery concerned in the removal of secretions is modified or injured by a canula in the larynx or trachea. The mechanism of coughing, as he understands it, is simply getting as much air into the lungs as possible, condensing it, and allowing it to escape suddenly, on the same principle as the air-gun. To accomplish this, the glottis is firmly closed, coincidently with spasmodic contraction of the expiratory muscles, until the imprisoned air is sufficiently compressed, not only to give it power to project any offending substance before it, like the ball from an air-gun, but also to increase the friction between it and the lining membrane of the air-passages to such a degree as to scrape off, so to speak, secretions that may be adherent.

Considerable condensation, with great velocity of the expired air, is, therefore, necessary to give the maximum expulsive power. The latter without the former would accomplish nothing, because the same volume of air can be driven through the open or half-open glottis just as rapidly as in the act of coughing, without the least power to remove a particle of mucus even from the larynx, much less from the bronchial tubes. This can be demonstrated by trying to cough while retaining the vocal cords in the expiratory position—the lack of power resulting solely from inability to compress the air to any appreciable extent.

Coughing through a canula is identical with this act when performed with a partially open glottis, and the only means left of subjecting the air to any condensation whatever is the much shorter time occupied in expelling it through the same space by which it more slowly entered.

An excellent and forcible illustration of this argument, and one the mechanism of which is identical with that of coughing, is the familiar act of blowing the nose. There is little or no ability to remove secretion from this organ without first reducing the nostrils to a small fraction of their normal calibre, or by momentarily producing complete occlusion, as in closing the glottis, until the air is sufficiently condensed to force the secretions out with it. Very little power can be developed even by closing one nostril and forcing all the air through the other, if normally patulous. If secretions can be removed more effectually from the air-passages through a canula of the dimensions advocated by the authorities already quoted, for the same reason it should be easier to remove accumulations from the nose without compressing the nostrils.

He claimed, therefore, that while the artificial opening must be large enough for the perfect performance of the respiratory function, the power to expectorate is still further diminished, and in exact proportion to its increase beyond this limit.

DR. WILLIAM PEPPER said that the extreme value of iodoform in local treatment he could confirm. Soluble in ether, miscible with glycerin and with oils, capable of use as powder, it is the best of all local applications, and may be applied to all cases and conditions. He would, however, interpose a mild protest against the too sweeping condemnation of the steam atomizer. Used with that gentleness, so wisely insisted upon, and the confidence of the child obtained, the relief to oppression is soon recognized, so that we can secure intelligent cooperation in its frequent and regular use.

The problem of internal treatment is the most difficult one, a problem which largely and continually occupies our thoughts. He was glad to hear Dr. Jacobi's clear and outspoken adherence to the mercurial treatment, although he limits it to a certain group of cases. His longer experience has but abundantly confirmed his early impressions of its value—preëminently in laryngeal diphtheria, whether primary or descending; and he is constantly impressed with the tolerance of children to the bichloride, and equally to the mild chloride. But he would go further. If in a form conspicuous as a dangerous one, which is usually not primary but associated with rhinitis and faucitis, this treatment proves efficacious, why is it not equally good where the nasal or faucial disease has not extended into the larynx? He has found cases of nasal diphtheria which were a source of great anxiety yield in a most remarkable way, and it has seemed to prevent the local spread as well as septic infection.

He agreed with Dr. Jacobi that it is well to begin treatment with the chloride of iron, and that the association of chlorate of potassium is a matter of comparative indifference, and that large doses should be given at short intervals. But he had not been so fortunate in seeing it usually well borne by the stomach. When gastric or intestinal irritation manifests itself, it is well to stop the iron abruptly and to substitute mercurials. Or, when in the beginning of a case of glandular involvement, the faucial tumefaction, the constitutional symptoms, give evidence of rapid sepsis, we cannot depend upon iron and must give the corrosive or the mild mercurial chloride at once.

DR. CARL SEILER said that in his experience the addition of chlorate of potassium to the chloride of iron has been of great use, although he agreed with Dr. Jacobi that chlorate of potash alone is of little use. From laboratory experiments he attributed this to the disengagement of chlorine gas when the two solutions are mixed. In the same way, at the suggestion of Dr. L. Wolff, he finds Labarraque's solution an efficient disinfectant in the proportion of 1 to 5. He uses this as a spray to the nasal cavities or fauces, and has had excellent results.

DR. E. E. MONTGOMERY said that since August, 1886, he had performed some thirty or forty intubations, having previously done some twenty-eight tracheotomies. Fifty per cent. of the children intubated have recovered. His experience is that this operation largely reduces the necessity for tracheotomy, and he believes that if intubation were done early in every case, tracheotomy would rarely be necessary.

DR. M. PRICE said that in the evolution of steam from lime he had for the last fifteen years depended upon the same method as country people use in the scalding of hogs. Put a few pieces of lime in a bucket with hot water, place a blanket over the bed and let steam pass over the child's head. Soon the child acquires confidence and asks for relief, and will even bend his head down over the bucket trying to get the vapor into his throat. Now, if every half hour a hot stone or brick or piece of metal be added to the water, it will keep up the heat without any stove or fire being needed in the room. It keeps the room clean and the atmosphere sweet; he had not found so much danger of contagion when lime is used.

DR. J. SOLIS-COHEN said in regard to local treatment that where it can be properly applied to the extreme margins of the pseudo-membrane, he had found the topical use of chloride of iron, by firm and gentle pressure with brush, or, preferably, cotton wad, the most serviceable agent he had used. The drug has an astringent and a disinfectant action, and assists the detachment of false membrane, and apparently prevents the extension of the infection. Concerning the value of chloride of iron internally, the importance of large and frequent doses, the advantage of mixture with glycerin to assist its local effect, he can only confirm what has been said. So, too, as to the bichloride of mercury.

Empirical observation has long taught us the preëminent value of the chlorine compounds in general in the treatment of diphtheria; and the mercury chlorides, more particularly calomel, however, have always enjoyed a high reputation in the internal treatment of membranous laryngitis. The topical action of steam is very important. It has always seemed to him that in the natural course of the disease, the membrane is thrown off by an accumulation of fluid beneath it, which softens it and secures its detachment. We aim, then, by furnishing artificial moisture, to imitate the natural process of recovery. And this led him to speak of the value of the vapors from lime in the process of slaking. Using a large wash-tub or wash-boiler, and keeping up a supply of large pieces of lime, we secure an abundant disengagement of the hot vapor of water, carrying up with it particles of lime, which mechanically assist by prying up the edges of the pseudo-membrane, and thus favoring the access of the vapor of water beneath it.

There is another method of local treatment which he had employed with great satisfaction, more especially in former years, when he saw more of the disease—that is, inhalation of carbolic acid in the spray of a steam atomizer, in very large doses. Twenty to twenty-five grains would be added to the ounce of water, and from half an ounce to an ounce sprayed into the throat every hour, or even half hour, until commencing discoloration of the urine gave evidence of saturation, when the remedy was to be stopped until the urine again became clear. Under this method he would advise the attending physician to see the child four or five times a day, always having the urine last voided saved for him, and when the olive discoloration was noticed to intermit the carbolic acid. This seemed to him to disinfect the system, and thereby improve the local condition, and, at the same time, to prevent or diminish the danger of systemic sepsis. He was not aware, before to-night, that such small doses of carbolic acid, as Dr. Jacobi mentioned, could be of service.

His own experience with tracheotomy led him to favor large tubes, the largest that can be introduced without touching the walls of the trachea. He still believes that he has seen life saved by taking out small tubes and substituting larger ones. But facts are stronger than theories, and as the small calibre intubation tube does seem to give air enough, and as enough is all that is wanted, he is ready to profess his satisfaction with its present calibre.

He asked Dr. O'Dwyer to make clear the question as to the impaction of membrane. Some years ago he was called to a case of membranous laryngitis, and had proposed tracheotomy, which had been declined. As he turned to leave the room the mother called piteously, "Oh, Doctor, don't leave my child without trying to do something for it." He said to his assistant, "we will try to save this child," and taking a catheter he cut off the end, and passed the instrument into the larynx. The child instantly became black in the face, and there was nothing for it but, without asking any questions, to plunge his knife into the trachea as the child lay on its mother's lap. He inserted the same catheter through the orifice deep into the trachea, and then he performed artificial respiration; his assistant inflating the child's lungs through the tube with his own breath, and his hands exercising compression of the thorax in respiratory rhythm; and, after a while, he had the satisfaction of leaving the rescued child sleeping peacefully with unobstructed respiration. But this experience cost him some of the most anxious moments of his life, and has left a fear of the danger of crowding down membrane in front of a tube introduced into the larynx, which may, perhaps, make him overanxious.

Dr. Jacobi said that the slaking of lime has the further advantage that it is the only way to utilize lime. A lime-water spray is useless, but in slaking a large amount is carried up into the air and air-passages. The suggestion of the President that carbolic acid should be used in spray until discoloration of the urine is noticed, he did not feel inclined to adopt. Diphtheria is the very disease in which no complications should be allowed to exist, and we must not tempt them. A single case in which we should have to blame ourselves for a possible nephritis would, in his judgment, condemn the treatment. Besides, young infants are sometimes poisoned by very small quantities.

Dr. O'Dwyer said that pushing down of membrane does occur, though rarely. The difference between the liability to the accident in catheterization and intubation, is that the catheter has an open, comparatively broad end, while the intubation tubes are comparatively probe-pointed. One pushes and catches the membrane, the other slides past it. He has crowded membrane down in only two cases out of two hundred sufficiently to produce asphyxia. In those two, on removal of the tube, the cast was coughed out. If we take away the tube because the child is breathing badly, and the trachea is full of membrane, the child, not having the strength to cough it out, chokes from the absence of the tube, not from its previous presence. His attention is now being directed to devising a means to get rid of the membrane, and he hopes to present something practical before long. Blocking with membrane, while the tube is in, may occur. Formerly, when the swell of the tube was not so great, it would be coughed out, but now it is not coughed out, and suffocation may take place. The original tube was better in this regard.

The earlier tubes were made to fit into the ventricles with the idea of permitting the approximation of the ventricular bands, but it did not work. It is true that the epiglottis is merely an accessory, but in an intubation case the ventricular bands being held open we have to depend upon it; and that is the reason, the dependence being a poor one, that solids and semisolids which can go down in mass are better than liquids.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, June 5, 1888.

The President, George W. Jacoby, M.D., in the Chair.

Dr. Frederick Petersen read some

NOTES ON THE PRINCIPLES OF CRANIOMETRY.

After a review of craniometric nomenclature the reader stated that, while separate convolutions exert no specific influence upon the bones of the head, the shape of the skull is modified in correspondence with the gross divisions of the brain beneath it. The left temporal bone was said to be depressed in congenital aphasia. In infantile spastic hemiplegia there was flattening of the side of the skull opposite to the paralyzed part. Cerebral localization has been concerned mainly with motor and sensory functions. Ideational localization had yet to be developed. In his own opinion the temporo-sphenoidal lobes, and perhaps the occipital, contained cortical centres for depressing emotions. Musical ideas had their origin in the temporo-sphenoidal lobes together with the rest of the auditory memories.

Benedikt has reduced craniometry to a science, showing that the skull is built upon crystallographic principles. The measurements taken should be sufficient to reconstruct the skull. Triangulation of the skull should be required in asylums in the case of every patient, and in prisons in the case of every criminal. We are behind European countries in this matter. Even in Italy fourteen measurements are required for asylum records. The reader thought eleven measurements at least should be made: 1, the circumference of the skull; 2, the naso-occipital arc; 3, the naso-bregmatic arc; 4, the bregmatic lambdoid; 5, the binauricular; 6, the antero-posterior diameter, taken from the glabella to the maximal occipital point; 7, the greatest transverse diameter; 9, the two auriculo-bregmatic radii; 10, the facial length; 11, the greatest height of the skull. A calipers, tape-line and a strip of lead two feet long only are required. For more detailed measurements other instruments are required. Benedikt's calipers were recommended.

The pathological and forensic importance of such measurements are shown by the fact that minimal and maximal measurements are more common among the insane and criminal classes than among other people. The bregmatic-lambdoid arc was said to be shortened in epilepsy. The reader referred to one hundred cases of his own observed at the Hudson River State Hospital, at Poughkeepsie, in which asymmetry had been observed.

The measurements do not present any practical difficulties; the eleven measurements can be obtained and a drawing made in the course of fifteen or twenty minutes. In measuring the length of the parietal bone care must be exercised in getting the points correctly, but only a tape measure is needed.

Dr. J. A. Booth presented the report of a case of

PROGRESSIVE MUSCULAR ATROPHY WITH ANÆSTHESIA.

The patient was forty-two years of age, a shoemaker by trade, and still under observation. There was no family history of nervous disorders, no history of alcoholism or syphilis in the case. The patient had been married eighteen years, and had had two children; one, a girl of five years, had never walked. The affection had commenced in October, 1878, with general weakness, debility and weakness in the arms and hands. In January, 1879, the patient's voice had commenced to be husky. Six months later he had developed a feeling of cold and numbness in the left shoulder and side of the neck, with subsequent decrease in size. The atrophy commencing in the deltoid had spread to other muscles of the trunk and upper extremities. At the present time the patient weighed 155 pounds. There was marked sinking of both shoulders. There was weakness of the upper extremities with marked atrophy of the interossei. There were scars and abrasions about the hands and a scar upon the neck. The patient stated that he did not know when these injuries were received, that he had not felt them. There was no ataxia in walking or upon standing. The voice was harsh, the left side of the palate was paretic, the uvula being drawn to the right. The larynx had been examined by Dr. A. H. Smith. The left superior constrictor, the left palato-pharyngeus and the adductors of the left vocal cord were paralyzed. There was slight deviation of the tongue to the right.

There were marked fibrillary contractions in the atrophied muscles. The patellar reflexes were exaggerated. There was sluggishness of the accommodation, but no change in the visual field and no diplopia. Taste, smell and hearing were not impaired. It was apparently a case of progressive muscular atrophy with bulbar symptoms. The reader called attention to the sensory impairment as an unusual complication, and suggested to account for the anæsthesia and analgesia a lesion in the peduncle or pons on the right side.

DR. STARR found the case interesting, but remarked that the anomaly mentioned had been recorded by Ross in his text-book, and by Gowers in his text-book. In cases of this character post-mortem examinations had shown abnormal cavities in the cord, due chiefly to the degeneration of gliomatous tumors. Schultze had described cases; Bäumler also in his article upon syringomyelia. The case reported by Dr. Booth was, in his opinion, a case of this kind. The fact that the senses of touch, pain and temperature were all abolished would support this view. Touch sometimes escapes in syringomyelia, but not always. The three tracts are found in the formatio reticularis of the medulla and pons, and extend through at least one-fourth its extent. A lesion affecting them all would involve also the cranial nerves passing through this part. The symptoms reported could be more satisfactorily explained by a lesion in the cord, and the case as one of syringomyelia.

DR. SACHS had the same impression of the case, the combination of sensory and motor symptoms being a prominent feature in syringomyelia. From the fact that the anæsthesia had not affected the leg, it appeared that the grouping was exactly similar to that in this disease.

DR. PETERSEN asked whether the designation syringomyelia could be proper where cranial nerves were involved.

DR. SACHS replied that the cavity might extend upward into the medulla; that a number of cases of syringomyelia had been reported in which the cavity had involved the medulla. In regard to the question of nomenclature, we were not yet in a position to say whether the cord ended below the medulla or above it.

DR. BOOTH asked whether in these cases there was paralysis of the limbs.

DR. STARR replied that there was paresis proportioned to the atrophy, not paralysis in the sense of hemiplegia or monoplegia.

DR. J. C. SHAW followed with a paper upon

DEGENERATION OF THE PERIPHERAL NERVES IN LOCOMOTOR ATAXIA, WITH MICROSCOPIC SECTIONS.

The patient, forty-seven years of age, had been a typical case of locomotor ataxia. Following an attack of hematuria he had had two epileptic seizures, and had died the following day. On post-mortem examination the hemorrhage was found to have come from the right kidney. Pieces of the sciatic, plantar and popliteal nerves had been removed for examination; part of the specimens being stained with osmic acid, and part with the bichromate of potash solution. Changes were found which the reader considered distinct from the Wallerian degeneration. The changes consisted in granular degeneration, liquefaction and even absorption of the myelin sheath, with persistence of the axis-cylinder, and in some places a collapsed sheath of Schwann.

NEWS ITEMS.

American Association of Obstetricians and Gynecologists.—The following preliminary programme of the Annual Meeting, to be held in Washington, D. C., September 18, 19 and 20, 1888, has been announced:

The President's Annual Address. By William H. Taylor, M.D., of Cincinnati.

Discussion: Extrauterine Pregnancy. 1. Pathology. 2. Diagnosis. 3. Treatment. By Mr. Lawson Tait, Dr. Franklin Townsend, Dr. E. E. Montgomery, Dr. Charles A. L. Reed, Dr. A. Van der Veer.

The Relations of the Abdominal Surgeon to the Obstetrician and Gynecologist. By Albert Van der Veer, M.D., of Albany.

Operation for an Unusual Case of Subserous Uterine Fibroid. By Hampton Eugene Hill, M.D., of Saco, Me.

Drainage in Abdominal and Pelvic Surgery. By Joseph Price, M.D., of Philadelphia.

Double Ovariotomy during Pregnancy; a Successful Case Going on to Full Term. By William Warren Potter, M.D., of Buffalo.

The Indications for Artificial Aid in Labor. By Thomas Opie, M.D., of Baltimore.

The Technique of Vaginal Hysterectomy. By James H. Etheridge, M.D., of Chicago.

The Surgical Treatment of the Perineum. By William H. Wathen, M.D., of Louisville.

Laparotomy in Peritonitis. By E. E. Montgomery, M.D., of Philadelphia.

Tumors of the Abdominal Wall. By Charles A. L. Reed, M.D., of Cincinnati.

Uterine Fibroids; their Diagnosis and Treatment. By Thomas J. Maxwell, M.D., of Keokuk.

Dermoid (Fibroid) Tumors of the Abdominal Walls. By Edward J. Ill, M.D., of Newark.

Ruptured Perineum. By J. Henry Carstens, M.D., of Detroit.

A Contribution to the Study of Pelvic Abscess. By Clinton Cushing, M.D., of San Francisco.

The Female Perineum: its Anatomy, Physiological Function and Methods of Restoration after Injury. This paper will be illustrated with lime-light and screen. By Henry O. Marcy, M.D., of Boston.

Heart Failure in the Puerperium. By Thomas Lothrop, M.D., of Buffalo.

Treatment of Suppurative Peritonitis. By William H. Myers, M.D., of Fort Wayne.

Operative Treatment in Uterine Carcinoma. By George R. Shepard, M.D., of Hartford.

The Reflexes Reflexed; or Some Things that Retard Progress in Gynecic Surgery. By Joseph Eastman, M.D., of Indianapolis.

Some Points in Relation to the Diagnosis of Pregnancy in the Early Months. By James P. Boyd, M.D., of Albany.

Vaginal Tamponnement in the Treatment of Prolapsed Ovaries. By W. F. Manton, M.D., of Detroit.

Mr. Lawson Tait, F.R.C.S.E., of Birmingham, England, will also present a paper on "The Methods of Success in Abdominal Surgery."

A Testimonial to Mr. Bryant.—On May 31st, in the Anatomical Theatre of Guy's Hospital, on the occasion of

his retirement from the surgeonship, a testimonial, from past and present students, in the form of a handsome silver punch-bowl, with an illuminated book, containing photographs of various parts of the hospital and the names of the subscribers, was presented to Mr. Bryant.

Test for Plumbing.—The New York Board of Health has led the way for other municipal authorities by adopting a mandatory test for plumbing. On and after July 1 the work under plans filed after that date must be tested by the plumber in the presence of the inspector, by means of an air pump and pressure-gauge, in the same manner as the gas-pipe system of the building. This is claimed to be the most effective test possible, as the pressure is equal all over the building. The department of public works will issue no permit for water for domestic uses until the certificate of the health department is presented.

A Milk Epidemic.—An important investigation under the direction of Dr. Russell, health officer of Glasgow, Scotland, is in progress. It is no less a matter than the alleged direct infection of a number of people in the West End of Glasgow with scarlet fever, by means of milk from a dairy farm. The cattle on the farm in question were found "slightly ailing" with the very disease which, when transmitted through milk or meat to human beings, brings on scarlet fever. The result was a severe epidemic. No other epidemic, of late years, has offered such a field for investigation, and Dr. Russell's work will be followed with a great deal of interest.

Still Another Test for Sugar.—Fischer detects glucose in the urine by the formation of crystals of phenyl-glucosazine. A little phenyl-hydrazine hydrochlorate is put into a test-tube, together with twice its weight of sodium acetate; water is then added and heat is applied. An equal volume of the urine to be examined is now added, and the mixture is boiled twenty minutes and then cooled, when yellow crystalline needles separate if glucose is present. When the quantity of glucose is minute, it is necessary to have recourse to the microscope to find the characteristic crystals. By the aid of this reagent Van Jaksch has been able to show that sugar is present in the urine after inhalation of chloroform, in cases of asphyxia, after taking large doses of sodium salicylate, etc., where the reaction with Fehling's solution is in the nature of things inconclusive.—*Pharmaceutical Era*, June, 1888.

The Epidemiological Society of London, at its meeting of May 24th, elected Max v. Pettenkofer an honorary member.

A Risk of Travel.—The reported indisposition of the Duke of Edinburgh, from drinking impure water at a foreign station, gives prominence to what is perhaps the most usual and frequent source of danger in foreign and Continental travel. Many of the sanitary authorities who have looked into the question have, from time to time, uttered warnings to Continental travellers as to the dangers of the ordinary drinking water to be found abroad. The pollution of table water at foreign hotels and houses is due to a great variety of causes. The water supply of foreign cities is, as a rule, to which there are only few exceptions, taken from sources lamentably liable to sewage pollution, either in open streams or uncovered reservoirs, or from defective sanitation in the house supply. A large part of the domestic supply of drinking water is, moreover, from surface wells, which are constantly liable to sewage filtration. An examination, made only a few years since, of siphons of sparkling "seltzer" in a great Continental city, disclosed the fact that they were horribly polluted with sewage, and that the effervescing fixed air with which they were charged only served to conceal unutterable contaminations of a most dangerous kind. Sir Henry Thompson and Dr. Herman Weber, who have both given attention to the subject, are very emphatic in their counsel to travellers to avoid ordinary drinking water abroad. The easiest and most agreeable means of avoiding the danger is the habitual use of a pure natural mineral water in lieu of the doubtful drinking water of the hotel or the private house.—*British Medical Journal*, June 2, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 12 TO JUNE 18, 1888.

Waters, William E., *Major and Surgeon.*—Granted leave of absence for twenty-days, to take effect about June 15, 1888.—*S. O. 64, Department of Columbia*, June 8, 1888.

Calvin, DeWitt, *Major and Surgeon.*—Granted leave of absence for one month, with permission to apply for an extension of one month.—*S. O. 39, Department of Dakota*, June 9, 1888.

Birmingham, Henry P., *Captain and Assistant Surgeon.*—Granted leave of absence for one month.—*S. O 117, Division of the Atlantic*, June 11, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING JUNE 16, 1888.

McMurtrie, Daniel, *Surgeon.*—Detached from the Naval Hospital, Yokohama, Japan, and ordered to return home.

Gravatt, C. U., *Surgeon.*—Detached from U. S. S. "Michigan," and ordered to the Hospital at Yokohama.

Edgar, John M., *Passed Assistant Surgeon.*—Ordered to the U. S. S. "Michigan."

Mackie, B. S., *Surgeon.*—Ordered to the U. S. S. "Ossipee."

Parker, J. B., *Surgeon.*—Detached from the U. S. S. "Ossipee," and await orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING JUNE 16, 1888.

Wyman, Walter, *Surgeon.*—Detailed as a member of the Board of Examiners, vice Surgeon Fessenden, excused on account of physical disability, June 15, 1888.

Fessenden, C. S. D., *Surgeon.*—Granted leave of absence for thirty days, on account of sickness, June 15, 1888.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

ORIGINAL LECTURES.

PLEURISY,

With Large Hemorrhagic Effusion.

A Clinical Lecture delivered at the Philadelphia Hospital.

BY FREDERICK P. HENRY, M.D.,
PHYSICIAN TO THE HOSPITAL.

GENTLEMEN: The serous membranes are the tissues of which the study has given us almost all the exact knowledge we possess concerning the process of inflammation. The exudation of plasma, the deposit of fibrin, and, most important of all, the migration of leucocytes, have all been studied in serous membranes, and, therefore, when one of them is inflamed, it might be supposed that we would have an accurate mental picture of the process that is going on, and be able to predict the precise period and mode of its termination. Such, however, is by no means the case. We may know, for example, that the pleura is inflamed; that fibrin is forming on its surface; that serum is exuding, and leucocytes migrating into its cavity, but we cannot foresee at the beginning of the attack whether the fluid products of inflammation will be so small in proportion to the solid that the pleurisy may fairly be called dry or fibrinous, or whether they will be poured out in large amount. With all our intimate knowledge of what may be called the physiology of inflammation, we are obliged to study each case separately, using all the means at our command to determine, first, whether inflammation is, or has been, present, and, secondly, what are the situation, the nature, and the amount of its products. I propose to make such a study of the patient before you; but before doing so, will make some remarks upon the diagnosis of pleurisy, with large effusion, as I believe that thereby your appreciation of the case, which is a most typical one of its kind, will be somewhat enhanced.

The presence of pleurisy, with large effusion, may be suspected, but its diagnosis cannot be made by mere inspection. On baring the chest the dimensions of one lateral half may be seen to be greater than those of the other, and its intercostal spaces distinctly widened. In addition, the respiratory movements of the same side may be diminished or entirely suppressed, and the heart's impulse detected in an abnormal situation, and yet, notwithstanding the concurrence of signs, each one of which is more or less diagnostic, no competent physician would think of trusting solely to them, but would proceed to the next step, which is *palpation*. By this means the chest walls which were seen, may now be felt to be more or less motionless on one side, and by placing a hand on each lateral region of the chest and directing the patient to take a deep breath, the contrast between the diminished or absent movement of the affected and the free, perhaps exaggerated movement of the sound side, becomes very marked. By palpation also, the absence of vocal fremitus on the side of the effusion is ascertained.

Auscultation.—The next step in the examination is auscultation, and although the signs which it furnishes are, for the most part, negative, they are none the less valuable on that account, for what single fact can be more significant than the absence of breath sounds and vocal resonance over a greater portion, perhaps the whole, of the affected side? And here also the contrast with the sound side, on which the breathing may be puerile, and the vocal resonance increased, is very striking. These remarks apply to cases of large effusion. In slighter degrees, in which the layer of fluid between the lung and the chest wall does not, perhaps, exceed two inches, the breathing and voice, although distant, may be distinctly bronchial. This bronchial character of the voice and respiration is due to the compression of the lung, and disappears as the effusion increases, simply because the resistance becomes too great for the sound waves to overcome. In a case of pleurisy in this hospital last month, in which I removed twenty-two ounces of serous fluid by aspiration, I have entered in my notes that the dulness behind extended upward to the middle of the scapula, and that over the same area the breath sounds were inaudible, while the voice was distant and bronchial. In that case, as you perceive, the effusion, although moderate, was sufficient to extinguish the breath sounds, but not those dependent upon the voice. Do not forget that bronchial breathing and bronchophony are signs which are not limited to pneumonia, but are often the accompaniments of a moderate pleural effusion.

The heart sounds may be very faint or inaudible in their normal situation, while they are distinctly heard in some other spot. In right-sided effusion they may be heard most distinctly in the axillary region, and when the effusion is in the left pleural sac they may be loudest at some point to the right of the median line.

Although the impulse of the heart has been already referred to under the head of inspection, it is so intimately associated with the sounds that it is more natural to speak of it here. It may be most distinct to the left of the left nipple, or may actually be pushed over to the right mammary line. The impulse felt when the heart is pushed far to the right, is not caused by the apex of the heart, but by some portion of its right cavities, auricle or ventricle. Again, the heart's impulse may be imperceptible over any portion of the thorax. This may be due to the fact that it impinges against the posterior surface of the sternum, in which case auscultation will reveal the site of the displaced organ. Finally, in left-sided effusion, the pericardium may have become adherent to the lung, and, as the effusion increases, both heart and lung are carried backward together so that neither cardiac sound nor impulse can be detected. I have never seen an instance of this anomaly, but its possibility should be borne in mind.

Percussion.—I am accustomed to depend more upon percussion than on any other single means employed in the diagnosis of pleurisy with large effusion, I might say than on all other means combined. The information thereby obtained derives its value not only from the alterations of the normal sounds in various regions of the chest, but also from the sense of resistance felt by the percussed finger. This affords a striking instance of the great superiority of the fingers over any instrument employed to facilitate percussion. The sense of touch is, in my opinion, as much concerned in obtaining the best results from percussion as that of hearing.

The dulness, or rather flatness, on percussion, may not only occupy the whole area of the thorax in which, in health, the pulmonary resonance is obtained, but may even extend beyond it, and this fact constitutes one of the most important diagnostic signs of pleurisy with large effusion. On the right side the weight of the fluid may press the liver downward until its lower border is felt on a level with the umbilicus. On the left side anteriorly, there normally exists an area of tympanic resonance caused by the splenic end of the stomach. It has the shape of a half moon with its convexity upward, and is known as the semilunar space of Traube, who first called attention to its diagnostic importance. In left-sided pleurisy with large effusion, the semilunar space of Traube is abolished, and its place occupied by dulness.

A remarkable exception to the universal dulness, in large pleural effusion, is found at the apex anteriorly, where there is often a well-marked, low-pitched, tympanitic resonance, or, sometimes, even a cracked-pot sound. The explanation of this phenomenon has called forth a great deal of discussion which could not be entered upon without a preliminary consideration of the theories in vogue concerning the production of the normal sounds. This is altogether foreign to our present purpose, and, therefore, I merely repeat that, in large pleural effusion, there may be dulness not only over the entire area normally occupied by lung, but even extending beyond it, with, at the same time, tympanitic resonance in the infra-clavicular region. In the highest degrees of effusion, even this tympany is absent and the dulness becomes universal.

Let us now endeavor to apply these general facts to the particular case before us.

On inspection, it cannot be said that either half of the chest is larger than the other, but, on looking for the cardiac impulse, it is not seen in its normal position. This is not an unusual circumstance, even in health, when the subject is in the recumbent position; but, on continuing the search, the heart's impulse is plainly seen in the second intercostal space on the right side, barely within the right mammary line. This extraordinary dislocation of the impulse may be perceived by those seated nearest the patient.

On placing the hands on each side of the chest and directing the patient to take a deep breath, the respiratory movement of the right side is found to be much greater than that of the left. On auscultation, the breath sounds are inaudible both in front and behind, but the voice, very faint and distant, may be heard over the back of the chest. On the right side, both the respiratory murmur and the vocal resonance are exaggerated. The heart sounds are faintly heard in their normal situation, but loudest in the second right intercostal space, where the impulse is most distinct. On percussion, the dulness is found to be universal, including the semilunar space of Traube and the infra-clavicular region. A few days ago, I obtained a well-marked cracked-pot sound in the left infra-clavicular region, and its disappearance in the interval shows that the effusion has been steadily increasing. The case is undoubtedly one of large pleural effusion of the left side.

The want of distention of the left lateral half of the thorax may be correlated with the remarkable displacement of the heart. On measuring the two sides of the chest I found that the left side was only half an inch larger than the right, and this is due to the unyielding character of the thorax, which, in its turn, is dependent upon the man's age, which is sixty-two. The pressure of the fluid has told with greatest effect upon the mediastinum, which, in yielding, has carried the heart with it.

The case is such a typical one, every symptom being present in such bold relief, that it cannot be mistaken for any other condition. Aneurism is out of the question, there being neither thrill, murmur, pain, dyspnœa, nor dysphagia. The dulness due to a tumor would neither be so extensive nor so regular in outline, and vocal resonance and fremitus would probably be obtained at one or more parts of the chest-wall. The most common error with reference to accumulations of fluid within the thorax is that of mistaking a large pericardial for a pleural effusion. Dr. Fagge states that all the cases of large pericardial effusion admitted to Guy's Hospital were mistaken for pleurisy. The distinct character of the impulse of the heart and its displacement forbid the possibility of such mistake in this case.

I have said that there are cases of large pleural effusion, in which, on account of adhesions between pericardium and lung, neither cardiac sound nor impulse can be detected. I have made this statement on the authority of others, without having seen satisfactory evidence of its truth. Should I meet with a case of fluid accumulation on the left side of the chest without being able to detect the heart-sounds or impulse on either side, I would regard the effusion as pericardial.

Treatment.—Valuable time will be lost by perseverance in an exclusively medical treatment of this case, and, therefore, I propose to remove some of this fluid with the aspirator. I have already withdrawn, by means of a hypodermatic syringe, the fluid in this test-tube, which has, as you see, the appearance of pure blood. That it is not pure blood is proved, first, by the fact, that although it has been in this tube since yesterday afternoon, it has not coagulated; and, secondly, by examination with the instrument I show you, which is Gowers's hæmoglobinometer. By means of this instrument I had no difficulty in determining that the amount of blood in this effusion was less than one per cent. In other words, if I remove fifty ounces from this pleural cavity the amount of blood which it will contain will be less than half an ounce. This fact is one of decided importance, for often, after tapping, the fluid reaccumulates with great rapidity. In the case before us we may now feel confident that if the fluid removed be replaced by a new effusion of the same composition, the amount of blood thereby withdrawn from the vessels will be too small to injure materially the already feeble patient.

As to the point of puncture in aspirating a pleural effusion I prefer the seventh intercostal space, just ante-

rior to the border of the latissimus dorsi. On account of this patient's age, and the unyielding character of his thorax, I will remove but a portion of the effusion, stopping the aspirator on the first symptoms of cough or epigastric distress. The largest amount of fluid that I have removed at one operation was 127 ounces. The effusion was serous, and had occupied the right pleural cavity for six months. The patient was a young and previously strong Irishman, an inmate of the Episcopal Hospital, where the operation was performed on May 7, 1886. Notwithstanding the great accumulation of fluid, the patient did not complain of dyspnœa while in bed, and *could lie on either side*. In that case the improvement was rapid aud continuous. In a week the man was out of bed, and, a few days later, left the hospital, believing himself to be well. I could have removed still more fluid, but desisted when the patient began to cough slightly, and complained of a painful sensation in the epigastrium.

A few words with reference to the character of the effusion in this case. It has been stated that a hemorrhagic effusion into the pleura is invariably indicative of the fact that the inflammation giving rise to it is of a tubercular nature. To those who hold that all pleurisies are tubercular, such a statement is, of course, a truism. Taken in the sense that a tubercular pleurisy necessarily gives rise to a hemorrhagic effusion, it is absolutely incorrect. That the inflammation of the pleura giving rise to large effusion, whether serous, purulent, or hemorrhagic, is usually tubercular, is a generally accepted fact. Kelsch and Vaillard (*Arch. de Phys. Norm. et Path.*, 1886) give reports of the minute examinations of sixteen cases of pleurisy, in all of which tubercles were found, and they state that in all the autopsies of pleurisy that they had made for three years, tubercle was present. Exception may be taken to their report on the ground that, although the anatomical appearances were those of tubercle, nothing is said with reference to the presence or absence of the bacillus.

As Fraentzel remarks: When we consider the delicate structure of the newly formed vessels, and their great abundance, in the pleuritic pseudo-membrane, as well as the frequency with which hemorrhagic spots are seen on its surface, the wonder is that every effusion is not hemorrhagic.

The presence of numerous maculæ on the surface of this man's body, one of which, in the groin, is as large as a silver dollar, leads me to the belief that purpura is the cause of the bloody effusion in this case. Hemorrhagic pleural effusion, in general, is dependent rather upon a constitutional condition, such as scorbutus or purpura, than on any local peculiarity of the inflammatory process.

NOTE.—When twenty-eight ounces of hemorrhagic fluid had been removed, the patient coughed slightly, and became somewhat uneasy and restless. The aspiration was, therefore, stopped.

It is ten day since the operation was performed, and, in the interval, there has been a steady improvement in both symptoms and signs. The heart has receded somewhat toward its normal position, and there is normal resonance at the left apex where, also, puerile vesicular murmur may be heard. There has been also a marked improvement in the appetite and digestion of the patient.

ORIGINAL ARTICLES.

SOME POINTS IN TREATMENT AT THE MEMORIAL HOSPITAL, ORANGE, N. J.

BY JOHN H. BRADSHAW, M.D.,
HOUSE PHYSICIAN.

THE following notes are merely brief records of some of the more recent cases and methods of treatment at this institution.

Bisulphite of soda solution is mainly depended upon for the treatment of erysipelas. The usual fifty per cent. solution of the shops is diluted with water three times, and is used locally under oiled silk, continuously until all redness of the skin has disappeared.

Cellulitis of the hand has met with a steady check by the continuous, cold, permanganate of potash drip, half a grain to a pint of water.

Fistula in ano has here (after the method inaugurated by Dr. Pierson, in 1876) received a most radical, sharp spoon treatment. All sinuses are laid open, and their diseased walls are dissected or scraped away. The wound is then united, under strict antisepsis, with sutures. Several extensive multiple fistulæ are recorded as healed by first intention.

Heaton's operation for hernia has not been successful at this hospital; four cases are recorded.

Nerve stretching for sciatica has met with uniform success. Out of seven cases recalled, six were permanent cures, after having been for years treated in vain by almost every conceivable method. The seventh case was discharged improved.

The diachylon ointment of Hebra has proved the best all-around ointment for squamous eczema. It should be made with *olive* oil.

Only selected cases of hemorrhoids are injected. The clamp, scissors and cautery have given best results.

Burns, if extensive, after first being dressed with some protective oil or powder combined with bicarbonate of soda, are, upon the removal of sloughs, actually peppered with skin grafts. The compound resin ointment, with carbolic acid, then serves as a mildly stimulating dressing.

The use of dry powdered boric acid packing for cervical endometritis, erosions and ulcers of the cervix uteri has done away with the glycerine tampons.

Fractures are treated with Levis's splints, or Buck's extension, or plastic or silicate of soda immovable splints, as indicated. If of the jaw, the hospital dentists mould a rubber interdental splint. There is an intentional scarcity of fracture apparatus.

Morbus coxarius, if in the first stage, receives a light plaster, or glass spica, high shoe, and crutch. If the child is too young to use crutches, it is kept as much as possible running about in a Darrach

wheel crutch (see *Orthopedic Surgery*, Sayre, 2d ed., p. 466). The suppurative stage receives operative treatment, and rest in cuirass (opus cit., p. 302). Spinal caries is treated by the support of a Sayre plaster jacket and wheel crutch.

Ulcers of the leg, of whatever variety, are usually first poulticed, if sloughy, and, when clean, a dry powder dressing of bismuth, boric acid (impalpably powdered) or calomel is used under bandage from the toes up, with elevation of the affected extremity. Should granulations be protuberant, they are strapped with the ordinary basket strapping of surgeon's plaster.

A recent case of laparotomy for cystic degeneration of both ovaries was delivered, six weeks before the operation, of a healthy child. Only after her confinement, when her abdomen remained over forty-four inches in girth, was she suspected of having an ovarian tumor. A noteworthy peculiarity about this case was that the umbilicus was protuberant, as is seen in ascites. A double ovariotomy was made, and the patient walked about her room on the fourteenth day.

For all operations which are likely to expose and chill the lower extremities, the legs and thighs are wrapped in cotton batting, and loosely bandaged by the nurse, before the patient is brought to the operating-room.

Hick's vaginal speculum has been found to be all that it claims; it is absolutely self-retaining, and gives a wider field for operations upon the cervix uteri than others.

For the last five years Billroth's anæsthetic mixture (introduced here by Dr. Simpson: ether, three pints; alcohol and chloroform, each one pint) has been employed for operations. It is thought to be followed by less nausea than is ether, and is decidedly more agreeable to the patient. The average time of anæsthesia is eight minutes.

In our lying-in department we recently had a case of empyema in a woman in her ninth month of gestation. The right pleural cavity was aspirated of a little over a quart of pus at each tapping three times successively during the five weeks preceding labor; the last aspiration was made two days before her confinement. She was delivered under careful antiseptic midwifery, and recovered from her labor with no untoward symptoms, although her right pleural cavity was again full of pus on the tenth day. She refused permission to make free drainage openings, and, after another aspiration, she carried her child away to her own home, where she was lost to observation.

Pleuritic accumulations of serum are almost invariably removed by aspiration; but when not, active counter-irritation and diuretic treatment are practised.

More care is bestowed to make operations aseptic than ever before. Great cleanliness, free use of antiseptic solutions, sterilized instruments, silk, catgut, and wire; the use of boric acid, iodoform, free drainage, sublimated gauze, and indefatigable care and supervision on the part of the head nurse, have made a revolution here as elsewhere. The Lister spray is only used to wash the air of the operating-room before operation. There was recently an abortive attempt to revive the use of the Lister protective. The Mackintosh is still sometimes used when indicated to keep the dressing from becoming too dry.

At this hospital stimulants are given only when indicated, there being no record of their routine use.

Typhoid fever is treated expectantly. In hyperpyrexia antifebrin in four-grain doses has proved more efficient and safer than antipyrine.

Pneumonia is treated with the so-called pneumonia-jacket (cotton batting under oiled silk), and occasionally poultices are employed. No medicine is given unless demanded by alarming symptoms.

Those of our consumptives that survived the Bergeon treatment find great relief and sometimes actual benefit from the compound cannabis Indica mixture, introduced here by Dr. J. W. Stickler. Its formula is as follows:

R.—Tr. cannab. Ind.	℥ss.
Vironicæ (blue verbena) . .	gr. viijss.
Ext. buchu fl.	℥j.
Pulv. verbas. thap. (mullein) .	gr. xv.
Sacch. alb.	℥j.
Spts. vin. rect.	℥jss.
Mel. despumat.	℥ij.
Spts. chloroformi	℥ij.—M.

A tablespoonful of this on going to bed acts as a sedative and anodyne, and is followed by quiet sleep. The dose one drachm to one-half an ounce is given during the day, p. r. n., for cough. There are three standard cough mixtures: 1. Expectorant (mur. of amm., as its base). 2. Sedative (hydrobromic acid and chloroform with syrup). 3. Expectorant and tonic (mur. ammon. and digitalis its principal ingredients). We have found a mixture of quinine and alcohol, twenty grains to one pint, of much service as a bathing lotion for night sweats. When this fails we give the "ward sweat mixture," which contains to each dose atropine one-one hundred and twentieth of a grain, morphine one-sixteenth of a grain, acid sulphuric dilute ten minims.

Acute articular rheumatism is treated to best success at first with full doses of salicylate of soda at frequent intervals, followed in convalescence by iodide of potash and ferruginous tonics. Chronic rheumatism of a gouty history receives iodide of potash or the old Alonzo Clark mixture:

R.—Vin. colch. sem.,
Sod. et potass. tart.,
Aquæ . . . āa *partes æquales*.—M.
Sig.—one drachm t. i. d.

The histories of our patients are recorded as follows: We have an initial history sheet, and the usual Memorial Hospital Training School daily ward charts. The former contains blank spaces to be filled in on the first day of the patient's arrival by the assistant house physician, under the following printed headings: personal history, hereditary history, "special" (being a record of a woman's uterine history), past illness, past treatment, invasion of present illness, condition on admission, symptoms, physical signs, urine.

This sheet is kept not in the doctor's room or office of the hospital, but must be in the ward as long as the patient remains there. Thus, although there is no resident physician, and the house physician may not be present, the attending physician can review the "initial history" of the patient readily and by the bedside whenever he wishes to call for this sheet. All operative measures are recorded as soon as performed on the reverse side of the same paper. When the patient is discharged a brief *résumé* of the case, the condition of the patient on discharge, and the date of the same is written on the reverse side of this same initial history by the house physician with his signature. These sheets are now filed away in numerical order in covers containing lots of one month each. Twelve of these lots, from January to January, are deposited in one drawer of a little cabinet, made for this purpose, and the date belonging to them is painted on the outside. This arrangement is at once convenient and labor saving, and places the histories where they can readily be found. To find a record under this plan the name or the disease only of the case being in mind, the patient's register is first consulted and the number of the case noted, as well as the date of the patient's arrival. Knowing these facts it is a process of a very few moments to find the desired records.

ON THE MICROORGANISMS OF WATER.

BY CHARLES SMART, M.D.,
MAJOR AND SURGEON, U. S. ARMY.

LESS than a decade ago the title of this paper would have awakened in the mind of an appreciative observer a line of thought wholly different from that which it conjures up at the present day. The great world "spins forever down the ringing grooves of change;" and, perhaps, in nothing is this so evident as in the manner in which we have ceased to view the little world that lives and moves and has its being in the minute drop of water-sediment that we used to, but do not now, place on the microscope stand and study for hours for the light it shed on the possible quality of an unknown water. These microörganisms are there now, as they were then, although the pathways of inquiry lead no more to their open, animated fields, but reach past them into the dim obscurities of those microscopic nebulæ, the germs of the infinitesimal.

We were acquainted with bacteria in those days, but their presence was associated merely with the destruction of the organic débris of the microscopic field; and only when they formed a characteristic rather than an accident of that field did they become of importance as suggesting a putrefactive tendency in the water under examination. Many of these minute forms of life, formerly studied by sanitary inquirers, were of favorable rather than unfavorable augury, as they were met with in waters which experience showed to be wholesome. Among them were the symmetrical desmids and diatoms, the filamentous oscillatoriæ and nostocs with their transverse markings and constrictions, and the confervoid genera, the endochrome of which becomes converted into motile zoöspores, as in zygnema, spirogyra, zygogonium, conferva, œdogonium, and chætophora. The nostocs, however, when in great profusion were, from the experience of the Boston and many other ponds, occasionally suggestive of pigpen and other unpleasant odors and tastes. The lively motion of the tentacled infusoria, and of the ciliated acomia, alyscum and enchelys, gave rise to no thought of special impurity; nor did the entromostraca, cyclops, cypris, daphnia, etc.; the macrobiotus and hydrachna, or even the rotifers, unless present in excessive numbers; but oxytricha, kerona, and euplotes spoke of impurity, and when the anguillula was found, or the flat worms, the ciliated paramecia, or the elongated amphileptus or lachrymaria, the chemical inquiry was sure to develop doubts as to the character of the water. Lastly, when the palmellaceous algæ in their gelatinous fronds were associated with numerous vorticels, encysted or in full vitality, sluggish amœboids, or more active protoplasmic masses, such as monas, cyclidium, cercomonas, etc., the water which contained them might be set down without further examination as related rather to the swamps than to pure potable supplies.

When the teeming life of a water-sediment was first seen through the early microscopes there was opened as fascinating a field for speculation on the causation of disease as that which has recently dazzled the eyes of the scientific world with the splendor of its promise; but all this died out as the progress of time and science permitted a more intimate acquaintance with the so-called animalcules. It is needless to recall the occasional mistaken observations which sought to throw the onus of a particular disease on some innocent organism, as when Salisbury was led to saddle the paroxysmal fevers on a poor palmella. Not one of these organic forms was at the last in anyways connected with the development of disease, although the ever-varying shapes of

the amorphous protoplasmic masses of swamp waters looked, no doubt, to many, as if they might be the essential leaven of malarial disease. The existence of the infusoria in a water was noted merely as furnishing evidence corroborative of that yielded by the chemical examination.

And that examination had just succeeded in attaining to a certain degree of scientific accuracy. It had escaped from the thraldom of methods which seemed to be empiric; and that which it could do was well recognized and discriminated from that which it aimed to do but could not. Is it true that the less we know of a given subject which is our special study the greater is our assumption of knowledge? When the analyst burned the dried residue of his evaporations and found out how much was dissipated by the ignition, did he deceive himself as well as others when he announced that the water contained so many grains of organic matter in the gallon? No. He was merely embodying his results in an intelligible expression which would obviate the necessity of explaining in every instance the manner and method of his analytical work. He was familiar with all its shortcomings and fallacies, and his aim was ever their removal or the substitution of a more accurate method. Following the rough estimation of the organic matter from the loss of weight on ignition came the determination of its carbon and nitrogen as giving infinitely greater precision to the expression of its quantity; but the easier methods of approximating to the nitrogen by transforming it into ammonia, and of ascertaining the totality of the oxidizable elements by the use of permanganate of potash, gave a stronger impulse to the study of potable waters than the determination of the organic elements. In each of these instances a better expression for the organic matter was obtained than by the method of ignition, and as the results from one water were always comparable with those from another, scales of purity or impurity were created for each method based upon the results which were obtained from waters that were known to be wholesome or unwholesome, or contaminated in various ways and yet not convicted of unwholesomeness. The analysts, therefore, in announcing an examined water to be one of great organic purity, of medium purity, of doubtful purity, or an impure water, gave expression not only to the results of their analysis of the particular water, but to the results of their experience with other and known waters of the classes mentioned. What the chemical examination succeeded in doing was this: It compared one water with another, or the same water at different times, or after subjection to different modes of purifying treatment; and it intimated with more or less precision whether the organic matter present was fresh or decomposing, vegetable or animal, from the uplands or the sewers. What it failed to do was to associate with unwholesomeness the impurities it detected, or with wholesomeness the purity which it announced. A water impure from vegetable matter or human excrement might be harmless, while another rated as of great organic purity might contain the germs of a typhoid epidemic. But practically, these possibilities, which it failed to indicate, were more than offset by the probabilities that there was a greater likelihood of pathogenic development where there was much than where there was little impurity.

Just at this stage of their progress the analysts were pushed into the background by the brilliant promise of bacteriological research. Davaine had discovered the bacillus of anthrax, and Obermeyer the spirillum of relapsing fever, but neither of these events interfered with the progress of sanitary analysis. Koch introduced the slender bacillus of tubercle to the profession, but not until the day of his comma bacillus did the new era dawn. In investigating the causation of cholera, he discovered in the water of some tanks near Calcutta that peculiar curved microörganism, which he had already found in Egypt and in India in the stools of cholera-patients, and which he regarded as the cause of the disease. It was evident, from the want of attention to cleanliness so common in India, that this tank-water was tainted with cholera dejections. A local epidemic existed around it in the huts which obtained their water from this source; and on the subsidence of the epidemic the bacillus was found to have disappeared from the water. In the progress of his studies, Koch developed a method of cultivation for the bacteria in water, and since then it has seemed as if the whole aspect of the water question had changed. The impurity of the chemist, which might or might not be harmful, and the purity, which might or might not be harmless, were to give place to positive information. Wholesomeness or unwholesomeness were to be determined instead of purity and impurity, and bacteriological cultivations immediately supplanted the study of the innocent organisms which were briefly enumerated in an antecedent paragraph. The scientific world was fascinated with the possibilities of the new method. The educated and intelligent public were kept informed of the developments and expectations by popular lectures and scientific writers, and scraps of information filtered down through the columns of the daily press to ordinary humanity. The germs of the invisible myriads that swarm as an omnipresent cloud in the "air we breathe," and in yet denser masses in the "water we drink," were susceptible of cultivation on a gelatinous field. Suspected individuals of the bacteriological flora could be transplanted to special beds where they might reach the acme of their development unimpeded by any struggle for existence with the ordinary bacterio-

logical weeds. The microscope would reveal the distinguishing characters of the new plant—root, stem and branch, bud, blossom and fruit—and biological inquiry would settle its position as a pathogenic element. But the anticipations of the enthusiasts, onlookers of course, continue to await their realization; while the workers labor sedulously in the rut of the master, realizing only a fresh illustration of the well-appreciated fact that progress in an inquiry of this kind is a plant of uncommonly slow growth. Something, however, has been accomplished. The new method has succeeded in developing the difficulties by which it is surrounded, and in casting doubt on its own results as a gauge of the quality of the water-supply; it has, in fact, reached that stage of its history which finds its parallel in the history of sanitary analysis when the chemists recognized that loss on ignition could no more be regarded as giving expression to the totality of the organic matter, and that their work must be set aside as of no practical value unless something was done to improve the methods.

The bacterioscopic method of water analysis is, like every development relating to the bacteria, so well and generally known that a reference merely is needful to its details. The culture-medium is a peptonized meat-juice, containing about ten per cent. of gelatin, which keeps it solid to about 77° F. It is prepared by digesting chopped meat in distilled water for twenty-four hours in a refrigerator. After expressing the meat, the resultant liquor is boiled, to coagulate its albuminoids, and strained through flannel. The gelatin, with some peptone and chloride of sodium, is then added, and the whole filtered while hot. Any acidity that may have developed is neutralized by the cautious addition of carbonate of soda. It is then transferred to a series of test-tubes, each receiving about ten cubic centimetres (two and three-quarters drachms). The charged tubes are sterilized by an exposure of ten or fifteen minutes in a steaming vessel on each of three successive days, and after this, if the jelly remain free from bacterial developments for several days, it may be regarded as fit for use.

When a water is to be examined, the jelly in one of these tubes is liquefied, and the water dropped in from a small-nozzled pipette, and intimately mixed by agitation. If the water is known to be poor in germs, half a cubic centimetre (eight minims) may be added; but if its character is unknown, a much less quantity should be used, or several tubes may be taken, each to receive a different quantity, or the same quantity of a different dilution. The jelly is then poured on a level glass-plate, over which it spreads, scattering its contained water-germs in its progress, and fixing each in its separate place by a rapid congelation, artificially promoted. The plate, reposing in a moist glass chamber, is then set aside at the proper temperature, about 68° C., for germination and growth. After a few days the bacterial colonies appear. They vary in size and shape, some minute, some larger and spreading, some round or oval, smooth or tuberculated, and some liquefying the jelly which is their nidus. The colonies are counted, and the deduction from the experiment is that the water is good because it contained but few germs, or it is bad because it contained many germs, just as a quarter of a century ago, in the undergraduate days of sanitary analysis, the deduction was made that the water was good because there was no blackening on ignition and little loss of weight, or that it was bad because there was much loss of weight, blackening, and nitrogenous or nitrous fumes; but, as will be seen directly, the collateral experience which gave a certain amount of precision to the dictum of the chemist fails to support the deductions from the biological experiment.

There are, in the first instance, several objections to the *method* of the cultivation experiment. Bacteria may exist in the water in chains and zoöglæa masses which will not be broken up by the agitation of the tube; and, in consequence, germs which, if properly distributed, would have given rise to many points of bacterial growth, may in the actual experiment originate but few. Again, the results may differ according as the field under cultivation is exposed to or excluded from the influence of light; and in this connection Bischof has made a suggestion which may prove to have a practical value, to the effect that cultivations which are intended to develop pathogenic organisms should be conducted in the dark, as it is unlikely that those which find congenial conditions within the human body are materially dependent on the influence of light for their development and growth. There is also an important objection to the *material* of the culture-field. As in agriculture the same crop does not grow equally well on all soils, so in bacterial cultivation, germs that are found to thrive luxuriantly in one soil may fail to prosper in another; and, as a matter of fact, many organisms that do not germinate in the peptonized meat-jelly are successfully grown on potato, Iceland moss and other vegetable substances.

But, passing over such objections as these, and supposing the colonies of the culture-field to give an accurate representation of the number of germs present in the water under examination, what bearing has this number on the important question of wholesomeness? In reply to this, Bischof has presented for the consideration of the Society of Health Officers of Great Britain his experiments on the storage of New River water. A sample of this water, freshly drawn and acknowledged to be of good quality, yielded fifty-three colonies per cubic centimetre. Now, it is well known that the bacteria of certain

waters increase and multiply during the storage of the water; but there is no evidence that a wholesome water becomes unwholesome merely because it has been stored in the cistern or reservoir for so many days before it is distributed for use. On the contrary, the evidence is overwhelming that a good water remains good, and even that an impure water, chemically speaking, becomes purer during the period of its storage. Changes are in progress in the water, but these are all, still speaking chemically, in the interest of the consumer, for organic matter becomes transformed into the transition product ammonia, and this into the purely inorganic and harmless nitric salt. The present writer, in the course of Prof. Mallet's inquiry into the value of chemical analysis as a means of determining the wholesomeness of water-supplies, made many experiments, recorded in the *Report of the National Board of Health for 1882*, on the progress of purification during storage. Organic matter disappeared, and ammonia, nitrous acid and nitric acid were in sequence formed,—a retrograde movement from the notoriously pathogenic possibilities of putrefying organic matter to the harmlessness of inorganic salts. But these were merely chemical results. What did Bischof find? He found that when the water of unquestioned quality, which gave only 53 colonies per cubic centimetre (16 minims), had been stored five or six days it yielded on the gelatin-culture plate 770,000 bacterial colonies, a number seventeen times in excess of that obtained from the Thames water at London Bridge. Must we believe that the wholesome water became unwholesome during that short period of storage, although chemical experience shows the tendency of storage to be toward purification, and practical experience throws no suspicion on the quality of the stored water? We can only conclude that 770,000 colonies per cubic centimetre are not inconsistent with wholesomeness; and if a water may contain from 53 to 770,000 without question as to its wholesomeness, what value, it may be asked, attaches to the intermediate hundreds, to the intermediate thousands, to the intermediate hundreds of thousands? Nor should it be forgotten that these extreme results were obtained from the same water. The number of colonies seems, therefore, to depend on whether the water was examined on one day or on another. Of a truth, the chemical inquiry is more consistent in its views of the same water from day to day than is the bacterial culture.

The detection of minute quantities of sewage in a water, impure from other causes, is regarded by chemists as a difficult problem; but sewage in large quantity in an impure water, or in small quantity in an otherwise pure water, presents no difficulty. How does the bacterioscopic inquiry deal with this question? Bischof again replies: He added sewage to a sample of New River water, and after storing it for six days, as in the parallel experiment with the pure water from the river, he found that the bacteria in the latter exceeded those in the tainted sample almost twenty times. Again, the inquiry is presented: What is the value of the number of colonies per cubic centimetre of the water examined? Since their number throws no light on the wholesomeness of a water, and gives no intimation of the existence of that which is known to be often a dangerous contamination, the chemical analyst may be exonerated from all imputation of personal, professional or scientific prejudice if he inquire,—what then is the value of the gelatin-culture in practical sanitary work?

Necessarily the bacteriologist has to fall back upon his ability to discriminate between the microphytes —to distinguish those that are harmless from those that are harmful. To do this he has to transfer them to blood-serum, potatoes, bread paste, and other nutritive media to obtain pure cultivations, and to examine these microscopically for the determination of their characteristics, which are simple enough, it is true, but complex in their very simplicity. The bacteria are thick or thin, straight or curved, oval, rounded or square at the ends, long and filamentous, or so short as to merge into the torula or coccus; the cocci of all sizes, consistent with their individuality as cocci, and presenting every form of aggregation from single to zoöglæa; and the whole, perhaps, mixed with shreds of mucor, mycelial threads, spores, etc. Every water has a variety of forms, though in some the bacteria, and in others the cocci predominate. The observer is lost in the uncertainties of his field, and no one knows which of the forms, if any, are dangerous.

When facts are lacking, speculation never fails to come to the front. The possibility of the transformation of species, as suggested by Buchner and Nägeli, looms up before the mind of some and envelops every microbe in an obscurity of pathogenic possibilities,—harmless they may be under ordinary circumstances, but capable on account of the rapid succession of generations, of becoming developed into dangerous characters. A series of ages was necessary for the evolution of the imperial man of to-day from the shivering savage of pre-historic times, but the bacterial ages are so brief that with a changed environment a day may suffice to alter forms, dispositions and endowments. And the clinical experience and general knowledge of the physician start into prominence in this connection, recalling how tonsillar and other inflammations assume a diphtheritic aspect, and fevers a typhoid type, and how even the dangerous typhus, nay, even the plagues and pestilences of former times would assuredly be recalled by a return to the insanitary conditions that were associated with their outbreak. Other observers, while exonerating many of the

bacteria from the charge of virulent possibilities, are inclined to believe that in numbers there is danger; that there is a greater likelihood of the presence of pathogenic species in a water that contains many species than in one that has few. Others, again, recognizing the harmlessness of bacterium termo, are inclined to believe that in numbers there is safety; that there is a greater likelihood of the presence of pathogenic individuals in a water that contains few individuals or species than in one that has many. These remember the destruction of septic poison by the progress of putrefaction; they remember Koch's opinion that the comma bacillus probably gives way before the putrefactive bacteria; they recall the struggle for existence that pervades creation, and that the dominating race to whom the conditions are congenial, usually denies the means of vigorous growth to the unacclimated stranger. Hence, when a water contains few microbes they fear that the pathogenic germ, if present, will have full possession of the field and attain the utmost development of its virulence unchecked by the aggressive growth of other and harmless competitors.

Fortunately, in this incertitude, there is one thing certain, and that is, that the majority of the water bacteria are harmless. Daily experience proves this, in view of the numbers in every glass of water. The bacteria of putrefaction cannot be considered pathogenic. A draught of tainted water may occasion diarrhœa, but this appears to be due to the products of their vital action on dead organic matter rather than to the action of their vitality on the living system. In the retrogression of the elements of dead organic matter to the inorganic state, effected, as is now known, by the vital processes of the microphytes, there are many transition products, some of which are surely unwholesome, but nature, careful always, has attached to them this putrefactive taint to indicate that the work of the microbe is as yet unfinished, and the material unfit for human ingestion. Taken by themselves, without their organic nidus, there is no evidence that these bacteria are injurious. They are present in many waters in association with decomposing matters, but this association negatives their claim to be considered water-bacteria.

The water-bacteria of potable waters are, however, allied to the microbes of putrefaction by the nature of their work. Like the latter, they are engaged in the regeneration of the world, preparing the ammoniacal results of putrefactive fermentation for assimilation by superior vegetation. From what source do our waters obtain their myriads of bacteria? Pure rain-water—that is, water that has been collected after the atmosphere has been cleaned by a previous fall—has few organisms, and deep well-waters have also few; but water that has come in contact with the surface of the earth has many. The water-bacteria are derived from the surface of the soil. Dr. Theo. Smith, of Washington, D. C., in cultivating the waters of the Potomac River on the gelatin-field from month to month,[1] was surprised to find that in summer they yielded only from 50 to 200 colonies per cubic centimetre, while in winter the number ran up to 4000. Temperature appeared to him to be at fault as a developmental agency; but he explained the causation of the increase in noting the facts that the smaller numbers were always associated with a clear and unclouded condition of the stream, while the larger numbers were as invariably associated with turbidity. The bacteria were washed into the stream with the particles of their habitat. Warington has lately shown that the organisms of nitrification are confined mainly to within one or two feet of the surface. In the soil these bacteria complete the transformation of organic ammonia into nitric salts, and when washed by rainfalls and snow-meltings into the river course, they continue their work on the ammonia of the water as the agents of the so-called purification of the running stream. Several years ago the present writer experienced much difficulty in explaining the favorable change which took place in cistern-waters that are stored underground, as compared with similar waters contained in clean cypress-wood tanks; and the anomaly of finding a purer water in a wooden cistern with a thick layer of foul sediment at the bottom than in one that was new or newly cleaned, was even more unintelligble until the fact was recognized that the bacteria of nitrification had been introduced into the one set of reservoirs and not into the other. The dust of summer, settled on the shedding roofs and washed into the cisterns with the inflow of subsequent rainfalls, accumulated in the progress of time to a fermenting mass which tainted the water; but for a long time before this ultimate result was reached it effected the dissipation of ammonia, and, chemically speaking, improved the character of the water by the introduction of the microbes of nitrification. The same purification would have been effected by substituting for the organic compost from the roof a layer of clean sand or gravel from the surface of the soil. The writer has frequently started the process of nitrification in laboratory experiments on dilute ammoniacal solutions by dropping into them a fragment of clean gravel or straw picked from the surface of the ground. These bacteria which enter into our river waters by thousands in every cubic centimetre when the streams are turbid, exercise no injurious influence on the human system. They seem even to have no transition products to complicate this question; for the nitrogen on which they operate is already on the verge of the inorganic state. It is true that the presence of

[1] THE MEDICAL NEWS, 1887, l. p. 404.

nitrates in notable quantity in a water is generally regarded as lowering the standard of its quality on account of the association of such waters with the propagation of typhoid fever; but this reputation of nitrified waters is referable to the material from which the nitrates are formed, not to their bacterial manufacturers. Excess of nitrates in a water is due to preëxisting sewage, and we know the typhoid germ to be the occasional associate of the sewage. In fact, the results of sanitary investigations into the propagation of acute infectious diseases by the water-supply, point clearly to animal excreta as the causative agencies. A peculiar bacillus or micrococcus may be concerned in each instance, as in cholera we have the comma bacillus, but if there is no sewage in the water the probability of danger is small. If sewage be excluded, the number of microbes in the cubic centimetre is of comparatively small consequence in determining questions of wholesomeness.

We must conclude from this brief review of certain questions relating to the existence of the micro-organisms of water, that the gelatin culture-test is valuable only in its doubtful promise for the future. At present, in the hands of the sanitary inquirer, it gives but little information, and that little is surrounded on all sides by interrogation points. In the laboratory of the scientific investigator new methods may be discovered by which pathogenic germs may be isolated and identified; but until that time arrives the sanitary analyst must depend upon the chemical results as translated in each particular instance by the aid of the ascertained sanitary environment of the water, and however much he may cultivate the microbes, he should not forget to inspect that other field of microscopic life to which reference was made at the beginning of this paper.

MEDICAL PROGRESS.

Silico-fluoride of Sodium as an Antiseptic.—ROBSON, in the *British Medical Journal* of May 19, 1888, reports that the following are the conclusions to which he has come, after an extensive and varied trial of the fluosilicate.

1. That "salufer" (silico-fluoride of sodium) is an efficient antiseptic.

2. That the powder is a strong irritant, even acting as a caustic if dusted on a raw surface, and is, therefore, in that form, unavailable for surgical purposes.

3. That a solution of one grain to an ounce of water is quite strong enough for ordinary purposes, in that strength being apparently unirritating.

4. That a solution of ten to twenty grains to a pint may be safely used to syringe out closed cavities, even where one cannot be certain of all the fluid returning.

5. That the solution is unirritating to the hands, which is no small advantage to those operators whose fingers are easily irritated by the ordinary antiseptic solutions.

6. That the solution acts on the glaze of porcelain after long use, and corrodes steel instruments, but that sponges are unaffected by it. Mr. Thomson kindly suggested to him the addition of bicarbonate of soda to the solution of "salufer" to prevent it corroding steel instruments; this certainly diminishes its action on steel.

8. That a very convenient and comfortable antiseptic poultice may be made by soaking Gamgee tissue or absorbent wool in a hot solution (ten grains to the pint), wringing it free from excessive moisture, applying it to a wound, and covering with gutta-percha tissue.

8. That although for ordinary surgical work he may still employ perchloride of mercury, in all cases where there is danger of absorption, as in syringing out cavities, he will employ "salufer."

9. That he believes "salufer" will prove to be of great use to obstetricians, it being both safe and efficient.

10. That it acts very efficiently as a deodorizer to the hands. After examining carcinoma of the uterus or rectum, by washing and steeping the hands in a saturated solution, the odor was removed more efficiently than by any solution with which he is acquainted. Messrs. Reynolds & Branson have made some compressed tabloids, each containing forty grains—that is, sufficient to make a quart of solution. They have also been good enough to carry out his wishes in making a dressing of "salufer" wool.

In all the cases related this "salufer" wool has been the dressing employed, a layer of gauze wet with the "salufer" lotion covering the wound, and intervening between it and the wool.

For Painful Menstruation.—DR. B. W. RICHARDSON (*Asclepiad*, No. 18) recommends the following formula:

R.—Croton chloral	gr. ij.
Oil of juniper	♏iij.
Glycerin	℥j.
Distilled water	℥iss.

To make a draught; to be repeated every five or six hours until relief is obtained.

The Prevention and Treatment of Cholera.—CANTANI, at the recent Congress für Innere Medicin, at Wiesbaden, presented a paper on this subject, of which the following is a résumé.

Until recently the treatment of cholera has been, in the main, symptomatic. Some attacked the diarrhœa with opiates, alum, acetate of lead, etc.; others endeavored to eliminate the poison by emesis and purgation; still others attempted acidifying the stomach, alcoholic measures, hydrotherapy, etc.,—still, on the whole, these therapeutics were unsuccessful. A change took place as it was recognized that: 1. One cause of death from cholera is the coagulation of the blood. 2. The comma-bacillus is the source of the intestinal irritation. 3. A second cause of death is the collapse from acute, chemical cholera poisoning. Both causes may act alone or together. Still, the danger depends upon the bacillar infection of the intestine.

From the preceding, the demands for treatment are indicated: 1. Limitation of bacillus multiplication in the intestine. 2. In the removal, or neutralization of the cholera poison, and 3. In relieving the coagulation of the blood. The first indication can only be met in the beginning of the disease, be it by unfavorably affecting their soil by acids, or by destroying the bacilli; but

they are not to be reached by mouth and stomach, but only through the rectum by enemata.

The only remedy which renders sterilization of the intestinal canal possible, without doing the patient harm, is tannic acid. Hot injections of tannic acid (100.4°-104°) in the strength of 75, 150 or 300 grains to two or three pints of hot water, with the addition of 20 to 50 drops of laudanum, are capable of destroying the bacilli in the intestinal canal or at least of checking their development. This has been demonstrated by experiment as well as by experience at the bedside. Tannic acid enemata find special application in the incipient diarrhœa. Rightly applied, they are capable of checking the development of the disease. In times of cholera, they should be used in every suspicious diarrhœa.

Concerning the second indication, there is to-day no longer any doubt of the existence of a chemical cholera poison, which may cause collapse without any notable diarrhœa. The condition of the intestinal contents has a definite influence upon the development of this poison (ptomaine); the more bacilli in the canal, the more the poison. We know no antidote; fortunately, tannic acid is capable of restraining the poison already formed in the intestinal canal, and preventing its absorption.

For the coagulation of the blood and its sequelæ, we have the introduction of water into the organism, be it by injection into the veins or into the subcutaneous connective tissue. The latter is entirely harmless and easily performed, and to be preferred to the dangerous and difficult intravenous injection. The hypodermatic injection of a solution of carbonate of sodium 3 parts in 1000 with a solution of chloride of sodium 4 parts in 1000, replaces the lost water, meets the need of the tissues for acids, and furthers the elimination of the noxious matters in the blood.

In conclusion, the tannic acid enemata and the salt water hypodermatic injections fulfil the three chief therapeutical indications, but both are stimulant and reviving by reason of their warmth. The enemata are used preferably in the beginning, the hypodermatic injections only in the later stages of the disease, but in advanced cholera it is best to use both.—*Wiener medizin. Presse*, May 20, 1888.

Exsection of the Vermiform Appendix in Perityphlitis with Consecutive Suppurative Peritonitis.—The Vienna correspondent of the *British Medical Journal* of June 9, 1888, writes that DR. BRENNER, Assistant to Professor von Dittel, showed a patient, aged nineteen years, who had been admitted into Professor von Dittel's clinic in March last, with symptoms of severe intestinal obstruction. The history of the case and the intense pain in the cæcal region led them to conclude, with a certain degree of probability, that they had to deal with perityphlitis and consecutive suppurative peritonitis. Laparotomy was performed on the day of admission. After opening the abdomen, a great quantity of pus escaped; the intestines were washed with a solution of salicylic acid; and on close examination it was found that there was an abscess in the region of the cæcum, around the vermiform appendix, which was perforated. The vermiform appendix was ligatured and removed. The part of the cæcum which had become affected by the suppurating process was drawn forward and fixed to the abdominal wound by means of sutures, as resection of the intestine could not be done, owing to the collapsed state of the patien during the operation. The abdominal wound was closed and healing took place by first intention. Three other cases of suppurative peritonitis following perityphlitis were treated in the wards of Professor von Dittel by laparotomy, but all ended fatally. Dr. Brenner remarked that the recent advance in the surgical treatment of these cases consisted in the fact that operation was resorted to at an early date, and that the affected part of the intestine was removed from the abdominal cavity. This was the first case of healing after exsection of the vermiform appendix when general peritonitis was already present.

Salicylate of Mercury.—The *Revue Générale de Clin. et de Thérapeutique* of May 17, 1888, gives the following formulæ for salicylate of mercury, as used in Brazil:

In pill form:

Hydrarg. salicylat. . . .	gr. ⅙.
Ext. geissosperm. læv. . .	gr. ⅚.
Ext. glycyrrhiz., Glycyrrhiz. pulv. . . .	āā q. s.

M. ft. in pil. ten in num.
Dose from two four pills daily.

For external use:

Hydrarg. salicylat. . . .	2 to 5 parts.
Vaselin.	30 "

Hypodermatically:

Hydrarg. salicylat. . . .	gr. $\frac{1}{15}$ to ⅙.
Aquæ destill.	℥ 2½.

For an injection.

By urethral injection:

Hydrarg. salicylat. . . .	gr. 2¼.
Sodii bicarbonat. . . .	℥ 7¾.
Aquæ rosæ	℥ 2¾.

For an injection.
These injections should be given daily.

Saccharin Diabetes and Alterations in the Pancreas.—LANCEREAUX, in a recent communication to the French Academy of Medicine, expressed the view that diabetes, as the term is commonly used, includes several processes one of which especially affects the pancreas. The first he described as acute diabetes, having a rapid evolution and course, and accompanied by well-marked changes in the pancreas. The second is a type better known than the first, accompanied by an increase in the patient's flesh, by chronic disease of the articulations, and not usually characterized by lesions of the pancreas; this condition is known as constitutional or fatty diabetes. A third type is that produced by a lesion of the nervous system, traumatic or emotional; it is accidental, accompanied by mild symptoms, is wanting in pathological organic changes, and tends to recovery. Lancereaux thought that the clinical significance of this classification is evident.—*Gazette Hebdomadaire*, May 4, 1888.

Acute Parenchymatous Tonsillitis Treated by Cocaine.—At a recent meeting of the Clinical Society of London, DR. DE HAVILLAND HALL read notes of three cases.

Case 1.—A laborer, aged twenty-eight, was admitted into

Westminster Hospital on Sept. 28, 1887, suffering from quinsy. He had had two similar attacks in the last five years. On admission, he had been ill four days. The right tonsil and adjacent soft parts were enormously swollen, and he was unable to swallow without the greatest difficulty and pain. On the 30th there was complete inability to swallow, but, after painting a twenty per cent. solution of cocaine freely over the whole of the fauces, the patient was able to swallow some bread and milk. The same night the left tonsil became affected, and the cocaine solution was applied again next day with an equally good effect, and the day following he was able to swallow bread and butter. No suppuration occurred. The patient left the hospital quite well after being in one week instead of four and three weeks respectively, as on the two former occasions.

Case 2.—A publican, aged twenty-five. When seen, his complexion was dusky; he was suffering from some dyspnœa and great dysphagia. Both tonsils and the soft palate were greatly swollen, and were covered with a viscid secretion, but there was no false membrane. Pulse 120, feeble. Urine, specific gravity 1030, loaded with albumen. The patient's condition was a most anxious one. The throat was swabbed out with a twenty per cent. solution of cocaine, and the application was repeated in ten minutes. Five minutes later, the patient was breathing more easily, and was able to swallow half a pint of egg, milk and brandy. During the next two days, applications of cocaine were made night and morning, and one on the third day. The patient gradually improved, no suppuration occurred, and a week later the urine was free from albumen, and he was well.

Case 3.—A porter, aged thirty-nine, attended at the Throat Department of the Westminster Hospital on Nov. 16, 1887, complaining of sore throat and inability to swallow for thirty-six hours. He was previously quite well. The left tonsil and adjacent parts were swollen, and there was a yellow patch on the tonsil. Pulse 88, fair volume. Temperature 102.2°. The urine contained a trace of albumen. A twenty per cent. solution of cocaine was applied, and the patient was soon able to swallow half a pint of bread and milk. Four days later the patient had no difficulty in swallowing, and was practically well.

In all three cases, as soon as the patients could swallow easily, tincture of the perchloride of iron, with or without quinine, was ordered. Dr. Hall pointed out that cocaine has a twofold action in these cases; it diminishes the sensibility of the parts to which it is applied, and at the same time lessens the blood supply; hence deglutition is much facilitated. He also thought that it checks suppuration. He advised the throat to be sprayed with a solution of bicarbonate of sodium, ten grains to the ounce, before the cocaine is applied; by this means less cocaine is needed, as it appears that cocaine acts more efficaciously in the presence of an alkali. Dr. Semon said he had seen cases in which cocaine had been too freely used. Patients obtained cocaine pastilles from the chemist, and used them indiscriminately. A lady suffering from hay asthma, with cough, coryza, etc., being ordered a ten per cent. solution, procured one of twenty per cent., which she used occasionally for two years to the nostril. One night, after so using it, she awoke from sleep feeling very ill, and with her heart's action very irregular. She recovered after a time, and had since then had a wholesome fear of cocaine. Another patient, a gentleman, had severe poisonous symptoms from the use of only the sixth part of a grain. In fact he (the speaker) was of opinion that some patients could not use it. On the other hand, he had seen a patient suffering from tonsillitis, who had had aphasia for twenty-four or thirty-six hours, become able to swallow with some comfort only ten minutes after an application of cocaine to the fauces.

Dr. Hall, in reply, mentioned that last week he had used a twenty per cent. solution of cocaine to the nostril of a young man, who was very strongly affected by it, became faint, and had to lie down for nearly an hour before the effects passed off, although ether and other stimulants were given. He always applied the solution now with a brush, all the cases in which untoward symptoms had showed themselves having been when he used the spray. He observed that peri-tonsillar inflammation seemed to take place in some cases when practically no tonsillar tissue was left. He thought that cocaine was only of use in parenchymatous tonsillitis; the same good results had not followed its use in follicular tonsillitis.—*British Medical Journal*, May 19, 1888.

Laxatives in the Treatment of Fatty Heart.—Kisch, in the *Internat. Klin. Rundschau*, No. 10, 1888, prescribes a useful purgative for this condition as follows:

℞.—Pulv. rad. rhei.,
Extr. alœs,
Ext. jalap. . . . . āā gr. 30.
Pil. mass. . . . . q. s.
Ft. pil. thirty in num.
Sig.—One pill at evening.

In anæmic patients:

Ferri sulph. pur. . . . . gr. 45.
Extr. alœs . . . . . gr. 30.
Pil. mass. . . . . q. s.
Ft. pil. thirty in num.
Sig.—One pill morning and night.

When compensation is becoming exhausted digitalis may be combined with laxatives as follows:

℞.—Pulv. rad. rhei.,
Ext. alœs. aq.,
Pulv. fol. digital. . . . āā gr. 30.
Pil. mass. . . . . q. s.
Ft. pil. thirty in num.
Sig.—One pill every three hours.

Erythrophlœin.—Dr. Adolf Onodi gives, in the *Orvosi Hetilap*, a summary of his observations on twelve patients, and concludes that erythrophlœin is undoubtedly a powerful anæsthetic, the effect of which comes on more slowly, but, on the other hand, lasts much longer, than that of cocaine. Local anæsthesia persists for eight hours and even longer from the time of instillation. It has, nevertheless, very disagreeable after-effects, such as headache, giddiness, sometimes even fainting fits; in particular it dims the cornea for several hours. When applied to the nose, the mouth, the soft palate, and the external orifice of the urethra, a 0.20 per cent. solution caused a slight sensation of burning. He did not venture to use stronger solutions.—*British Medical Journal*, May 19, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JUNE 30, 1888.

THE INFLUENCE OF HYDROFLUORIC ACID ON TUBERCLE BACILLI.

IN THE NEWS of May 5th, DR. E. L. TRUDEAU narrated some carefully performed experiments, showing the influence of hydrofluoric acid in retarding or checking the growth of the bacilli, and he found that in rabbits inoculated, less tubercle invaded the lung tissue in those subjected to the inhalations. In the *Bulletin Médicale* of June 3d, GRANCHER and CHAUTAUD report the results of their studies on this important question. Rabbits inoculated with tubercle cultures, and exposed for two hours daily to an atmosphere which had passed through a ten per cent. solution of hydrofluoric acid, died about the same time, and showed the same lesions as animals not subjected to the treatment. Solutions of greater strength, forty per cent. and sixty per cent., were also ineffectual, and they conclude that the inhalations have no action on the evolution of the bacilli in experimental tuberculosis. They found the resisting powers of the bacilli in cultures much greater than had been supposed. Even cultures treated for four hours with vapors from solutions of forty, sixty and eighty per cent., and, lastly, the pure commercial acid destroyed life, but more slowly, indicating that the action of the gas diminished the virulence of the bacilli. The authors regret that these observations do not encourage the hopes which have been entertained as to the high therapeutic value of inhalations of hydrofluoric acid in phthisis.

A MONUMENT TO THE DISCOVERER OF CHLOROFORM.

THE Jefferson County (N. Y.) Historical Society proposes to erect a monument to the discoverer of chloroform, Dr. Samuel Guthrie. That Society assumes this graceful duty in addition to that of perpetuating the memory of the soldiers who fell at the battle of Sackett's Harbor, the battlefield having been secured in the interests of these two patriotic undertakings.

Dr. Guthrie was born in 1782, his father having been a physician of Brimfield, Mass.; he died in 1848. During the War of 1812 he was examining surgeon, and did chemical work for the military posts in northern New York. In 1817 he took up his residence at Sackett's Harbor. He published in *Silliman's Journal* for October, 1831, an article describing the preparation and properties of "A Spirituous Solution of Chloric Ether." The ether was made by distilling chloride of lime with alcohol. His paper was in the hands of the publisher as early as May 8, 1831, and was completed some months before that date. These data conclusively establish the priority of the American discovery of the world's great anæsthetic, since Liebig had not published his account until November, 1831, and Soubeiran's did not appear until January, 1832. The race between these three independent discoverers is a close one, but to Guthrie must be awarded the honor of first making and describing the substance which we now know as chloroform—a name originated by Dumas in 1835. It is a curious fact that Guthrie, during forty years of his life, devoted much time and thought to the improvement of gunpowder, and it is quite possible that both that destructive compound and the anæsthetic that was to be were in hand at one and the same time.

THE Centennial volume of the *Transactions of the College of Physicians of Philadelphia* has been made the subject of a *feuilleton* by Dr. Joseph Schreiber in a recent number of the *Wiener klinische Wochenschrift*. As an illustration of the appreciative and sympathetic style of the original, we may quote the concluding paragraph.

"The impression we have received from reading the *Transactions* is truly beneficial and satisfying. We meet a medical society composed of *savants* and practitioners, in useful sympathy with the community, and honored and supported by public opinion; a medical society which, con-

ducted on true democratic principles and animated by a spirit of perfect equality, has for its president one who, though clothed with no academic dignity, has acquired a name, as author and physician, that resounds far and wide. May the fresh pulsating life and youthful energy of the College be preserved for all the centuries to come."

The new Institute of Hygiene at Rostock, of which Dr. Uffelmann is director, was opened at the beginning of the present summer-course. The southern wing of the former Gynecological Institute has been reconstructed for the purpose—the northern wing being occupied by the new chemical laboratory, and contains, besides rooms equipped for experimentation on animals and the servants' apartments, eight rooms for the purposes of academic instruction. On the ground floor there is a room for specimens, another for bacteriological research, another for the library and the room of the director; on the upper floor the lecture room, two rooms for practitioners, and one for scales and other fine instruments. Adjacent to the Institute on the west is an extensive garden, permitting of the study of the earth and of the air.

The advance which the opening of this Institution brings with it is most marked, as the building hitherto devoted to instruction in hygiene was, in extent and accommodations, insufficient to meet the demands. The present building, however, is satisfactory in all respects. The practical courses of the Institute are well attended.

The Rhode Island Medical Society, at its seventy-seventh annual meeting, held at Providence on June 14th, elected Dr. Albert Potter to the presidency for the ensuing year.

The American Rhinological Association will hold its sixth annual meeting at Cincinnati, Ohio, September 12, 13 and 14, 1888.

The Trustees of the Fiske Prize Fund have awarded a premium of $200 for the best essay on "What changes has the acceptance of the Germ Theory made in measures for the prevention and treatment of consumption?", by Dr. Charles V. Chapin, of Providence. No award was made for any essay on the subject, "Antisepsis in Medicine and Surgery, with original observations and experiments."

The following subjects are submitted for the years 1888–1889: 1. "The Surgical Treatment of Wounds and Obstructions of the Intestines." 2. "Asepsis *versus* Antisepsis in Surgery and Midwifery." 3. "The Rôle of Ptomaines in Infectious Diseases." 4. "The Pathological Effects of Chronic Alcoholism." For the best essay on either of these subjects a prize of $200 is offered.

On the occasion of the celebration of his seventieth birthday, at Utrecht, on May 28th, the Medical Society of Munich elected Prof. Donders an honorary member of the Society.

Recent explorations at the Island of Cos have unearthed the site of the renowned temple of Æsculapius, the third in prominence in the mind of the Greek world. The only ones that were held in higher esteem were the temples at Epidauros and Athens. An altar has been found and a marble serpent, the well-known attribute of the god of medicine. The description that Strabo gives of the temple at Cos would indicate the possibility of a rich harvest if systematic excavations are carried on at this site. He says that its shrines were full of votive offerings, including priceless works of art, and its walls abounded in inscriptions recording the cures wrought there, which Hippocrates is said to have studied and from which he learned much of his medical lore. The excavations at the Asclepieion at Athens have yielded valuable results, but much remains to be learned concerning the cult and ritual of Greek medicine, which can only be discovered by the bright spade of the scholarly explorer.

The conditions, symptoms and treatment of the rabid dog are the subject of an interesting circular just published by Dr. S. W. Abbott, of the Massachusetts State Board of Health. This circular makes the surprising statement that the total number of human deaths, registered during the past forty-six years in that State, has been not more than seventy-two by hydrophobia. This leaflet by Dr. Abbott is manifestly designed for popular distribution—the public statutes requiring its publication—and it is probably for that reason that he makes use of the term hydrophobia, instead of rabies, in describing the disease in the dog, wolf, cat, and other lower animals; although at the same time he states plainly that the dread of water is not to be looked for in the mad dog, but rather an uncommon desire for water.

SOCIETY PROCEEDINGS.

THE ONTARIO MEDICAL ASSOCIATION.

The Eighth Annual Meeting, held at Toronto, June 13 and 14, 1888.

(Specially reported for THE MEDICAL NEWS.)

THE meeting was convened at 10 o'clock on Wednesday, June 13th. The chair was taken by the President, Dr. J. W. Rosebrugh, of Hamilton. This meeting was the largest and most interesting yet held by the Association. There were about two hundred members present, exclusive of guests. The papers were of marked interest, the large majority being of a surgical character.

WEDNESDAY, JUNE 13TH.

After the reading of the minutes Dr. Graham presented the report of the Board of the

ONTARIO MEDICAL LIBRARY ASSOCIATION.

A joint stock company had been formed under this title, the shares being placed at $5 each, payable in five annual instalments. Already stock amounting to $4000 had been subscribed, and about one thousand volumes, besides many pamphlets, had been donated. He appealed to the Association individually and collectively for support.

The report was adopted and a donation of $150 voted from the funds of the Association.

DR. F. W. ROSEBRUGH then delivered

THE PRESIDENT'S ADDRESS.

He suggested that this society should affiliate with the British Medical Association, which has now over twelve thousand members and forty-seven branches, and under whose auspices is published the great *British Medical Journal*. He referred to the history of medical science; said that science is still largely empirical, but that the truth is becoming more and more firmly established, that in order to conquer nature you must obey her. The president gave an interesting account of the old days of medicine and medical education in Toronto, mentioning the names of Widmer, Rolph, Bovell, Beaumont and Workman. He urged that better facilities for scientific research should be provided for students in Canada, so that it would not be necessary for them to go abroad. These facilities being provided, the higher the standard was the better, both for the student and his patients.

DR. GRASSETT, of Toronto, read a paper on

URETHRAL DISCHARGES.

After referring to their frequency and the depressing mental effect produced in many patients, he classified them, according to the nature of the discharge:

1st. *Urethritis*, a catarrhal inflammation, of which there are:

a. Simple urethritis, caused by leucorrhœal discharges, excessive coition, mechanical irritants, etc.

b. Specific urethritis, or gonorrhœa. It is not yet proven that this is due to the gonococcus, but the almost constant presence of this microbe in the discharges indicates that it possesses causative properties.

As to treatment, both the abortive and the expectant plans have proved disappointing. The plan found to be most satisfactory might be summarized as follows: Rest in bed, cleanliness of the urethra, secured by frequent passage of urine or by irrigation with hot water. The penis should be allowed to hang in a natural position to permit of the escape of the discharge, and a dressing of salicylic gauze covered with a rubber bag might, with advantage, be applied over the end of the penis. The diet should be unstimulating; alcohol and tobacco forbidden. Alkalies, to keep the urine normal or slightly alkaline, may be given. Injections, other than hot water, are injurious in the early stage. Sulphate and sulphocarbolate of zinc in dilute solution are beneficial later, as also is silver nitrate.

2d. *Gleet*. This may occur in spite of the most careful treatment the circumstances will allow. Probably due to extension of the inflammatory process to the submucous tissue, causing thickening, with some stricture. There may be a granular condition of the mucous membrane. The stricture should be dilated, and any injections used should be only slightly stimulating; astringents to be frequently changed. Caspar, of Berlin, recommends a combination of mechanical and chemical therapeutics. He used nickel-plated bougies with grooves which are filled with medicated paste, which is melted on inserting the bougie into the urethra. After trying iodoform, resorcin, zinc, etc., he has the best results from this combination:

Ol. theobrom.	100 parts.
Argent. nitrat.	1–1½ "
Bals. copaibæ	2 "

This lessens the discharge at once, and the microscope shows a rapid reduction in the proportion of pus cells.

3d. *Prostatorrhœa*. First accurately described by Dr. S. W. Gross, of Philadelphia. It consists of a clear, glairy mucus, most frequently seen after straining at stool. It comes from the acini of the gland, and is increased by masturbation, excessive venery, hard riding, etc. Several cases were cited illustrating the good effects following tonics and the local application of silver nitrate.

4th. *Spermatorrhœa*. Used by quacks and empirics to include even physiological nocturnal emissions. The causes of spermatorrhœa are, among others, hyperæsthesia or irritation of the genitals, inflammation of the prostate or urethra, phimosis, etc.

The treatment should be largely hygienic. Avoid alcohol and tobacco. Empty the bladder before retiring and the first thing in the morning. Give light diet, keep the bowels open and abstain from exciting exercises, as horseback riding. Bromide of potash often acts beneficially; circumcise a long prepuce; treat all causes of rectal irritation, as fissures, piles, etc. Passing large bougies and the local application to the prostatic urethra of silver nitrate (gr. x to xx, ad ℥j) are also useful.

The depressed mental condition of the patient must not be neglected, as much depends upon his intelligent coöperation.

DR. MCFARLAN, of Toronto, thought that boys in school should be carefully cautioned against the evils of self-abuse.

DR. GROVES, of Fergus, drew no distinction between simple and specific urethritis, as they could not be distinguished from each other. Absolute rest in the early stage was essential, and the administration of alkalies, unless the urine were intensely acid, is of doubtful utility.

DR. BURT, of Paris, thought spermatorrhœa should not be grouped with the other diseases discussed, as it had no pathological connection with the urethra. A solution of silver nitrate (one-quarter per cent.) is best in the treatment of urethritis. In stricture, an instrument which can be dilated after it enters the urethra should be used, since one sufficiently large to dilate thoroughly the stricture cannot be passed through the meatus, that being the narrowest part of the canal.

DR. A. W. JOHNSTON, of Danville, Kentucky, then read a paper on

SOFT MYOMA OF THE UTERUS.

He showed that the soft myoma is an homologous growth of the adenoid lining of the uterus, being more nearly akin to the mucous polyp, and not a variety of the hard myoma or fibroid. There is a constant cell development going on in the endometrium, and over-development of this adenoid tissue constitutes the soft myoma.

A case under the care of Lawson Tait was here cited in which a soft myoma occupied the whole uterus. These cases are extremely rare, the reader having met with but two cases. The growth consists of a loose network of fibrils inclosing lymph spaces, with also some of the muscle cells of Billroth, the whole a soft, fluctuating, myxomatous mass. Several engravings of microscopical sections were here shown. There are two main causes of these growths: 1st. The result of the damming back of lymph into the spaces of the adenoid uterine lining; 2d. Unusual development of the uterine follicles. From their peculiar structure it is evident that tapping and electricity must alike be futile, and the only successful treatment is early and complete extirpation.

DR. WHITEMAN then read a paper on the sources of error in the diagnosis and treatment of

EMPYEMA.

One case, which had been treated for three months for "warm fever," recovered in six weeks after opening and drainage. Another, a case of "diaphragmatic empyema," gave much trouble in diagnosis, from its first acting like an attack of biliary colic, from which the patient had suffered two years before. Opened between ninth and tenth ribs, and about one and a half pints of fetid pus discharged. Recovered with free drainage and antiseptic washings. A third was one of double empyema in a child four years old. Open drainage of the right side and three aspirations of the left; recovery.

In treatment, he illustrated the importance of a double drainage with free ingress and egress of air by a case in which a single opening had been made, and the attending physician, fearing evil consequences from admission of air, had wedged one end of a long rubber tube tightly into the opening; the other extremity of the tube being placed under carbolized water in a vessel beside the bed. Being called, as the woman was dying, Dr. Whiteman removed the tube, when about a quart of very fetid pus escaped. In this case, daily washings of the chest cavity were said to have been made, using the tube as a siphon. He maintained that such a course is dangerous, if the lung has in any measure lost its elasticity from long pressure, or is bound down by adhesions, in which event one might as well try to wash out a keg, through such a tube, with a single opening and without admission of air.

DR. T. K. HOLMES, of Chatham, presented a report of twenty-two cases of empyema occurring in his practice, with eight deaths and fourteen recoveries. Four died of phthisis, and one each from traumatism, embolism, asphyxia and pyæmia.

He recommended that the pus be evacuated as early as possible by the introduction of a drainage tube through a single opening made by a large trocar. This maintains free and constant drainage, is simpler than the double opening and admits of irrigation of the cavity, should this be thought necessary.

A study of the twenty-two cases led the author of the paper to the following conclusions:

1. The importance of recognizing cases early.

2. Of the necessity of giving free and constant exit to the pus.

3. That when pus has discharged through the bronchi with no amelioration of symptoms, an external opening may be followed by the best results.

4. That the most unpromising cases are those occurring in the puerperal state and those in phthisical subjects.

5. That resection of the ribs is necessary in but a small class of cases.

6. That the entrance of unpolluted air into the pus cavity does not prevent cases doing well.

7. That washing out the cavity is unnecessary when the pus is sweet.

DR. MACCULLUM, of London, then read notes on

THE PAST YEAR'S WORK IN PHYSIOLOGY AND HISTOLOGY HAVING A PATHOLOGICAL AND CLINICAL BEARING.

After showing proof that collapse of the lung does not often follow opening the pleural cavity, and that the jar given by the heart aids in the elimination of CO_2, Martin's experiments on the coronary arteries were taken up. From the fact that they fill by blood-pressure alone during systole, no degenerative changes can be present in a heart muscle, from disease of the aortic valves, whilst good blood-pressure is being maintained, unless the coronary arteries themselves are diseased. Gaskill's (*Journ. Physiol.*, vol. vii.) experiments proving that inhibition of the heart is essentially a nutritive process led the author to draw the following conclusion: That frequent electrical stimulation of the vagus would be proper treatment of degenerative change in the heart muscle (seeing that stimulation of the vagus has a nutritive effect on the heart).

DR. MULLIN, of Hamilton, opened a

DISCUSSION ON MALARIA AS A CAUSE OF DISEASE.

He pointed out the frequency with which symptoms were ascribed to hidden malarial poison, which were really due to some other cause not patent to the eyes of the careless or unmethodical observer. We do not know what malaria is, and should, therefore, not be in haste to ascribe all variety of symptoms to it. A diagnosis of malaria is often disproved by the intractability of the disease to even enormous doses of quinine. Dr. Holmes, of Chatham, coming from a malarious district had met with malaria under many forms and displaying a great variety of symptoms, singly and grouped. He had again and again proved his diagnosis by the magic influence of a few doses of quinine.

(*To be concluded.*)

CORRESPONDENCE.

A CORRECTION.

To the Editor of THE MEDICAL NEWS,

SIR: In an editorial published in your journal of June 16th, on page 672, you say that but three colleges east of the Ohio River require a three years' course previous to graduation; viz., Harvard, the University of Pennsylvania, and now Jefferson Medical College. This is a mistake. I think there are at least three others, but I am sure that there is one other—the Medical Department of Niagara University, located in the city of Buffalo. The Medical Department was organized in 1883, and by request of the faculty the State Legislature made a three years' course necessary. The college was established in the interest of higher medical education, and it maintains that position now. A three years' course is obligatory, and a four years' course is recommended.

Respectfully yours,

HENRY D. INGRAHAM,
Prof. of Gynecology and Pædiatrics,
Niagara University.

BUFFALO, N. Y., June 20, 1888

THE FIRE AT THE UNIVERSITY OF PENNSYLVANIA.

To the Editor of THE MEDICAL NEWS,

SIR: Will you have the kindness to publish the following resolution, passed at a special meeting of the Medical Faculty, June 1st:

Resolved, That the thanks of the Faculty be extended to the Resident Physicians of the Philadelphia and University Hospitals, to the students of medicine and others who aided so energetically in saving preparations, books and apparatus from the recent fire in Medical Hall.

Respectfully yours,

JAMES TYSON,
Secretary

NEWS ITEMS.

Changes at the Harvard Medical School.—Dr. F. C. Shattuck has been appointed Professor of Clinical Medicine; Dr. J. Orme Green, Clinical Professor of Otology; Dr. Clarence J. Blake, Professor of Otology; Dr. F. I. Knight, Clinical Professor of Laryngology, and Dr. W. H. Baker, Professor of Gynecology.

Dr. E. N. Whittier has resigned the position of Assistant Professor of Clinical Medicine.

The Building Fund of the New York Academy of Medicine, in response to the appeal for subscriptions, has received nearly twelve thousand dollars.

A Successful Operation for Pyloric Stenosis.—Loreta's operation, or the digital divulsion of the pylorus for stenosis, with dilatation of the stomach, was performed, June 11th, by Dr. William T. Bull at St. Luke's Hospital. The patient, a man aged thirty-seven, had suffered for twenty months from daily vomiting, pain, acid eructations and heartburn, and was much reduced in flesh, despite treatment by lavage of the stomach, careful diet and internal remedies. He was made the subject of thorough investigation by testing chemically the fluids of the stomach, by Dr. F. P. Kinnicutt, and the diagnosis of stenosis from cicatricial contraction of an ulcer arrived at. The operation confirmed the diagnosis, the pyloric orifice being found so small as to admit only a bougie of a diameter of three-sixteenths of an inch. Through a wound two inches long near the pylorus the orifice was stretched gradually with bougies and the fingers till it was over two inches in diameter. No accident followed the operation, and the patient may be now (June 19th) considered out of danger. There has been neither pain nor vomiting, though for several days considerable quantities of liquid diet have been taken by the mouth. A full report of the case will be presented at the October meeting of the Practitioners' Society. This is the first successful case of this operation yet reported in this country.—*The Medical Record*, June 23, 1888.

A Generous Endowment.—Joseph Hyrtl, the eminent anatomist, has offered to endow six scholarships, in the Vienna Medical School, for worthy students without means, without distinction of nationality or creed.

Prof. v. Bergmann has been elected an honorary member of the St. Petersburg Chirurgical Society.

Adulteration in Europe.—The sanitary authorities in Roumania, in their report for 1887, mention the discovery and seizure of macaroni colored with naphtalin yellow, picric acid and binitro-cressol, and confectionery colored with auramin, anilin yellow, fuchsin, mononaphtol and dinitro-naphtol. Considerable vinegar essence, intended for the manufacture of vinegar, was seized on importation because it contained picric acid. Analyses were made of distilled spirits, and resulted in finding brandy made from unrectified ethylic alcohol, and colored with picric acid, benzoyl, heleanthin (methylorange) and chrysanilin. Some of it was flavored with ethylic ether, acetic ether, amyl nitrite and prussic acid. The wines sold in inns were nearly all alcoholized and flavored with amylic ether.

In Poland, wheat flour is largely adulterated by the addition, to make weight, of valueless ground vegetable matter, as well as the admixture of from ten to fifty per cent. of barley and rye flour. The result of these vegetable admixtures has been frequent cases of poisoning, including several cases of ergotism.

In Norway, where no anti-adulteration laws exist, the simply honesty of the people has, so far, precluded much adulteration, although milk and butter have not escaped deterioration by adulteration. The medical authorities have, however, found considerable illness caused from the use of arsenical colors in the dyeing and printing of carpets, curtains, furniture coverings and wall paper, especially that imported from England.

In Germany, Dr. Schweissinger found cod-liver oil made of resin and mineral oils, and olive oil entirely made of rape-seed oil.

In Holland, Dr. Van Hamel Roos found 705 milligrammes (11 grains) of common salt in a litre (a quart) of wine imported from the south of France.

In Belgium, an advertisement in the public journals, emanating from Saintes, in France, offers a bottle of wine essence for a little less than a dollar, which essence is guaranteed, by the addition of water, to make 230

litres (61 gallons) of wine. Dr. H. Thorns seized a quantity of milk adulterated with ultramarine.

In Austria, saffron was found to be heavily adulterated with sulphate of baryta, colored with eosine.

In England, a so-called Coleman's-Liebig's extract of meat and malt wine, said to be composed of port wine and Liebig's extract of meat, was found to be nothing but port wine having a considerable addition of salicylic acid.

From Germany comes a circular offering a champagne at 15.60 francs ($3.12) per dozen bottles, including cases, packing and freight to Antwerp or Rotterdam, and adding that any kind of label desired will be furnished.

In Goirle (Brabant), a shoemaker died in consequence of having inoculated a wound by handling leather made from hides imported from Buenos Ayres, which had been treated with poisonous preservatives.—*American Analyst*, June 15, 1888.

Cremation of Garbage. — Milwaukee disposes of its garbage effectually by cremation. The cost of this method is not excessive. To consume forty tons of garbage, about five tons of fuel are required. Even in winter the furnace is in operation only from eight to ten hours daily, and the cost of incinerating the garbage is only about eighty-six cents per ton. Detroit is about to adopt the same system.—*Pharmaceutical Era*, June, 1888.

A New Antiseptic Soap.—At a recent meeting of the Society of Chemical Industry, held at Edinburgh, Mr. John Thomson reported the results of his experiments on the preparation of an antiseptic soap.

The mercuric salts being so powerfully antiseptic, the author experimented with a number of them, but found only one of them to resist decomposition when introduced into soap. This salt was the red iodide (biniodide), which has long been known to be more powerfully antiseptic than even the bichloride. Biniodide of mercury combines with soap of almost any kind without in any degree losing its antiseptic properties. A variety of soaps prepared by the author, and containing mercuric iodide, were tested by several bacteriologists, and were found to be most efficient. The tests were made by introducing silk-threads impregnated with various septic materials (of known origin) into a solution of the soap of a known strength (usually 1 in 120), and leaving them there 10 minutes, which time was sufficient to render them perfectly aseptic.

The biniodide soap has been tried in the treatment of cases of eczema with most marked success, especially where the irritation has been produced by the fermentation of accumulated secretions.

It has also been used in parasitic skin diseases, such as favus and ringworm, with marked success.

The biniodide soap contains from one to three per cent. of biniodide dissolved in iodide of potassium.—*American Druggist*, June, 1888.

NOTES AND QUERIES.

THE DEMAND FOR IMPROVED MEDICAL EDUCATION.

To the Editor of THE MEDICAL NEWS,

SIR: A word of encouragement, though a *mite*, may not fall unheeded. I am proud to see the journal of my choice for twenty-three consecutive years taking the lead in "An Advance in Medical Education." I believe the profession at large will indorse the *three-year course*. The subject was discussed at the recent meeting of the Indiana State Medical Society, and while no definite action was taken, yet all seemed to agree that a higher standard is imperatively demanded.

Respectfully, S. E. HAMPTON, M.D.

MILTON, KY., June 20, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING JUNE 23, 1888.

CRANDALL, R. P., *Assistant Surgeon.*—Detached from the "Minnesota," and ordered to the "Saratoga."

SHIPPEN, EDWARD, *Medical Director.*—Placed on the retired list, June 18, 1888.

SAYRE, J. S., *Assistant Surgeon.*—Ordered to the Navy Yard, New York.

BRADLEY, MICHAEL, *Medical Inspector.*—Ordered to examination for promotion.

KERSHNER, EDWARD, *Surgeon.*—Ordered to the Marine Rendezvous, New York.

WHITE, C. H., *Surgeon.*—Detached from the Museum of Hygiene and await orders.

TRYON, J. RUFUS, *Surgeon.*—Detached from the Marine Rendezvous, New York, and ordered to special duty at New York.

MCCARTY, RUFUS, *Passed Assistant Surgeon* —Detached from the Naval Hospital, Chelsea, Mass., and ordered to the "Yantic."

HENNEBERGER, L. G., *Passed Assistant Surgeon.*—Detached from special duty, New York, and ordered to the "Minnesota."

KITE, J. W., *Assistant Surgeon.*—Detached from the "Yantic," and ordered to the "Richmond."

Surgeons WOOLVERTON, WHITE, WOODS and DUBOIS ordered for examination, preliminary to promotion to the grade of Medical Inspector.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 19 TO JUNE 25, 1888.

MCPARLIN, T. A., *Colonel and Surgeon* (U. S. Army).—Granted leave of absence for one month, with permission to apply for an extension of one month.—*S. O. 52, Department of the Platte*, June 20, 1888.

BROWN, J. M., *Major and Surgeon.*—Will take charge of the office and duties of the Medical Director, Department of the Platte, during the temporary absence of Colonel McParlin.—*S. O. 52, Department of the Platte*, June 20, 1888.

WHITE, ROBERT H., *Major and Surgeon.*—Ordered from Angel Island, California, to Fort Myers, Virginia.—*S. O. 142, A. G. O.*, June 20, 1888.

MUNN, CURTIS E., *Captain and Assistant Surgeon.*—Ordered from Fort Klamath, Oregon, to Angel Island, California.—*S. O. 142, A. G. O.*, June 20, 1888.

TORNEY, GEORGE H., *Captain and Assistant Surgeon.*—Relieved from duty at Fort Monroe, Va., and ordered to Fort Randall, Dakota Territory.—*S. O. 142, A. G. O.*, June 20, 1888.

MCCREERY, GEORGE, *Captain and Assistant Surgeon.*—Relieved from duty at Fort Meade, Dakota Territory, and ordered to Fort Monroe, Va., for duty.—*S. O. 142, A. G. O.*, June 20, 1888.

GORGAS, WILLIAM C., *Captain and Assistant Surgeon.*—Relieved from duty at Fort Randall, Dakota Territory, and ordered to Fort Barrancas, Florida.—*S. O. 142, A. G. O.*, June 20, 1888.

MORRIS, EDWARD R., *First Lieutenant and Assistant Surgeon.*—Leave of absence granted in S. O. 61, May 28, 1888, Department of Arizona, extended one month.—*S. O. 142, A. G. O.*, June 20, 1888.

POINDEXTER, J. D., *First Lieutenant and Assistant Surgeon.* —Granted leave of absence for one month.—*S. O. 55, Department of Dakota*, June 18, 1888.

SWIFT, EUGENE L., *First Lieutenant and Assistant Surgeon.* —Ordered from Fort Spokane, Washington Territory, to Fort Klamath, Oregon, for temporary duty.—*S. O. 142, A. G. O.*, June 20, 1888.

INDEX.

ABDOMEN, gunshot wound of, Brown, 180
Mackie, 628
Abdominal section, Mastin, 287
Abscess, cerebral and spinal, successful drainage of, 669
cold, treatment of, 296
ovarian, 80
peri-cæcal, diagnosis and treatment of, 584
perityphlitic, laparotomy for, 535, 536
Accident, a curious, 42
Acetanilide in enteric fever, Way, 11
Acid, acetic, as an ecbolic, 522
boric, poisoning from, 208
toxicity of, 237
camphorated carbolic, 694
hydrofluoric, as a destructive agent to the tubercle bacillus, 486, 717
in pulmonary tuberculosis, 668
osmic, in intercostal neuralgia, 101
Acne, treatment of, 209
Aconitine and digitaline, 492
poisoning by, 345
Address, anniversary, Loomis, 141
Adulteration in Europe, 721
Agnew, Cornelius R., death of, 474
tribute to, 504
Agnew, D. H., jubilee, 414, 417
nephrolithotomy, 115
Alanin-mercury, hypodermatic administration of, in syphilis, 693
Albumen, albuminuria and renal lesions following injection of, 293
Albuminate of iron, 264, 640
Albuminuria, cataract and, 102
following injections of albumen, 293
Alcohol for children, 155
use of, as a digestive tonic, 640
Alcoholism, treatment of, 126, 522
Alkaloids, doses of the, 124
Allen, gouty sore throat, 663
Aluminium, aceto-tartrate of, 71
Amblyopia Brightii *versus* retinitis albuminurica, Cocks, 312
tobacco, 237
Amylen hydrate, 99, 239, 291
Anæmia, pernicious, and the bothriocephalus latus, 211
with jaundice, Guitéras, 689
Anæsthesia, dental, antipyrin and cocaine for, 321
Anæsthetic for minor operations, 668
is chloroform a safe, for children, 576
Andrews, Rectal and Anal Surgery, review of, 247
Aneurism, a remarkable, 241
cardiac, in insane man, 331
thoracic, treatment of, Schultz, 150
MacDonnell, 1
Angina, diphtheritic, treatment of, 212
Anophthalmos, unilateral, Young, 636
Anthrarobin, 412, 574
Antifebrin in phthisis, 99
in variola, 15
Antipyrin, 14, 16, 39, 40, 43, 70, 71, 99, 101, 122, 189, 223, 240, 264, 266, 321, 363, 377, 379, 381, 439, 463, 492, 521, 575, 669, 695
Antisepsis, contents of a surgical bag for, 264
in midwifery, 296
Antiseptic ammunition, 647
silico fluoride of sodium as an, 714
Antiseptics, incompatibilities of, 640
influence of, upon the kidneys, 696
Anus, fissure of, treatment of, 670
Apartments, disinfection of, 639
Aphthæ, treatment of, 494
Appendages, uterine, removal of, 48
Kelly, 36
Appendix vermiformis, abscess following perforation of, 531
functions, pathology and treatment of, 583, 586
pathology of, Ransohoff, 603
removal of, 499, 715
Arm, enlargement and congestion of muscles of, 330
Army hospital corps, 103
Arnold, Matthew, life of, from a medical standpoint, 536
Arsenic, pharmacology of, 304
Artery, superficial femoral, ligature of, 410
Ascarides lumbricoides in hens, 308
Ascites, sudden death in, 554
treatment of, 210
Asexualization as a penalty for crime, Everts, 341
Asphyxia, death due to, in "blizzards," 280
Asthma, treatment of, 123
Astigmatism, rapid measuring of, 533
Ataxia, locomotor, degeneration of peripheral nerves in, 703
Atrophy, progressive muscular, with anæsthesia, 702
Atropine, oleate of, suppositories of, 155
in pilocarpine poisoning, 694
Auricles, erysipelas of, following piercing of lobe, 185
Automatism, ambulatory, Charcot, 309

BACILLUS, cancer, 306
tubercle, hydrofluoric acid as a destructive agent to the, Trudeau, 486
Bacteria, tolerance of, by lining membrane of uterus, 670
Baldy, exploratory laparotomy, 456
Ball, Rectum and Anus, review of, 130
Bandage cases, 390
Bartholow, address in medicine, 537
Basedow's disease, 353
Bassereau, Leon, death of, 28
Benzol, 155, 238
Berens, angioma of thymus gland, 408
Beri beri, micrococcus of, 14
Bernutz, Dr., death of, 84
Bile, effect of tight lacing on secretion of, 434
Biniodide of mercury and potassium iodide, antiseptic action of, 126
Bladder, cystotomy for foreign body in, Gihon, 233
intra peritoneal rupture of, 212, 612
painless distention and prolapse of, Radcliffe, 120
tuberculosis of, treatment of, 500
Bleeding, menstrual, from a laparotomy scar, 436
Blepharitis, treatment of, 40
Blood, chemical changes in, in tuberculosis, 83
pressure, effect of douches on, 307
Bone cells, ostengenic power of, 217
parietal, depression in, 327
sarcoma of, Dennis, 29
successful reimplantation of a trephined button of, 433
Bones, resection of, to remedy loss of soft tissues, 500
Borofuchsin, 552
Bothriocephalus latus, pernicious anæmia of, 211
Bougies, urethral medicinal, 434
Bowel, obstruction of, 247
Bradshaw, some points in treatment at Memorial Hospital, Orange, N. J., 707
Brain, arachnoid cysts of the, Bruen, 118
hardening the, for anatomical study, 522
occurrence of coma in lesions of, Browning, 175
recent advances in surgery of the, Nancrede, 85
surgery, interesting cases of, 317
tumor of, 353
Brains, great, 168
Bramans, Dr., 306
Bread as a disinfectant for walls, 279
Brinton, modified staff for lateral lithotomy, 491
Bronchitis, treatment of, 238, 412, 463, 493
in children, Mays, 290
Brown, gunshot wound of abdomen, 180
Browning, Wm., occurrence of coma in lesions of brain, 175
Browning, Alfred G., death of, 415
Bruen, arachnoid cysts of brain, 118
Buboes, treatment of, 13
Bullets, aseptic leaden, 292
Bun poisoning, 382
Burnett, extraction of cataract without an iridectomy, 197
Burns, treatment of, 667

CABINET, an antiseptic surgical, 613
Cæcum, pathology of, Ransohoff, 603
Cæsarean operation, progress of, in the United States, 349
records, comparison of English and American, 413
section, Neale, 253
conservative, Jaggard, 405
Caffeine intoxication, 71
Cahall, epidemic cerebro-spinal meningitis, 429
Calculi, multiple salivary, 409
Calculus, vesical, with chyluria, Gross, 666
Cancer, arsenic in, 42
bacillus, 306
etiology of, 18
hysterectomy for, 558
inflammation masking, 409
resorcin in, 125
treatment of, 494
Candies, poisonous, tests for, 620
Candy, adulterated, 223
Carbuncles, malignant, treatment of, 500
Carcinoma, high rectectomy for, 127
Caries, dental, cause of, 363
Carpet-beating, dangers of, 503
Cartwright lectures, 365, 393, 539, 565
Cataract, 241
and albuminuria, 102
dangers of simple extraction of, 319
extraction of, without an iridectomy, Burnett, 197
operation, general rules for, 608
Catarrh, chronic pharyngeal, treatment of, 263
Catheter, an aseptic two-way, 326

Catheterism, retrograde, 348
Cavity, pleural, dangers of washing out, 619
Cerebrum, action of antipyrin upon heat centres of, 552
Cervix uteri, conservative divulsion of, 41
lacerated, simple operation for, 668
Chapman, Edwin N., death of, 326
Charcot, ambulatory automatism, 309
Chest, penetrating gunshot wounds of, 124
Children, administration of medicines to, 573
rectal alimentation in, 263
medication for, 606
treatment of intestinal affections of, 265
Chlorides, antiseptic value of, 208
Chloroform, antiseptic properties of, 610
fatal after-effects of, 186
monument to the discoverer of, 717
narcosis, treatment of, 552
safety of, as an anæsthetic for children, 576
water as a vehicle, 693
Cholecystectomies, 474
Cholecystotomy in children, 532
Edwards, 339
Cholera infantum, 219
treatment of, 262
prevention and treatment of, 714
relation of water of New York Bay to, 164
Cholesteatoma, 300
Choroid plexus, tumors of, Edes, 61
Christiani, Arthur, death of, 84
Christopher, summer complaint, 229
Circumcision, convenient dressing in, 345
Closet, a successful, 307
Club-foot, congenital, Jones, 63
Club-hand, Young, 519
Cocaine, 16, 183, 321, 322, 411
collapse following use of, 241
constitutional effects from nasal sprays of, 264
in urethral operations, 320
in diseases of genito-urinary organs, 639
poisoning, 390, 552
Cocks, amblyopia Brightii *versus* retinitis albuminurica, 312
Coffee, chronic poisoning by, 129
physiological effects of oil of, Hare, 337
Cognac, manufacture of, 447
Colic, lead, treatment of, 296
violent, treatment of, 552
Collodion, salicylic, 293
Colon, rupture of, 265
Combal, Prof., death of, 391
Cones, obstetric, 123
Congo paper, 364
Constipation, treatment of, 99
Consumption, pulmonary, apex expansion *versus* pure air, Mays, 257
female dress a determining factor in, Mays, 4
Contracture, general muscular, 132
Convulsions, treatment of, in children, 409
Copaiba, a useful emulsion of, 241
Cord, umbilical, ligature and dressing of the, 462
Cornutin, 100
Corrosive sublimate, best solvent for, 522
mode of action of, in poisoning, 321
Coryza, treatment of, 154, 292
Craniometry, notes on the principles of, 702
Craniotomy, Starck, 340
Crayons, caustic, formulæ for, 411
Creasote in diphtheria, 318
in pulmonary phthisis, 73, 124, 160, 186, 290, 696
Cremation, 223, 306, 447
Creolin, 182, 210, 346, 639
Criminals, anthropometrical method of identifying, 391
Crosby, George A., death of, 138
Crown Prince, case of, 81, 110, 164, 194, 221, 250, 697
Curling, Mr., death of, 336
Currier, influence of obesity upon menstrual and reproductive functions, 172
Cushions, rubber, for surgical purposes, 108
Cyst, pancreatic, 210
Cystitis, treatment of, 15, 182
Cystoscope, Leiter's improved, 262
Cystotomy for foreign body in bladder, Gihon, 233
relations of peritoneum to abdominal wound in, 182
successful, 50
suprapubic, 617
Cysts, dermoid, 191
extrauterine pregnancy, exsection of, 323, 591
hepatic, treatment of, 502

DA COSTA, relation of diseases of kidney to disease of heart, 477
Day, acute exophthalmia, 460
Dean, John, death of, 168
Death, positive test of, 294
De Bary, Anton, death of, 280
De Chaumont, Prof., death of, 497
Delirium tremens, treatment of, 237, 243
Delivery, hour of, 139
Dennis, sarcoma of bone, 29
Dentition and stomatitis, treatment of, 435
Dermepenthesis, 493
Diabetes, 194
saccharin, and alterations in the pancreas, 715
treatment of, 16, 276, 521, 575, 607, 670
Diabetic food, 378
Diarrhœa, infantile, causation and treatment of, Vaughan, 621
microörganisms in stomach and intestine in, 644
microscopic examination of stomach and intestine in, 645
treatment of, 156, 638
summer, treatment of, 238
treatment of, 263
Diathesis, gouty, dietetic treatment of, Draper, 202
Digitalin, aconitine and, 492
hypodermatically, 607
Digitalis, as a diuretic and laxative, 693
formulæ for use of, 464
when to give, 432
when not to give, 13
Digits, severed, preservation of, 249
Diphtheria, etiology of, 464
in a dissecting-room, 55
pathology of, 50
prophylaxis in, 106, 126
therapeutics of, Jacobi, 654
treatment of, 20, 50, 69, 164, 264, 318, 344, 347, 493, 638, 669
Disease, a new miasmatic, 610
aural, mental affections and, 41
cardiac, hypnotics in, 102
heart, Oertel's treatment of, 573
infectious, family hygiene during, 28
Diseases, contagious, isolation of school children suffering from, 123
nervous and mental, treatment of, 134
tubercular, treatment of, 493
Disinfectant, a good domestic, 411
compound, of sulphur and carbolic acid, 409
Douche, intra-uterine, use of, after parturition, 247
Draper, dietetic treatment of gouty diathesis, 202
Dropsy, idiopathic, 128
Druggists, limitation of number of, in Germany, 277
Drumine, chloride of, 40
Dunster, Edward Swift, death of, 525
Dysentery, bacillus of, 575, 641
Dysmenorrhœa, treatment of, 553
Dyspepsia, treatment of, 319, 435
Dyspnœa, treatment of, 184, 553
Dystocia, Starck, 340

EAR, differential diagnosis of peripheric and central disease of, Roosa, 421
Earthquakes, nervous shocks produced by, 308
Ecbolics, acetic acid and ergot as, 522
Ectocardia, relief of a case of, 696
Eczema, treatment of, 157, 186, 222, 522
Edenberg, von, Carl Langer, death of, 84
Edes, Therapeutics and Materia Medica, review of, 161
tumors of the choroid plexus, 61
Edwards, cholecystotomy, 339
Elbow-joint, loose body in, 574
Electricity, capital punishment by, 166
dangers connected with use of, in medicine, 335
human, 308
Elephantiasis, treatment of, 123
Emissions, nocturnal, treatment of, 264
Emmenagogue, value of potassium permanganate as an, 553
Empyema, treatment of, 12, 720
Endometritis gravidarum, relation of, to pernicious vomiting of pregnancy, 558
treatment of, 347
Enteritis, follicular, treatment of, 294
Epiglottis, angioma of, 211
Epilepsy, treatment of, 99, 279, 293, 435, 522
Epistaxis, treatment of, 71, 607
Epithelioma, endolaryngeal, destruction of, 70
excision of tongue for, 102
treatment of, 412
Ergot, as an ecbolic, 522
of oats, 321
Ergotin, injections of, into tissues of cervix uteri, 322
Erysipelas, treatment of, 552
vaccination and, 278
Erythrophlœin, 267, 413, 716
an unpleasant experience with, Theobald, 688
Etiology, studies in, Hunt, 281
Eulenburg, Prof., death of, 28
Everts, asexualization as penalty for crime, 341
Ewell, Manual of Medical Jurisprudence, review of, 48
Exophthalmia, acute, Day, 460
Exostosis bursata, 617
Expert testimony, fees for, 222
Eye, photograms of, 575
treatment of suppuration consecutive to traumatism of, 533
Eyes, what antiseptics may be used about, 154

FACE masks, 335
Fairman, omphalitis, 97
Faith cure, 497
Farre, Arthur, death of, 56
Fechner, Gustav Theodore, death of, 84
Ferric chloride, reduction of, by pepsin and other substances, 409
Fever, enteric, value of acetanilide in, Way, 11
general pathology of, Welch, 365, 393, 539, 565
hay, antipyrin in, 122
pernicious, intestinal occlusion in, 693
scarlet, Hendon cow disease and, 20
typhoid, at Cincinnati Hospital, 439
causation of, 159
Vaughan and Novy, 92
changes produced in oxyhemoglobin of blood by, 694
children's food in, 239
epidemic of, 305
initial angina of, 378
intestinal antisepsis in, 13
origin of, in hospitals, 671
repeated, 669
spontaneous and experimental, in animals, 641

Fever, typhoid, sudden death in, 187
treatment of, 240, 292, 493
vaccination against, 351
yellow, etiology and prophylaxis of, Sternberg, 449
inoculations, 465
urine, 188
Fibroids, uterine, treatment of, 14, 348
Fingers, syncope and asphyxia of, 301
Fistula, cæcal, treatment of, 502
Flexions, uterine, influence of tissue changes in producing, 157
Fœtus, a parasitic, 222
Fontanelle, anterior, dermoid cysts of, 499
Food and drugs, adulteration of, 17
and teeth, lime salts in, 279
Foot, resection of, Smith, 285
Foramen ovale, patent, 617
Fracture, multiple, 385
Furuncle and carbuncle, treatment of, 210
Furuncles, treatment of, 295
Fussell, fracture of larynx, 288

GALL-STONES, treatment of, 591, 696
Prentiss, 518
Galvanic currents, dangers and uselessness of strong, 182
new method of supplying, for medical use, 434
Gangrene, symmetrical, Veeder, 461
Garbage, disposal of, 333, 363, 722
Garrigues, laparotomy for ruptured uterus, 225
Gauze, corrosive sublimate, 436
Genois, deodorized iodoform, 181
Geoline, 15
Gerster, Aseptic and Antiseptic Surgery, review of, 643
Gihon, cystotomy for foreign body in bladder, 233
Gland, thymus, angioma of, Berens, 408
Glanders, beautiful clinical case of, 252
cervical, extirpation of, 497
Gleditschia triacanthos, 82
Glucose by synthesis, 139
Glycerin and cocoa cream, 263
enemata in intestinal obstruction, Mayer, 200
in treatment of habitual constipation, 99
use of, as a laxative, 637
Goitre, exophthalmic, 330, 358
Goldsmith, William Benjamin, death of, 362
Gonorrhœa, diagnosis of, in women, 39
treatment of, 669
Goodell, a year's work in laparotomy, 424
Graves's disease, 358
Griffith, treatment of insomnia, 546
Gross, vesical calculus with chyluria, 666
Ground-water and health, 224
Guaiac, 184
Guiacol in phthisis, 694
Guitéras, pernicious anæmia with jaundice, 689
Gymnema sylvestra, 347
Gynecology, how taught, 557

HÆMATURIA, 582
Hæmoptysis, antipyrin in, 43
Hæmostatic pill, 603
Hair papillæ, electrolysis for destruction of, Hardaway, 490
Hands, clean, 129
Hardaway, destruction of hair papillæ by electrolysis, 490
Hare, physiological effects of oil of coffee, 337
Hargis, oil of turpentine in treatment of recent wounds, 235
Hartshorne, mortality and treatment of pneumonia, 373
Harvard, fourth year at, 298
Haya, 267, 378
Headache, treatment of, 68
Health, national bureau of, 277
Heart and kidney affections, relation of, 495
Da Costa, 477
fatty, treatment of, 716
Hemorrhage, carotid, treatment of, 154
fatal tonsillar, 40
meningeal, treatment of, 72
tar water in, 696
treatment of, 379
Hemorrhoids, bleeding, treatment of, 125
Henry, diagnosis of hemorrhagic pleurisy, 408
pleurisy, 705
Hernia, omphalectomy for, 216
radical cure of, 274, 440
Hiccough, obstinate, cure for, 241
Hinsdale, injury to shoulder followed by paralysis, 116
Hirst, prenatal and post-natal pneumonia, 314
Hoff, hospital corps, 315
Hoffmann, Josef, health of, 214, 280
Homatropine hydrobromate, Stewart, 234
Hospital assistants, female, in Quebec, 280
corps, Hoff, 315
management, 112
House-choosing, 166
Hunt, studies in etiology, 281
Hydrocele, cocaine poisoning after injection for, 552
radical cure of, 383
Keen, 371
Hydrocephalus, Starck, 340
Hydrogen, use of, in diagnosis of intestinal perforation, Senn, 569
Taylor, 629
Mackie, 629
Hydrops amnii following nervous shock, 346
Hydrosalpinx, 327
treatment of, 493
Hygrine and cocaine, 435
Hyoscine, 125
poisoning by, 101
Hyoscyamine, poisoning by, 183
Hypnone, 101, 154
Hypochondriasis, "Tempus edax rerum" for, 252
Hysterectomy, 212, 500, 501, 558
Hysteria and malpractice, 166
treatment of, 670

Ice, impure, 675
pollution of, 502
Ichthyol, 156
Martin, 152
Icterus neonatorum, 389
treatment of, 435
Immigration, restriction of, 165
Incompatibility, an important, 306
Indigo, bacillus of, 410
Inflammation, peri-cæcal, diagnosis of, 22
morbid anatomy of, 21
treatment of, 24
Injections, technique of, 492
Inoculation, preventive, 555
Insane, action of antipyrin in, 101
amylen hydrate in treatment of, 99
colored light in treatment of, 345
pauper, care of, 218
Insanity, suicide, in its relation to, Reese, 57
Insecticide, naphthalin as an, 694
Insomnia, treatment of, Griffith and Kirby, 546
Instruments, surgical, tariff on, 137
apparatus for sterilizing, 695
Intestinal obstruction, 265
surgical aspects of, 588
perforations, tests for, 569, 579, 589, 629
Intestine, large, excision of, 192
small, removal of spoon from, 14
Intubation tubes, use of, 700
Iodine trichloride, 16
Iodoform, 183, 188, 433
anti-tubercular action of, 322
deodorized, 101
Iodoform, deodorized, Genois, 181
Iodol, 15, 102
Ipecac, wine of, by inhalation, 639
Iron, a new preparation of, 14
Irwin, fracture of sternum, 691
Ischuria from prostatic hypertrophy, 158
Ivy poisoning, 392

JACOBI, therapeutics of diphtheria, 654
Jaggard, conservative Cæsarean section, 405
Jambul, 670
Jaw, lower, excision of right half, 618
Joints, antiseptic irrigation of, 242
Jones, congenital club-foot, 63
Juice, gastric, relation of, to disorders of stomach, 380

KEATING, Diseases of Heart and Circulation in Infancy and Adolescence, review of, 383
Keen, omphalectomy, 205
radical cure of hydrocele, 371
Kelly, removal of uterine appendages, 36
Kephir, 667
imitation, 694
Keratitis, phlyctenular, treatment of, in children, 410
Kidney, effect of antipyrin on, 377
extirpation of, 433
floating, 437
large white, diet in, 294
movable, 69
relation of diseases of, to disease of the heart, Da Costa, 477
Kidneys, influence of antiseptics on the, 696
Kirby, treatment of insomnia, 546
Knock-knee and bow-legs, Roberts, 113, 169
Kollock, leprosy affecting the eyes, 207

LABOR, antipyrin in, 492
Lanolin, 185
Laparotomy, a year's work in, Goodell, 424
exploratory, Baldy, 456
for ruptured uterus, Garrigues, 225
successful, 303
unusual cause of death after, 211
Laryngitis, tuberculous, recovery from, 291
Larynx, cancer of, 41, 167
extirpation of, 16, 122, 391, 471
prognosis of, 522
fracture of, Fussell, 288
hysteria of, application for, 694
hæmatoma of, 185
impaction of a coin in, 209
needle ten months in, 123
recovery after removal of, 667
removal of foreign body from, 533
Laundry work, dangers of, 306
Lavaran, malarial germ of, 53
Lead poisoning, 55, 638
Lenses, cataract, 523
Leprosy, 335
affecting the eyes, Kollock, 207
Lipanine, 504
Lithium, convenient form to administer, 211
Litholeine, 156
Lithotomy, lateral, modified staff for operation of, Brinton, 491
suprapubic, in male children, 44
Liveing, Diseases of the Skin, review of, 190
Liver, carcinoma of, 304
cirrhosis of, recovery in, 47
suture of wound of, 639
Locomotor ataxia, Mitchell, 428
Loomis, anniversary address, 141
Loreta's operation, 279, 344
Loring, Edward G., death of, 476
Lungs, passage of germs through, 609
Lymphangioma, cavernous, 501

MacDonnell, treatment of thoracic aneurism, 1
Mackie, rectal insufflation of hydrogen in diagnosis of perforation of bowel, 628
Macroglossia, 240
Malaria as a cause of disease, 720
Malarial cachexia, treatment of, 521
Mania, hydrobromate of hyoscine in, 238
Manton, bloody discharges from uterus, 571
Martin, ichthyol, 152
Mastin, abdominal section, 287
Mayer, glycerin enemata in intestinal obstruction, 200
Mays, apex expansion *versus* pure air in pulmonary consumption, 257
female dress as a determining factor in pulmonary consumption, 4
treatment of chronic bronchitis in children, 290
Meat broth for children, 102
Mediastinum, dermoid cyst of, 378
Medical division of the Pension Bureau, 160
education, advances in, 672
Medicine, address in, Bartholow, 537
lay fictions about, 278
public, address in, Walcott, 510
Melancholia, treatment of, 264
Membrane, mucous, transplantation of, 520
Membranes, retained, treatment of, 464
Meningitis, cerebro-spinal, 269, 581
epidemic, Mills and Cahall, 429
multiple neuritis in, 357
treatment of, in children, 575
Menstruation, painful, treatment of, 714
Menthol, 156
cataract, 241
Mercury, glyceride of bichloride of, 412
salicylate of, 715
Methyl, chloride of, 238
Methylal, 182
in delirium tremens, 243
Michellacci, Auguste, death of, 336
Microbes, absence of, in expired air, 16
action of some substances upon secretions of, 16
Microörganisms in surgical wards, 668
of water, Smart, 709

from sewage farms, 223
jelly, 492
mixture to replace, in infant feeding, 266
powder, 492
Mills, epidemic cerebro-spinal meningitis, 429
Missionaries, medical, dangers of, 307
Mitchell, Doctor and Patient, review of, 130
locomotor ataxia, 428
tendon-jerks and muscle-jerks, 677
Monster, double, 391
Moore, sketch of the progress of surgery, 505
Morality, surgical, 494
Muscle-jerks, Mitchell, 677
Muscles, abdominal, paralysis of, 40
Muscroft, C. S., death of, 556
Musser, Milton B., death of, 308
Myoma, soft, of uterus, 720
Myopia in Russia, 40
Myxœdema, 692

Nails, ingrowing, treatment of, 492
Nancrede, recent advances in the surgery of the brain, 85
Naphthalin, 15, 265, 694
Naphthol, antiseptic value of, 296
Narcosis, profound, forced respiration in, 321
Naregania alata, 346
Naso-pharynx, fibro-adeno-enchondroma of, 605
Navy, medical corps of, 305
Neale, Cæsarean section, 253
Neoplasm, nasal and pharyngeal, removal of, 613
return of extirpated, 445
Nephralgia, 213
Nephrectomy, 80, 245, 246
Nephritis, calculous, 304
Nephrolithotomy, Agnew, 115
Nephrotomy, 193
Nerve, transplantation of, from rabbit to man, 643
Nerves, divided, suture of, 360
Neuralgia, death from, 167
intercostal, treatment of, 101
treatment of, 294
Neuralgias, liniment for use in, 576
Neuritis, alcoholic multiple, 357
peripheral, histology of, 695
Nicotinism, hypnotic suggestion in, 43
Nipples, fissured, treatment of, 378, 412, 494
Nitrates, antiseptic value of, 208
Nitrite of amyl, in warfare, 363
Nitroglycerin, 263, 293
Norment, Sänger-Cæsarean operation, 147
Novy, causation of typhoid fever, 92
Nurses, nuns as, in Paris, 279

Obesity, influence of, upon menstrual and reproductive functions, Currier, 172
Obstetrics, address in, Parvin, 649
Ohage, Sänger-Cæsarean section, 685
Oil, gray, use of, in syphilis, 693
Omeire, 99
Omphalectomy, Keen, 205
Omphalitis, Fairman, 97
Oöphorectomy, technique of, 77
Ophthalmia neonatorum, prevention of, 124
treatment of, 155
Ophthalmology, antisepsis in, 296
Opium, in England, 364
suicide by, in China, 392
Orbit, spontaneous hæmatoma of, 474
Otitis media, treatment of, 209
Ovariotomy, conception after, 607
Ovaroclosia, 122
Ovum, a four weeks', 191
Ozæna, treatment of, 608

Pain, obscure pelvic, early operative interference in, 560
rectal, treatment of, 551
theine in, 294
Pancreas, saccharin diabetes and alterations in the, 715
Papayotin, 493
Papoid digestion, 521
Paraldehyde, 348
Paralysis agitans, 589
Paralysis, congenital facial, 433
cerebral, study of, 133
diphtheritic, 615, 630
infantile, 132
Paraplegia, from disease of urinary organs, 122
Paresis, acute pulmonary, 43
Parvin, address in obstetrics, 649
Paste, arsenical cream, 101
Pasteur's treatment at Barcelona, 277
Patella, treatment of old dislocation of, 534
Patriotism, professional, 619
Pemphigus, treatment of, 213
Penis, squamous epithelioma of, 383
syphilitic ulceration of, 213
Peptones, koumissed, 100
Percussion hammer, new form of, 356
Perichondritis, laryngeal, 153
Perinea, anatomical differences in, of white and colored women, 669
Perineorrhaphy, death from sepsis after, 320
"Perineum distender," a modified, 80
Perineum, lacerated, treatment of, 71
Peritoneum, carcinoma of, 304
hairpin in, 295
tuberculosis of, treatment of, 435
Peritonitis, acute, treatment of, 560
chronic pelvic, treatment of, 241
Perityphlitis, 109
Pertussis, pathology and treatment of, Wendt, 598
Petroleum, poisonous effects of, 554
Pharynx, development of, in the embryo, 640
treatment of ulcers of, 72
Phenacetin, 608, 670
Philadelphia Hospital, 298
Philanthropy, Hindoo, 140
Phlegmasia dolens and œdema in infants, 436
Phthisis, etiology of, 214
laryngeal, treatment of, 156
meat in, 157
pulmonary, treatment of, 14, 15, 71, 99, 124, 160, 186, 210, 213, 291, 294, 295, 379, 410, 462, 553, 668, 694, 696
subacute, recovery from, 265
Physicians, mortality among, 502
Pill-vending, automatic, 306
Placenta, retained, treatment of, 68, 464
Plasmodium malariæ, 75
Pleura, chronic suppuration of, 443
Pleurisy, hemorrhagic, diagnosis of, Henry, 408
Henry, 705
sudden death in, 554
Plumbing, test for, 704
Pneumonia, contagious, in swine, 101
etiology, pathology, and treatment of, 560
mortality and treatment of, Hartshorne, 373
pre-natal and post natal, Hirst, 314
treatment of, 437
Poisoning, by antipyrin, 321
by aconitine, 345
by aniline oil, 409
by castor-oil bean, 364
by chrome yellow, 243
by cocaine, 390, 322, 552
by hyoscine, 101
by hyoscyamine, 183
by insect powder, 392
by pilocarpine, treatment of, 694
by potassium bichromate, 618
by quinine, 215, 637
chronic, by coffee, 129
ivy, 392
lead, 55, 638
opium, in England, 364
Poisons, antidotes for, 648
Politzer, Leopold Max, death of, 673
Polypus, laryngeal, spontaneous detachment of, 185
Polyuria, salicylate of soda in, Randall, 373
Population, care of a, 112
Porencephalus, 301, 303
Porro operations, two successful, 71
Potassium chlorate, caution, against common use of, 436
Potassium, permanganate of, value of, as an emmenagogue, 553
Potter, treatment of enlarged tonsils, 255
Pregnancy, albuminuria of, induction of premature labor for, 131
extrauterine, treatment of, 468, 559
relation of endometritis gravidarum to pernicious vomiting of, 558
Prentiss, treatment of gall-stones, 518
Prescription, an incompatible, 264
a poisonous, 140
Prescriptions, ownership of, 251
Prostate, enlarged, treatment of, 670
Prolapsus uteri, results of treatment of, 15
Pruritus pudendi, treatment of, 520
Ptomaine, poisonous, in expired air, 211
resembling strychnine, 306
Pulse, the, in children, 377
Purdy, Samuel A., death of, 84
Purpura, treatment of, 291
hemorrhagica caused by mental shock, 412
Pyloric stenosis, operation for, 721
Pylorus, digital divulsion of, 123
Pyonephrosis, nephrectomy for, 246

QUARANTINE, at Philadelphia, 674
inefficient, 641
New Orleans, disinfection at, 82
New York, station, 18
Quebracho, 184
Quinine, hypodermatic administration of, 377, 434
poisoning, 215, 637
